Myelodysplastic syndromes

David K.H. Webb

Over 95% of children with leukemia have acute myeloid leukemia (AML) or acute lymphoblastic leukemia (ALL); the others have more chronic myeloproliferative or myelodysplastic disease. Chronic lymphocytosis in childhood is usually a response to an infection or an immunoregulatory disorder (see Chapter 19) and there have only been a handful of reports of apparent chronic lymphocytic leukemia in childhood.

The myelodysplastic syndromes (MDS) were historically characterized by a cellular marrow with peripheral pancytopenia and were first described as smouldering leukemia or preleukemia. These were predominantly disorders of late adult life and have since been well classified in the extensive adult literature.

Early reports of chronic leukemias in childhood^{1,2} make no distinction between chronic myeloid leukemia (CML) and what would now be deemed MDS, and only in the last few years have any serious attempts been made to classify pediatric MDS, which differ in many important respects from the disease in adults.^{3–10} The advent of more effective treatment, in particular bone marrow transplantation (BMT), has made a rational approach to diagnosis and management of increasing importance.

Historical perspective

Over 40 years ago Hardisty *et al.*¹¹ distinguished two types of chronic granulocytic leukemia in childhood. The adult type, which had a relatively long survival and was associated with the Philadelphia chromosome; and the second form, subsequently often called juvenile chronic myelomonocytic leukemia,¹² which was associated with suppurative infections, severe thrombocytopenia, a nonspecific but very characteristic skin rash and a very poor prognosis. Further interest in this rare disorder was awakened by the reports of a consistently raised fetal hemoglobin (HbF) level and fetal red cell characteristics.¹³ A third chronic disorder was described

in young infants with a missing C group chromosome,¹⁴ which was subsequently identified as chromosome 7.¹⁵ These three conditions, dependent in part on clinical features for diagnosis, comprised the most clinically distinct myeloproliferative or myelodysplastic disorders in childhood but there was no systematic review of the associated blood and marrow morphology.

Meanwhile, the morphologic classification of MDS in adults was developed by the efforts of the French–American–British (FAB) group (see below),¹⁷ and terms such as preleukemia tended to be abandoned in favor of the appropriate FAB type of MDS. Retrospective and more stringent analysis of cases of pediatric AML showed that a proportion of cases, perhaps 17%, had an indolent prodrome and might be called myelodysplasia.¹⁶ More recently, an international consensus has been developed, subdividing MDS in children into a proliferative group comprising juvenile myelomonocytic leukemia (JMML), a group of adult-type MDS, and a number of very rare or secondary disorders.¹⁸

Incidence and epidemiology

MDS is largely a disease of the elderly and the incidence rises dramatically with increasing age.^{19,20} There have been a number of recent estimates of the incidence in childhood, but these have been derived from relatively small populations and it seems probable that the incidence of the more indolent forms has been underestimated. A population-based study in Denmark estimated that the incidence of MDS approximated that of AML at 4.0 new cases per million children annually, thus representing 9% of all hematologic malignancies,²¹ whereas in northern England the estimated incidence was 0.53 per million, or 1% of malignancies.²² A report from the national UK childhood MDS registry gave an annual incidence of 1.4 per million over a 10-year period.²³ These discrepancies could be due in part to the inclusion or exclusion of more aggressive forms (e.g., refractory anemia with excess

of blasts in transformation) as either MDS or AML rather than any true variation in incidence.

A characteristic feature of MDS in childhood is a strong association with congenital disorders and genetic syndromes (Table 18.1); in recent non-population-based reports between one-quarter and one-half of patients have shown some phenotypic abnormality. Some of these are nonspecific, such as mental retardation or small stature, but others are recognized genetic conditions. Children with Down syndrome have a 10–20-fold increased risk of development of leukemia, usually the pre-B or common type of lymphoblastic leukemia or the megakaryoblastic (M7) subtype of AML. Patients with megakaryoblastic leukemia often have a preceding phase of MDS, which may last some weeks or months. This evolving myeloid leukemia, which is fatal if untreated,²⁴ should not be confused with the transient abnormal myelopoiesis (TAM) seen in some newborn babies with Down syndrome and in occasional normal neonates; this condition resembles acute leukemia but usually resolves without specific treatment.²⁵ Constitutional trisomy 8 usually occurs in mosaic form and is associated with facial dysmorphism, skeletal abnormalities and mild-to-moderate mental retardation.²⁶ Trisomy 8 is a common cytogenetic finding in myeloid malignancies, and a number of patients with constitutional trisomy 8 have developed hematologic disorders including MDS.^{27,28} The precise frequency of constitutional trisomy 8 and AML is unknown.

There is an increased risk of JMML in the common autosomal dominant form of neurofibromatosis,^{29,30} and MDS with monosomy 7 is also associated with this disorder.³¹ A number of congenital bone marrow disorders predispose to the development of AML and MDS, including congenital neutropenia, in particular Kostmann syndrome (see Chapters 3 and 14), where treatment with granulocyte colony-stimulating factor (G-CSF) may improve symptoms and obviate the need for BMT, but has been associated with risk of the development of monosomy 7 and MDS.³² Patients with the Shwachman–Diamond syndrome of pancreatic exocrine

insufficiency and neutropenia have generalized abnormalities of hematopoiesis and are at increased risk of AML, ALL and MDS.^{33,34} Patients with Fanconi anemia are at significant risk of the development of AML and MDS.³⁵

There are a number of families described in the literature with no apparent congenital or genetic abnormality in whom more than one member has developed MDS or AML. MDS with monosomy 7 has been described in infant siblings,^{3,36} but in other families more than one member has developed AML or MDS in later childhood or adult life, sometimes in association with a familial platelet storage pool disorder.³⁷ In several instances, the development of MDS has been associated with evolution of a cytogenetic abnormality in the bone marrow, most often monosomy 7 or 5.

Immunosuppressive therapy with antilymphocyte globulin and ciclosporin has improved survival in patients with acquired aplastic anemia, particularly those without a histocompatible sibling donor (see Chapter 4). However, children treated by immunosuppression are at increased risk of MDS.³⁸

Secondary MDS with a predilection to development of AML was first described in patients treated for Hodgkin disease, multiple myeloma and ovarian cancer, and more recently after high-dose chemoradiotherapy and infusion of autologous bone marrow.^{39,40} By contrast, secondary acute leukemia in patients who have been treated with topoisomerase II inhibitors usually occurs without any dysplastic prodrome.

Clinical features

The symptoms and signs of MDS are more insidious than those of acute leukemia, and the diagnosis may even be made incidentally. Pallor is common, bacterial infections may be a consequence of neutropenia or defective neutrophil function, and bruising may be due to thrombocytopenia or defective platelet function. Patients may also present with a prolonged history of repeated infections, which is suggestive of congenital immune deficiency. Some children with JMML develop weight loss and failure to thrive. Lymph node enlargement is unusual except in JMML. The liver and spleen may be enlarged or not palpable. A characteristic skin rash, mimicking Langerhans cell histiocytosis, may occur on the face or trunk in JMML, and occasionally in infants with other types of MDS in association with monosomy 7.

Investigations

appearances are extremely variable, and a list of noteworthy features is given in Table 18.3. The essential diagnostic criteria are shown in Table 18.4. It is essential to examine the blood film and bone marrow in tandem and *the blood film is often more informative in reaching a diagnosis*. A trephine biopsy of the bone marrow should be obtained in all cases and important observations include:

- overall cellularity of the bone marrow;
- relative proportions and morphology of the three cell lines, especially the megakaryocytes;
- presence of fibrosis and reticulin and of abnormally localized immature precursor cells (ALIP), which are aggregates of myeloblasts and promyelocytes in the intertrabecular region in the bone marrow biopsy.

Immunohistochemical staining of bone marrow biopsies facilitates the identification of these immature precursors³⁹ and deserves further systematic study in children. Other investigations, such as measurement of HbF, neutrophil function and platelet function, may serve to confirm abnormalities of development of the three cell lines. Measurement of the HbF before any transfusions of red cells may be helpful in evaluating prognosis (see below) and is essential in JMML. Immunologic abnormalities may include low immunoglobulins, autoantibodies or even abnormalities of lymphocyte subsets. It may be necessary to exclude congenital viral infections. The hematologic appearances of HIV infection in adults may mimic MDS but this presentation has not been described in children.

Lastly, the diagnosis of MDS implies the finding of consistent hematologic abnormalities over a period of time, thus excluding patients with morphologic abnormalities in association with infection, which may resolve spontaneously,

Table 18.3 Common morphologic abnormalities in myelodysplasia.

Cell lineage	Blood film	Bone marrow
Erythroid	Macrocytes Punctate basophilia Poikilocytes Normoblasts	Dyserythropoiesis Multinucleate normoblasts Cytoplasmic vacuolation Ringed sideroblasts
Megakaryocytic	Giant platelets Megakaryocyte fragments	Small megakaryocytes Abnormal nuclear morphology
Granulocytes	Hypogranular Agranular Hypersegmentation Pelger forms	Promyelocytes with sparse granules Hypogranular precursors
Monocytes	Elongated lobes Azurophilic granules	Promonocytes sometimes present
Blasts	Usually small mononuclear blasts with scanty agranular (type I) or sparsely granular (type II) blasts	

Based on Ref. 16.

Table 18.4 Diagnostic criteria for myelodysplastic syndromes in children.²³

At least two of the following must be present:

- Blood cytopenia
- Bilineage dysplasia
- Excess of blasts (>5%) in bone marrow
- Cytogenetic clone in bone marrow

Diagnostic criteria for JMML⁴¹

Essential

- Monocytosis > $1 \times 10^9/L$
- Bone marrow blasts < 20%
- Absence of t(9;22)

Plus two from:

- White blood cell count > $10 \times 10^9/L$
- Myeloid precursors on blood film
- Cytogenetic clone in bone marrow
- Spontaneous growth of CFU-GM *in vitro*

or patients whose abnormalities progress to frank AML within weeks.

Morphologic classification: the FAB classification

The FAB classification¹⁶ has a number of limitations, especially in childhood MDS.

- Many children with MDS have a monocytosis, which thus automatically classes them as having JMML. However, in many such cases there may be > 5% blasts in the blood without an excess of blasts in the marrow. This finding should in theory mean reclassification as RAEB (refractory anemia with excess blasts) in transformation but in most pediatric studies such cases have been included in the category of JMML.
- There are a number of patients, e.g., those with eosinophilia and dysplastic blood and bone marrows, for whom it is impossible to assign an FAB type.

- Both therapy-induced MDS and MDS occurring in association with congenital bone marrow disorders may defy classification by the scheme, the bone marrow showing hypoplasia and/or fibrosis in addition to dysplasia.

Despite these limitations, systematic morphologic classification (Table 18.5) is important to facilitate the increasing number of collaborative studies and to assess prognosis and response to treatment. There have been a number of recent reports where the FAB classification has been applied to pediatric MDS.^{3,6,8,9,20} The relative frequencies of the various subtypes of MDS in children and adults, as determined by ongoing studies in the UK, are illustrated in Table 18.6, with the caveat that the results are not strictly population based.

The World Health Organization (WHO) recently published recommendations for the classification of myeloid malignancies, including MDS, and these have been modified for pediatric use (Table 18.7). It is recommended that these revised WHO criteria are used internationally in future.

Pitfalls in morphologic diagnosis of refractory cytopenias

Refractory anemia must be distinguished from congenital dyserythropoietic anemias (see Chapter 2) and megaloblastic anemia (see Chapter 6), and the presence of clonal cytogenetic abnormalities is helpful in confirming the diagnosis; without such abnormalities the diagnosis should be considered with caution.

Refractory anemia with ringed sideroblasts as a true MDS is exceptionally rare in pediatrics, with only one case identified in the UK registry; it can only be diagnosed with confidence in the presence of a cytogenetic abnormality. Congenital sideroblastic anemia, due to abnormalities of heme synthesis, is usually associated with a dimorphic blood film; abnormalities of megakaryocytes and granulocytes are not seen. Sideroblastic anemia is also a feature of

Type	Blood film	Bone marrow
Refractory anemia (RA)	Blasts < 1%	Blasts < 5%
RA with ringed sideroblasts (RARS)	As in RA	As in RA but > 15% of erythroblasts as ringed sideroblasts
RA with excess of blasts (RAEB)	Blasts < 5%	Blasts 5–20%
RAEB in transformation (RAEDt)	Blasts > 5% Auer rods	As RAEB but 20–30% blasts Auer rods
Juvenile myelomonocytic leukemia (JMML)	Monocytes > $1 \times 10^9/L$ Blasts < 5%*	Blasts < 20%

* JMML in children is often associated with a higher blast count in the blood, but marrow blasts should not exceed 20% and Auer rods should not be present.

mitochondrial cytopathies, a group of disorders characterized by cortical neurologic impairment, metabolic acidosis and multiorgan involvement. The most typical of these is Pearson syndrome, which is characterized by pancreatic insufficiency, neutropenia and a bone marrow showing vacuolated precursors and ringed sideroblasts.⁴² Hematologic abnormalities may be the dominant and indeed the only clinical feature of mitochondrial cytopathies at presentation and thus the distinction from MDS may be difficult.^{9,43} Mitochondrial cytopathies should be excluded in any patient with apparent sideroblastic anemia, and it may be necessary to look for abnormal mitochondrial DNA on several occasions and to perform a muscle biopsy to confirm the diagnosis.

MDS or AML?

The distinction between refractory anemia with an excess of blasts with or without transformation and AML is an arbitrary one because patients may present with an abnormal count but a low percentage of blasts in the marrow and develop overt AML within weeks or even days (see Chapter 16). A classical presentation of this type is the extramedullary leukemic deposit (sometimes called a chloroma) found in

patients with t(8;21) and M2 AML. The diagnosis of true MDS implies a more indolent course and in a French review an essential feature for the diagnosis was the presence of consistent hematologic abnormalities without evolution to AML over a 2-month period.⁹ The distinction between an MDS and typical acute leukemia presenting with a low blast count is potentially important because the latter may respond more favorably to chemotherapy. The distinction is helped by careful review of morphology, because patients with true MDS will exhibit multilineage dysplasia, and also by the cytogenetic findings: t(8;21), t(15;17), t(9;11) and inv(16) are all associated with *de novo* AML.⁴⁴

MDS or hypoplastic anemia?

A degree of dysplasia, particularly in the red cell series, is not unusual in chronic aplastic anemia, but the hypoplastic trephine appearances, absence of ALIP and absence of cytogenetic abnormalities in aplasia should help to make the distinction apparent.

Diagnosis of juvenile myelomonocytic leukemia

There can be occasional problems in distinguishing JMML from acute monoblastic or myelomonocytic leukemia but dysplasia in the granulocyte series is marked in JMML and the bone marrow appearances do not show such a pre-dominance of early monocytic precursors.

JMML in pediatrics is an extremely heterogeneous disease (see below) and in order to define prognosis and improve management there is a need for a systematic attempt at investigation. Additional investigations recommended in these patients, such as *in vitro* bone marrow cultures, are listed in Table 18.2 and are discussed further below. Cytomegalovirus,⁴⁵ parvovirus,⁴⁶ and Epstein–Barr virus infections,⁴⁷ particularly in infants, may mimic JMML and should be excluded by appropriate virologic investigations.

Cytogenetics

Investigation of bone marrow cytogenetics, supplemented when possible by fluorescence *in situ* hybridization (FISH), is essential in the evaluation of MDS. Cytogenetic abnormalities are found in about 50% of cases of primary MDS in both children and adults and in > 90% of patients with therapy-induced MDS.^{48,49} Some of the commoner findings are listed in Table 18.8. This list is not exhaustive and is based on the adult literature. The results of cytogenetic analyses in children with JMML and MDS and included in the UK national registry are shown in Table 18.9.

The most notable distinction between the cytogenetic findings in MDS and those in AML is the predominance of whole chromosome losses or partial deletions and the relative infrequency of translocations in MDS. There are some differences in the incidence of cytogenetic abnormalities between children and adults, most notably the marked

predominance of monosomy 7 in pediatric MDS.⁵⁰ Monosomy 7 is also the commonest cytogenetic finding in leukemia or MDS occurring in patients with congenital bone marrow disorders. Deletions of chromosome 5q, so common in adult practice, are rare in childhood. Cytogenetic abnormalities in MDS, unlike those in AML, are not usually associated with any specific morphologic subtype. The adult exception to this is the association of loss of part of the long arm of chromosome 5 (5q- syndrome) in elderly women with macrocytic anemia, a normal or raised platelet count, and relatively prolonged survival.⁵¹

Cytogenetic findings have been incorporated into several scoring systems to assess prognosis and, in general, the development of more complex abnormalities is associated

with a worse prognosis and/or progression to AML. Cytogenetic abnormalities are almost always found in MDS secondary to chemotherapy.

Biology and pathogenesis

Studies of variants of glucose 6-phosphate dehydrogenase and other X-linked restriction fragment length polymorphisms⁵² confirm that MDS is a clonal disorder. The use of FISH in combination with cytology and immunophenotyping⁵³ shows that in some cases the disease arises in progenitor cells restricted to myelopoiesis and erythropoiesis while in others the lymphoid series is involved as well, thus indicating malignant transformation in a more primitive hematopoietic cell. The event(s) initiating this change remain unknown.

Many of the chromosomal abnormalities in MDS involve the loss of genetic material, particularly from the long arms of chromosomes 5 and 7 (5q and 7q).⁵⁴ The regions involved in these cytogenetic changes are rich in genes with a role in hematopoiesis and it has been postulated that both 5q and 7q may be the site of tumor-suppressor genes. Intensive investigation of the critical region 5q31–q33 is underway to try to identify a tumor suppressor gene associated with the development of the 5q- syndrome, and similar critical regions have been identified on chromosome 7. An excellent review of the significance of the cytogenetic finding of monosomy 7 in pediatric AML and MDS emphasizes its frequent occurrence in many conditions with a predisposition to leukemia, including most of the congenital bone marrow disorders.⁵⁴ The authors postulate that loss of a gene(s) located on chromosome 7 may contribute to leukemogenesis as part of a final common pathway following a number of genetic events. It remains unclear if inactivation of both alleles is essential for disease progression (i.e., a tumor suppressor gene is involved), or if there is a gene dosage effect associated with deletion of one gene only.

The literature on MDS in adults is full of reports of mutations in various protooncogenes, including p53 mutations associated with a deletion in the short arm of chromosome 17,⁵⁵ in FMS in association with deletions in the FMS locus at chromosome 5q33 and mutations in the genes of the *ras* family.^{56,57} *Ras* mutations have been most extensively investigated in JMML in adults, and more recently in children. It seems probable that such genetic changes are part of a final common pathway in the development of disease rather than initiating events in MDS.

The search to identify crucial genetic changes has been accompanied by many investigations of cellular biology and cell culture in MDS. The paradox of cytopenias in the blood despite a cellular bone marrow has been debated for many years. However, investigations have shown that while cell proliferation in the bone marrow in MDS is high, with large numbers of cells entering S phase,⁵⁸ these cells rapidly

undergo programmed cell death (apoptosis) and thus never enter the circulation. Both proliferation and apoptosis are influenced by the complex cytokine network in the hematopoietic microenvironment, including tumor necrosis factor (TNF)- α , transforming growth factor (TGF)- β and interleukin-1 β . Increased levels of these cytokines have been demonstrated in biopsies of patients with MDS.

Factors influencing prognosis

Treatment of MDS, particularly when involving BMT, carries a significant risk of morbidity and mortality and it is thus important to determine which patients are at early risk of death from leukemia or pancytopenia and in which patients a more conservative approach might be appropriate. This search for prognostic factors has been energetically pursued in adult MDS, a disease of the elderly, where the approach to management may be justifiably conservative. Numerous attempts to assess factors influencing both survival and progression to leukemia have been made. The original Bournemouth score⁵⁹ and subsequent modifications^{60,61} used the presence of cytopenias, bone marrow blasts and ALIP. Other scores have also incorporated cytogenetics.⁶² Most recently, an international scoring system has been developed using cytopenias, the percentage of blasts in the bone marrow, cytogenetics, age and sex to predict evolution of AML and survival.⁶³ There have been few attempts to apply such systems in children and attempts have been hampered by the dominance and clinical heterogeneity of JMML and the fact that these scores do not afford sufficient discrimination between morphologic subtypes of pediatric MDS.⁸

There is little information about the risk of transformation of MDS to acute leukemia in childhood. The deterioration in JMML is associated with increasing requirement for blood products and systemic symptoms (see below), rather than development of a frank new acute leukemia. Analysis of prognostic factors in a retrospective review of 68 cases showed that age and sex were not significant prognostic factors,⁸ except that in JMML as previously reported,¹² younger children had a better prognosis. Both the unmodified FAB classification and the degree of cytogenetic complexity were also of some prognostic significance. A score was developed based on objective criteria that could be measured at diagnosis; each of the following scores 1 point if present:

- platelets $< 40 \times 10^9/L$;
- cytogenetic complexity score of 2 (i.e., cases with no clonal abnormalities score 0, those with a single simple abnormality score 1 and complex abnormalities score 2);
- HbF $> 10\%$.

The results of this scoring system in a cohort of children are shown in Fig. 18.1. In practice, most patients with a score of 0 have refractory anemia or RAEB with or without a simple cytogenetic abnormality such as monosomy 7, whereas those

Fig. 18.1 Actuarial survival curve for 68 children with myelodysplasia based on the objective criteria scoring system described in the text. Reproduced with permission from Ref. 8.

with a score of 2 or 3 tend to have either JMML with a low platelet count and raised HbF level, or thrombocytopenia and complex cytogenetic abnormalities. Subsequent analyses have demonstrated the strongly adverse prognostic significance of monosomy 7 in refractory cytopenia and refractory anemia with excess blasts,^{64,65} whilst confirming the adverse influence of older age, high HbF, and low platelet count in JMML.

Treatment

This section contains a general review of the methods of treatment available for patients with MDS; more specific recommendations about treatment are given in the individual subtype sections. There are no systematic prospective studies of treatment of pediatric MDS, and most of the information about chemotherapy is derived from studies of AML where patients with MDS have been identified retrospectively. Optimum supportive care with blood products (see Chapter 32) and appropriate management of infection (see Chapter 35) are essential for all patients.

Chemotherapy

There is limited information about the role of chemotherapy in children with MDS but it appears that response rates are inferior to those achieved in AML.⁶⁶ A comparison of 20 children treated for MDS with 31 who had AML showed that the remission rate was lower at 35% (74% in AML); resistant disease was more common, occurring in 25% (10% in AML); and 3-year survival was 15% (35% in AML); however, 8 of the patients with MDS had JMML, a subtype that in general responds poorly to chemotherapy (see below).⁶⁷ Comparison of outcome in children with classical dysplasia and those with AML with a low blast count showed that the remission rate was 30% for those with unequivocal MDS and 88% for the small number who had more typical AML; the latter group

largely consisted of children with M2 or M4 AML and several had chloromas. The 4-year event-free survival was 50% for the AML patients compared with 23% in those with MDS.

In a series from the UK, children with RAEB in transformation (RAEBt) had similar survival (63%) to those with *de novo* AML when treated with the same chemotherapy. Although children with typical AML cytogenetic changes were excluded it was unclear whether all these children had stable MDS before treatment. The outcome for children with RAEB was significantly worse (28%).⁶⁵ Monosomy 7 carried a strong adverse prognosis in both groups, and after allowance for adverse cytogenetics, which were more common in MDS, survival was similar to that for children with *de novo* AML.

Low-dose cytarabine was originally used in adults with MDS in the belief that it was a differentiating agent, but it probably acts as a cytotoxic drug. Few children have been treated with low-dose cytarabine and there is no evidence that it is effective.⁶⁸ Oral cytotoxic drugs such as mercaptopurine or hydroxycarbamide have been used to reduce the leukemic burden in MDS but, as expected, they do not achieve remission.

Cytokines and differentiating agents

There is understandable interest in whether or not these agents can reduce the consequences of pancytopenia in older patients with MDS where intensive chemotherapy or BMT may not be feasible. Clinical trials are in progress to evaluate various combinations of G-CSF, granulocyte-macrophage CSF (GM-CSF), interleukin-3 (IL-3),⁶⁹ and erythropoietin sometimes in combination with low-dose cytosine arabinoside. The growth factors may improve neutropenia,⁷⁰ but there are concerns that they may accelerate progression to AML. The newly available human megakaryocyte growth and development factor, or thrombopoietin, will no doubt be evaluated in the same way.^{71–73} A number of differentiating agents such as all-*trans* retinoic acid⁷⁴ have also been used in adults with little clinical benefit. There is some interest in these agents in JMML (see below). Despite this experience in adults, there is little justification for this approach in children where the aim of management is not palliation but cure.

Bone marrow transplantation

High-dose chemotherapy and/or radiotherapy with BMT is the only curative treatment for most patients with MDS. The first successful reports from BMT centers treating mainly adult patients showed a 3-year disease-free survival of about 40% for patients transplanted from an HLA-histocompatible sibling.^{75,76} Children tolerate BMT better than adults, but only about 1 in 3 children in the UK have a histocompatible sibling. However, in the last few years the potential role for BMT in treatment has been expanded by the increased availability of volunteer unrelated donors and the start of programs for the

use of cord blood. There is an increasing tendency to use peripheral blood stem cells (PBSC) rather than bone marrow, particularly in the context of autologous rescue from high-dose chemotherapy, and studies are in progress to evaluate allogeneic PBSC as a substitute for bone marrow.^{77,78}

Choice of regimen

The choice of a preparative regimen for BMT depends on the age of the child, the diagnosis and the type of transplant. The most widely used regimen involves various combinations of total body irradiation (TBI) and cyclophosphamide, sometimes with the addition of other drugs such as cytarabine and etoposide. TBI is used in various schedules, sometimes as a single dose but more usually fractionated over 3–4 days. The most widely used chemotherapy regimen is a combination of busulfan and cyclophosphamide, which was developed originally for CML and AML.^{79–81}

The choice between chemotherapy alone and regimens including TBI is in part dictated by consideration of the potential late effects of treatment, naturally an issue of extreme concern in the growing child. Although intensive chemotherapy carries the risk of significant late effects, including cardiotoxicity after anthracycline therapy, nephrotoxicity and potential sterility,⁸² TBI is associated with additional complications and younger children are most vulnerable. Children who have received TBI have growth failure, which is partly due to spinal shortening and partly to hypothalamic-pituitary failure; this will be exacerbated if there is chronic graft-versus-host disease (GVHD). Delayed puberty and gonadal failure are common, and there is a variable risk of hypothyroidism, cataracts and learning problems. The combination of busulfan and cyclophosphamide has not been subjected to such rigorous long-term follow-up studies as TBI and it may induce sterility, but it is unlikely to have such a significant effect on skeletal growth and neuropsychologic development.

Randomized comparisons of chemotherapy and TBI have been performed in adults with CML⁸³ and AML⁸⁴ with conflicting results, but in a comparative study of adults with refractory anemia the combination of busulfan and cyclophosphamide was as satisfactory as cyclophosphamide and TBI.⁸⁴ There are no randomized pediatric trials but the combination of busulfan and cyclophosphamide has been used in children with AML,^{85,86} and the two drugs in combination with melphalan are undergoing assessment in pediatric MDS.⁸⁷ Currently, therefore, it seems appropriate to use chemotherapy alone as a preparative regimen, at least in standard transplants from an HLA-identical sibling.

Type of transplant

The number of reports confined to BMT in children with MDS is small, with the exception of JMML (see below), but

overall results, as for other hematologic malignancies, show that younger patients and those with less advanced disease do better.^{88,89} For the many children with MDS who do not have a histocompatible sibling donor and for whom the only chance of cure may lie in BMT, it is reasonable to consider the use of alternative donors.⁹⁰ Most studies have involved the use of volunteer unrelated donors, and availability has increased significantly in recent years.⁹¹ The chances of finding a donor depend on the patient's haplotype and ethnic group. In the last few years, cord blood has been used as a source of stem cells⁹² but uncertainties remain about the risk of relapse and the stability of engraftment with this source.

Prognosis

There is a risk of relapse after BMT as after all other forms of treatment for MDS. This varies with the type and stage of MDS as well as the type of donor. The results of treatment after relapse are unsatisfactory. Donor leukocyte infusions have shown some promise in the management of relapse in CML,^{93,94} presumably by induction of a graft-versus-leukemia effect. The use of such infusions is limited by the ethical issues involved in leukapheresis of young siblings but is feasible in consenting older siblings and volunteer unrelated donors. This treatment is being evaluated in other hematologic malignancies and may play a role in the management of relapsed MDS. There are anecdotal reports of successful therapy for relapsed MDS and, especially, JMML.⁹⁵

An alternative form of high-dose therapy in MDS is the use of autologous rescue with bone marrow or blood stem cells. There have been several recent randomized trials of the use of autologous BMT (ABMT) in AML (see Chapter 17), and this form of treatment is being systematically evaluated in adults with MDS who achieve a stable remission. There are a few anecdotal reports of long-term remission after ABMT in children with MDS,⁸ but the value of this form of treatment has not been established and it cannot be recommended outside a clinical trial.

It is clear that BMT is the most encouraging form of treatment for MDS, and while the choice between TBI- and chemotherapy-based regimens will depend on the age of the patient and type of transplant, it would seem possible to avoid TBI in many instances. The results from donors other than histocompatible siblings leave room for improvement but consideration of this approach is justified in children with poor prognosis of MDS or myeloproliferative syndrome.

Diagnosis and management of MDS subtypes

Refractory anemia

The diagnosis of refractory anemia is easier in the presence of

a cytogenetic abnormality in the bone marrow. An expectant approach is reasonable if the patient is well, not dependent on blood products, and has no evidence of disease progression; indeed, such an approach is recommended particularly in the absence of any cytogenetic abnormality. The risk of such a policy is of course that the patient may develop acute leukemia, which is likely to be less responsive to chemotherapy than *de novo* AML. There is very little published information about the use of chemotherapy, as for AML, in refractory anemia and BMT is the treatment of choice. It is reasonable to consider early BMT in patients with a histocompatible sibling donor; in others the potential risks and benefits of an unrelated donor transplant must be carefully evaluated.

RAEB and RAEB in transformation

This category of patients includes both those with stable disease over months or years and those where the distinction from AML is a semantic one. In many national studies these patients are eligible for treatment with chemotherapy as if they had frank AML. In the absence of favorable cytogenetics such as t(8;21), such patients would in most centers be deemed eligible for BMT, at least if they have a histocompatible sibling donor. However, the use of chemotherapy where BMT is planned is contentious, and many centers recommend elective BMT without prior AML chemotherapy in stable patients. The role of unrelated donor BMT for patients with advanced MDS who have a good response to chemotherapy remains unclear.

Juvenile myelomonocytic leukemia

Clinical features and diagnosis

JMML is an extremely heterogeneous disease that is more common in boys^{8,12} and in children under 2 years of age. There is an association with neurofibromatosis,^{29,96} which may be found in 14% of patients, and with Noonan syndrome.^{96,97}

The clinical spectrum varies from a relatively benign disease in infants with hepatosplenomegaly and monocytosis to the classical disease, usually in older children, with bleeding, thrombocytopenia, enlarged lymph nodes and splenomegaly. Progression of the disease is accompanied by wasting, fever, infections, bleeding and pulmonary infiltrations. The typical skin rash, which may precede other symptoms by months, is classically of a butterfly distribution but may be more extensive, and on biopsy shows a nonspecific infiltration with lymphocytes and histiocytes.

Hematologic findings

While the morphologic features are consistent with the FAB description of JMML and monocytosis is always present, the blood count may also show eosinophilia, basophilia and a

higher number of blasts than would be acceptable for strict diagnosis of JMML on the FAB criteria. The appearance of the blood film is more diagnostic than that of the bone marrow, where abnormal monocytes and blast cells may be increased with, usually, dysplasia in all cell lines.

The original detailed hematologic description of JMML¹² has been complemented by a retrospective review of 110 cases strictly classified by the FAB criteria, except that > 5% blasts were allowed in the blood.⁹⁷ The median leukocyte count was $35 \times 10^9/L$ and exceeded $100 \times 10^9/L$ in only 7% of cases, eosinophilia was present in 8% of cases and basophilia in 28%, while over half the patients had thrombocytopenia of $< 50 \times 10^9/L$.

A characteristic feature of JMML is an increase in the HbF level,^{13,98} which may increase progressively as the disease progresses, and a fetal pattern of γ -globin chain synthesis.⁹⁸ This is accompanied by a raised mean corpuscular volume, fetal pattern of 2,3-diphosphoglycerate and red cell enzyme production, red cell i/I antigen and carbonic anhydrase.^{12,99} There may also be a number of immunologic abnormalities such as antinuclear antibodies and anti-IgG antibodies.^{12,100}

While the diagnosis usually presents little difficulty, some patients with classical clinical features, including a grossly raised HbF, have a blood smear dominated by normoblasts, almost suggestive of erythroleukemia, while in other patients the distinction from acute myelomonocytic leukemia may be a fine one. Cytogenetic analysis in classical JMML with a grossly raised HbF is usually normal, but monosomy 7 may be found in some cases (see below).

Biology

The assumption that JMML is a clonal disorder, which is difficult to establish in the absence of cytogenetic abnormalities, has been confirmed by X-chromosome inactivation studies.¹⁰¹ In addition, transplantation of cells from JMML patients can induce a JMML-like disease in irradiated severe combined immune-deficient mice.¹⁰² The laboratory hallmark of the disease is spontaneous *in vitro* proliferation of granulocyte-macrophage colony-forming units (CFU-GM), which are formed at low cell densities and without the addition of exogenous growth factors.¹⁰³ This phenomenon has been the subject of intense study over many years and has prompted investigation of the role of a number of cytokines, including IL-1, TNF- α and GM-CSF in JMML.¹⁰⁴ Cells from patients with JMML cultured *in vitro* exhibit profound hypersensitivity to GM-CSF compared with those from normal controls. This appears to be a selective effect because responsiveness to other cytokines is normal, and it is postulated that the other cytokines such as TNF- α , responsible for some of the clinical features in advanced disease, are produced as a secondary response by hyperactivated monocytes.¹⁰⁵ Investigations are in progress to determine whether a growth factor

hypersensitivity assay, which is claimed to be both sensitive and specific for pediatric JMML, can be used in the diagnosis and monitoring of treatment.

The precise mechanism for growth factor hypersensitivity in JMML remains unknown and there is no evidence that it is associated with mutations in the GM-CSF receptor,¹⁰⁶ but it has been attributed to abnormalities in the GM-CSF signal transduction pathway. The proteins encoded by the *ras* family of protooncogenes play a central role in this pathway, and *ras* mutations have been demonstrated in 20–30% of patients with JMML. It is of great interest, in view of the clinical association with neurofibromatosis, that neurofibromin, the protein encoded by the NF type 1 gene (*NF1*), also plays a role in the *ras* signaling pathway, and *NF1* may function as a tumor suppressor gene in hematopoietic cells. Inactivation of neurofibromin may provide an alternative means of deregulation of the Ras signaling pathway. Investigations have shown that hematopoietic cells from knockout mice, which are homozygous for the *NF1* mutation, exhibit marked hypersensitivity to GM-CSF,¹⁰⁷ and that transplantation of such *NF1*-deficient hematopoietic liver cells induces a disease resembling JMML in irradiated mice.¹⁰⁸ The net result of this deregulated pathway is a hypersensitivity of cells to GM-CSF with proliferation of monocytes and myeloid cells, which infiltrate tissues causing bone marrow failure, and produce TNF- α and other cytokines, thus accounting for the fever, wasting and inanition characteristic of advanced JMML. Mutations in the *PTPN11* (Noonan syndrome) gene have been described in 34% of JMML patients without Noonan syndrome.¹⁰⁹ The gene encodes for the SHP-2 protein, involved in regulation of the mitogen-activated protein kinase (MAPK) cascade. Mutations in *ras*, *NF1*, and *PTPN11* are mutually exclusive.

Management

The essential investigations are shown in Table 18.2; particularly in the younger child with normal cytogenetics, appropriate investigations to exclude a viral infection are essential. If there is any doubt about the diagnosis of JMML, especially in young infants, a period of observation is recommended: there is no evidence that this will prejudice the efficacy of any subsequent treatment.

It is clear that older children with JMML and those with a high HbF and a low platelet count have a worse prognosis. In all reports involving significant numbers of patients, there is a small number of children who may survive for many years with minimal or no treatment; these tend to be under 2 years of age at diagnosis, with higher platelet counts and without gross elevation of HbF. Intensive chemotherapy has been notably unsuccessful in patients with aggressive JMML with high HbF and rapidly progressive disease. Despite some reports of response, true remission does not seem to be

achievable and the survival in a group of 72 children with JMML who did not receive a BMT was 6%, with no difference between those patients who did and did not receive intensive treatment.^{110,111}

BMT is the only curative treatment for JMML, and if the patient has no histocompatible sibling a search for an alternative donor is justified in all children, save the small minority of infants with indolent disease; the disease is difficult to eradicate by BMT,^{112,113} and there is evidence that a graft-versus-leukemia effect plays an important role in cure.¹¹⁴ The results of transplants from both siblings and alternative donors leave much room for improvement.^{114–117} The first report of successful BMT in JMML from Seattle used a preparative regimen of TBI and cyclophosphamide. Survival in the largest case series to date of 43 children with JMML treated by BMT was 38% at 5 years for the 25 children with a sibling donor and 18% for those with an unrelated donor. The actuarial probability of relapse was 58%, and survival was superior for children whose preparative regimen did not include TBI. The combination of busulfan, cyclophosphamide and melphalan appears promising for both sibling and alternative transplants,^{118,119} and is undergoing further assessment. The role of intensive chemotherapy and/or splenectomy to reduce the burden of disease before transplantation remains unclear but either form of treatment may be indicated in some patients.

The refractory nature and unique biologic features of JMML have prompted the investigation of various differentiating agents and cytokines. The most widely used has been 13-*cis*-retinoic acid, reported as producing complete or partial response in 5 of 10 children;¹²⁰ with other retinoids, it is undergoing further study. Alternative approaches being studied *in vitro* include the use of antagonists to the GM-CSF receptor¹²¹ and the IL-1 receptor.¹²²

Down syndrome and abnormal myelopoiesis

Clinical and laboratory features of transient abnormal myelopoiesis

TAM or transient myeloproliferative disease (TMD)^{23,123,124} is usually discovered as an incidental finding on routine blood count in babies with Down syndrome, but has also rarely been described in normal nonmosaic infants. The precise incidence of TAM is unknown but preliminary reports from a screening program suggested that it might be found in up to 1 in 10 neonates with Down syndrome. TAM has also been diagnosed in hydropic fetuses *in utero*. Affected infants may have no associated clinical features but there is often enlargement of the liver and spleen with significant numbers of blasts in the blood, but a lesser degree of bone marrow infiltration. There is usually persistent evidence of hematopoietic maturation, with maintenance of hemoglobin, neutrophils and

normal or raised platelet count in many patients. The maturing blood cells may show a degree of dysplasia. Morphologically, cytochemically and on immunophenotyping the blast cells resemble those of acute megakaryoblastic leukemia and may exhibit clonal cytogenetic abnormalities; there are no real distinctions between these blasts and those of patients with unequivocal leukemia.

Prognosis and management

The majority of patients with TAM show spontaneous improvement, which usually occurs over weeks to months but may take longer. This condition is benign in the majority of patients, but there have been a number of reports of death in the neonatal period associated with TAM; a characteristic finding at post-mortem is extensive visceral fibrosis. In general, however, supportive care is all that is needed in the majority of patients, and cytotoxic treatment should be avoided; if indicated it would be appropriate to use low-dose cytarabine in the first instance. The risk of subsequent development of myeloid leukemia after TAM has been estimated at 20–30% but these proportions need confirmation from larger prospective studies.

Postneonatal period

Virtually all cases of myeloid leukemia in Down syndrome are megakaryoblastic or erythroblastic leukemia, subtypes that are exceptionally rare in other children and usually occur in the first 4 years of life. Many cases have a long prodrome of MDS with low platelets, dysplastic cells in the blood and a low proportion of blast cells in the marrow; thus cases may be classified at various stages as having RAEB or RAEBt or AML.¹²⁵ The cytogenetic findings are also distinctive, with very few instances of the typical translocations t(8;21) or t(15;17); the commonest finding is trisomy 8.¹²⁶ The patients may remain well without treatment for weeks or months, but in contrast to TAM deterioration is inevitable and patients die if untreated.²² There is good evidence that children with Down syndrome and AML respond very well to chemotherapy, although they exhibit more toxicity than others,^{127,128} and this may be related to enhanced sensitivity to cytarabine.¹²⁹ The event-free survival for such patients is, in several series, superior to that for other children without recourse to high-dose therapy and BMT. It has been suggested that a regimen of low-dose cytarabine may afford adequate treatment,^{130,131} but this approach has only been used in small numbers of patients, several of whom relapsed, and it cannot be recommended in view of the excellent results from conventional intensive therapy. There is no indication that early treatment during the prodrome of AML offers any advantage in these children, and it is usually appropriate to instigate treatment once symptoms develop.

Familial MDS and congenital bone marrow disorders

AML/MDS

There are a number of case reports from the older literature, usually reports of single families with a myeloproliferative or myelodysplastic disorder, which are imperfectly investigated compared with modern techniques, such as the large kindred described by Randall *et al.*¹³² More recently a number of families have been described in which more than one member has developed AML or MDS; this may be associated with emergence of a cytogenetic abnormality in the marrow, usually involving chromosomes 7¹³³ or 5,¹³⁴ and in some cases with platelet storage pool deficiency.¹³⁵ From the practical point of view, it is important when examining families for suitable donors to exclude the presence of familial or genetically determined MDS.

Fanconi anemia

Patients with Fanconi anemia (see Chapter 3) have an estimated actuarial risk of developing a myeloid malignancy of 52% by the age of 40 years,¹⁵¹ and may present with AML or MDS. The risk is higher in patients with clonal cytogenetic abnormalities, which most often involve chromosome 7,¹³⁶ however, clonal cytogenetic abnormalities are of little value for predicting leukemic change in the individual patient.^{137,138} Treatment of Fanconi anemia by BMT¹³⁹ is likely to be more effective when undertaken early and should reduce the risk of leukemic transformation, although not of solid tumors.¹⁴¹ Treatment after transformation is associated with a high risk of relapse. The results of unrelated donor transplants for patients without an HLA-compatible sibling are improving but all transplants will be more effective before development of MDS or leukemia.

Shwachman–Diamond syndrome

The Shwachman–Diamond syndrome of exocrine pancreatic insufficiency and neutropenia is a rare autosomal recessive disorder (see Chapter 3) characterized hematologically by variable neutropenia, thrombocytopenia and a raised HbF; it has been known for many years to predispose to the development of leukemia. In a review of 21 patients, MDS developed in seven and was associated in five with clonal cytogenetic abnormalities in the bone marrow; five patients progressed to AML.³⁴ While BMT could in theory correct the hematologic deficiency in Shwachman–Diamond syndrome, conventional BMT is too toxic and both patients in the series quoted died after transplantation, but there has been success with reduced intensity conditioning (mini BMT).

Congenital neutropenia (Kostmann syndrome)

In the last few years the use of cytokines, in particular G-CSF, has reduced the incidence of infections and improved quality of life for patients with a variety of neutropenias (see Chapter 34) and for those with severe congenital neutropenia (SCN). Treatment with G-CSF has been preferred to BMT, particularly in cases who lack a histocompatible sibling donor. Patients with SCN have previously been recognized as having a predisposition to the development of leukemia, but since the introduction of treatment with G-CSF the number of reports has increased. It is not known, however, whether this is a direct consequence of G-CSF treatment or a reflection of improved survival. Monosomy 7 and *ras* mutations have developed in the bone marrow of patients with severe congenital neutropenia undergoing malignant transformation during G-CSF therapy.³² Mutations in the G-CSF receptor gene have been demonstrated in some patients with SCN during development of AML/MDS.^{141,142} Patients treated with growth factors for SCN should be monitored with regular bone marrow examinations including cytogenetics.

MDS with eosinophilia

A raised eosinophil count is characteristic of chronic myeloproliferative disorders, JMML and the idiopathic hyper-eosinophilic syndrome,¹⁴⁴ and may, of course, be secondary to infections or infestation. There are a few reports of patients with marked eosinophilia and dysplastic blood and bone marrow whose hematologic features cannot readily be assigned to a FAB subtype; the author has arbitrarily classed such patients as having eosinophilic MDS.⁴ Two such infants had hepatosplenomegaly and leukocytosis in association with t(1;5), one of whom rapidly deteriorated and the other was a long-term survivor.¹⁴⁵ Another 8-year-old girl described with t(5;12)(q31;p12–13) had stable eosinophilia for 7 years,¹⁴⁶ while the author has seen translocation t(5;12)(q31;q13) in association with marked skin infiltration in a 7-year-old boy whose clinical condition remained essentially unchanged for over 5 years.¹⁴⁷ Recently, successful therapy with the tyrosine kinase inhibitor imatinib has been described in a number of patients, including this child, and this approach deserves further study.¹⁴⁸

Although both hydroxycarbamide and interferon therapy have been recommended in eosinophilic MDS, this has not been borne out in clinical studies, and BMT would appear to be the most appropriate form of treatment provided that there is strong evidence of a clonal disorder.

Therapy-related MDS

Clinical and laboratory features

Secondary MDS and AML were first reported in adults

treated for Hodgkin disease, but also after non-Hodgkin lymphoma, myeloma and a variety of nonhematologic solid tumors.¹⁴⁹ An associated genetic disease predisposing to malignancies, such as a Li-Fraumeni syndrome, cannot be confidently excluded in all cases, but preliminary investigation of the frequency of p53 mutations in 19 pediatric secondary malignancies showed a germline mutation in only 1 child, who had a family history of cancer.¹⁵⁰

Two main types of secondary AML/MDS are associated with cancer treatment and each is associated with development of a characteristic pattern of cytogenetic change. Alkylating agent-induced MDS/AML tends to occur after 4–5 years, is associated with a preceding phase of MDS, and is characterized by deletions from chromosomes 5 and 7.¹⁵⁰ This disease is refractory to chemotherapy. The second, more recently described type of acute leukemia is related to treatment with topoisomerase II inhibitors and is associated with a shorter induction period and presentation as acute leukemia without a preceding MDS. Although secondary AML/MDS is rarer in children than adults, the correlation between type of previous therapy and clinical and chromosomal abnormalities is similar.¹⁵²

Alkylating agent-induced AML/MDS is typified by patients treated for Hodgkin disease; the drugs implicated include cyclophosphamide, chlorambucil, procarbazine and nitrosoureas. The risk is highest with increasing numbers of treatment cycles containing alkylating agents, prolonged chemotherapy and splenectomy; it does not appear to be increased further by radiotherapy.¹⁵³ Alkylating agents are also the major risk factor in patients with other tumor types such as non-Hodgkin lymphoma: a high rate of secondary AML/MDS was observed in the first UK Children's Cancer Study Group protocol for non-Hodgkin lymphoma, in which the protocol contained nitrosoureas in addition to cyclophosphamide and epipodophyllotoxins.¹⁵⁴

High-dose therapy with autologous BMT (ABMT), usually performed for patients with high-risk Hodgkin disease or non-Hodgkin lymphoma, has been recognized to be associated with an increased risk of subsequent development of MDS, but it is difficult to dissociate the risks of the ABMT from the preceding chemotherapy that such patients have almost inevitably received. Secondary MDS/AML has also recently been described in patients with aplastic anemia who have been treated with intensive immunosuppressive therapy.

Patients with secondary MDS may be asymptomatic initially when an abnormal film or blood count may prompt investigation; subsequently, as in primary MDS, symptoms of bone marrow failure develop with a mean duration of the preleukemic phase of about 11 months.

Alkylating agent-induced MDS does not always conform to the FAB subtypes. There is often a relatively low proportion of blasts at the time of diagnosis but this is accompanied by marked morphologic changes in all cell lines. There may be basophilia in both blood and bone marrow and cellularity

is variable, with fibrosis in some cases producing a dilute aspirate. Clonal cytogenetic abnormalities are found in >90% of cases and the majority involve chromosomes 5 and 7.^{155,156}

Topoisomerase inhibitor-related leukemia, which may be lymphoblastic or myeloblastic, has been more systematically studied in children because of its increased incidence in children with ALL receiving intensive epipodophyllotoxin treatment.^{156,157} Secondary AML was diagnosed in 21 of 734 patients treated for ALL; the overall cumulative risk was 3.8% at 6 years, but in a subgroup of children receiving drugs weekly or twice weekly the risk was >12%. The scheduling of drug administration influenced the development of AML; the total dose, type of leukemia and radiotherapy had no influence on the risk of AML. More detailed study showed that the majority of patients had myeloid or myelomonocytic leukemia and that chromosomal translocations predominantly involved the 11q23 region, most commonly as t(9;11) or t(11;19).

Another group of therapy-related leukemias has been described in association with t(8;21), inv(16) and t(8;16) after topoisomerase inhibitor therapy, alkylating agent therapy or anthracycline therapy.¹⁵⁸ These do not usually have a dysplastic prodrome and the risk factors have not been so precisely defined, but there is a similar correlation between the cytogenetic findings, morphology and response to treatment, as in *de novo* AML, so that patients may respond to chemotherapy.

Management

The advent of a second cancer in a highly curable condition is, of course, a tragedy to be avoided if at all possible, and the identification of such cancers emphasizes the importance of morphology review and karyotyping in all cases of relapsed leukemia. Ideally, it is desirable to avoid this disastrous complication, and this is sometimes possible by alterations in choice of drug or scheduling, always bearing in mind that such changes must not prejudice the chance of cure.

There is relatively little reported pediatric experience in the management of secondary malignancies. It appears that the response to treatment can be predicted by the biology of the leukemia, but any remissions achieved tend to be short lived. Thus, secondary AML with chromosome 5 and 7 abnormalities is highly resistant to chemotherapy, and while remissions can be achieved with combination chemotherapy in children with 11q23 leukemia, long-term survival is extremely poor. The only exception to this poor prognosis is the small group of patients with more favorable translocations such as t(8;21), who tend to have a better response to treatment (as do those with AML).

A study of intensive chemotherapy for secondary AML showed a 2-year disease-free survival of only 8% for patients with abnormal cytogenetics, thus confirming the dismal pro-

gnosis.⁶⁶ It would appear that BMT affords the only chance of cure, and in such circumstances the use of unrelated donors is justifiable.

Conclusions

Pediatric myelodysplasias are a rare but challenging group of diseases that have only recently attracted systematic study. They frequently occur in association with other genetically determined disorders. A methodical approach to investigation and differential diagnosis is essential. The FAB classification can be applied to most cases but JMML in children is a heterogeneous disorder with unique clinical and biologic features, is resistant to chemotherapy and has a high relapse risk after BMT. A "wait and see" approach to treatment may be appropriate for children with refractory anemia or younger children with JMML, particularly in the absence of cytogenetic abnormalities. Children with MDS with an excess of blasts are eligible in many countries for inclusion in AML trials, and the role of intensive chemotherapy should thus become apparent within the next few years. BMT, the most effective treatment for MDS, should be considered in most children with a histocompatible sibling donor. The results from unrelated donor transplants still leave much room for improvement but these and other types of transplant should be considered in high-risk patients, particularly those with aggressive JMML and secondary leukemias. National and international collaboration is essential to afford a better understanding of these rare diseases.

5 Lymphocyte Disorders

19

Primary and acquired immunodeficiency

Andrew R. Gennery, Adam H.R. Finn and Andrew J. Cant

Overview of specific immunity

The immune system evolved to distinguish “self” from “non-self,” destroying microorganisms but leaving the organism’s proteins unmolested. Malfunction leads to infection and/or allergy and autoimmunity. The immune response begins when secreted protein and phagocyte defenses eliminate microorganisms. Acquired immunity acts as a slower but highly specific mechanism that retains “memory” and mounts a response of increasing magnitude and specificity at each encounter. Individuals with inherited or acquired deficiencies in their specific immunity are susceptible to unusual, abnormally frequent or severe infectious diseases. Our increased understanding of the immune responses to microbes has led to a better understanding of both primary and secondary immunodeficiency; patients with immunodeficiency have taught us much about the intricacies of immune function.

The innate immune system

Physical and chemical barriers are highly effective at excluding pathogens by antimicrobial effects or prevention of microbial attachment. On breaching these barriers, and invading tissues, pathogens are confronted by elements of the innate immune response, an early evolutionary adaptation lacking immunologic memory, so the magnitude of response is the same each time the antigen is encountered. The receptors that recognize pathogens are predetermined by germline genes and recognize a few highly conserved structures called pathogen-associated molecular patterns (PAMPs) present or abundant on or in microorganisms but not the host. After binding to these molecules, the effector cell is immediately activated, accounting for the rapid responses of the innate system. Neutrophils, monocytes and monocyte-derived cells such as macrophages, are critical phagocytic components that engulf and kill invading

pathogens; monocyte-derived and professional presenting cells also process antigen and present it to lymphocytes to initiate or regulate the adaptive response. Plasma complement proteins act in a cascading sequence, binding extracellular organisms when the epithelial surfaces are breached; they enhance phagocytosis as well as causing inflammation and cell death. The first pathway to evolve was activated by foreign material in a nonspecific way (confusingly called the “alternative” activation pathway, because it was described second). In addition, mannan-binding lectin can opsonize microbes and activate the lectin pathway, and antibody–antigen (immune) complexes can activate the classical activation pathway (Fig. 19.1). Complement activation releases a series of vasoactive and proinflammatory peptides (anaphylatoxins: C3a, C4a and C5a) as well as opsonic

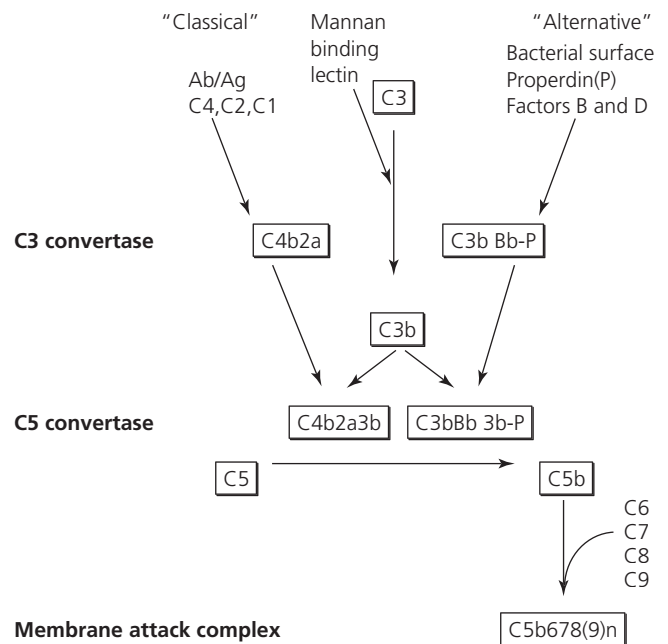

Fig. 19.1 The complement cascade.

proteins (e.g., C3b and C3bi), and culminates in the assembly of a large complex of proteins (C5b6789), which can lyse cell (or microbial cell) membranes and provoke inflammation.

Major histocompatibility complex

Major histocompatibility complex (MHC) antigens are highly polymorphic membrane glycoproteins expressed on all cell surfaces. Two classes, MHC I and MHC II, bind protein fragments in a surface groove and present them to T lymphocytes. MHC I molecules present viral or tumor proteins synthesized in the cytosol, whereas MHC II molecules present internalized and processed antigens. The MHC system is extremely polymorphic, to protect against the effects of novel pathogens, antigens of which might be ineffectively presented by monomorphic MHC and so condemn a whole species to fatal infection. Natural killer (NK) cells identify and eliminate cells, viral infected or malignant, that no longer express MHC by releasing intracellular toxic granules that promote cell death.

Recognition of antigen and heterogeneity

T and B lymphocytes of the adaptive immune response are generated in the bone marrow, thymus, lymph nodes, spleen and mucosal-associated lymphoid tissue. Each virgin lymphocyte has a unique antigen receptor, and in principle there is a lymphocyte bearing a receptor for every possible protein antigen that could be created. There are about 10^{16} different virgin B cells, each with specific antibody receptors; a similar number of virgin T cells, each with a specific receptor (TCR), are also generated from fewer than 400 TCR germline gene segments. Recombination activating genes 1 and 2 (RAG1; RAG2) cut the DNA between the gene segments which are then repaired by the normal DNA repair processes (Fig. 19.2). This remarkable diversity of T- and B-cell receptors is achieved by recombination processes that cut, splice and modify lymphocyte receptor genes. This process of extreme polymorphism, essentially random in its initial stages, generates both self-reactive lymphocytes, which are eliminated, as

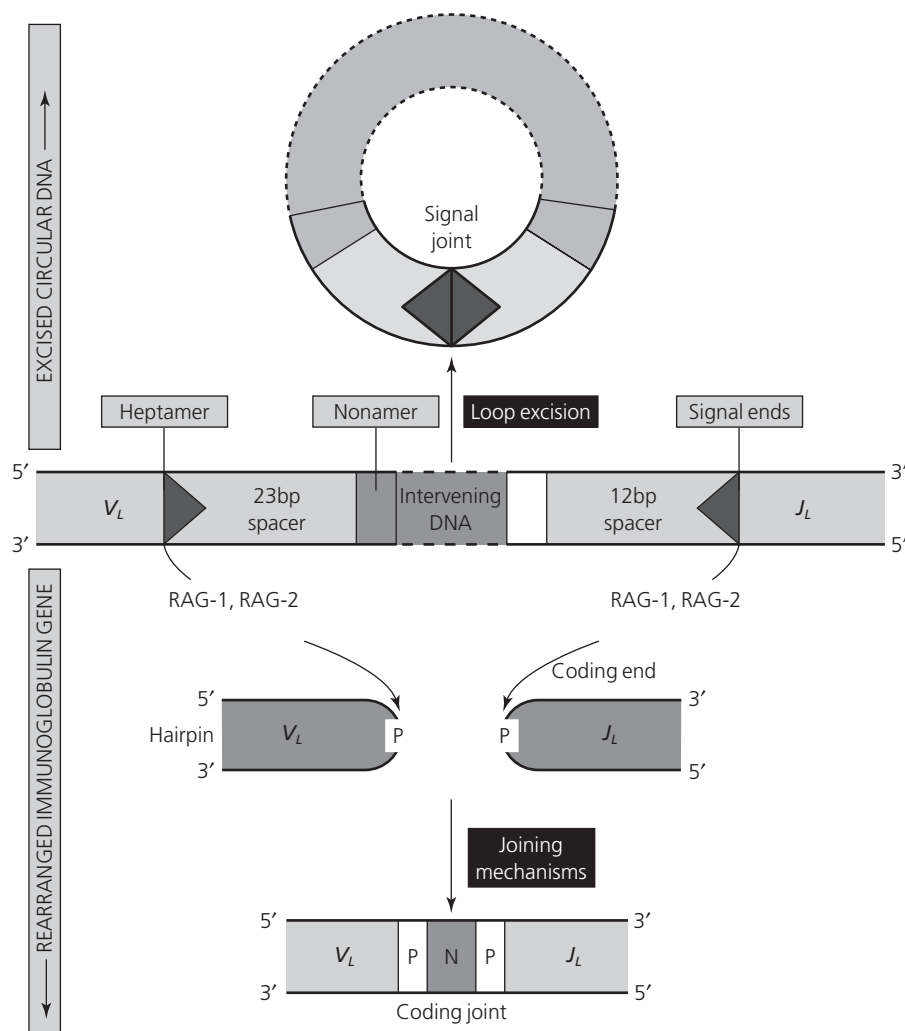

Fig. 19.2 Genetic mechanism for generating diversity in antibodies/T-cell receptors.

Recombinase enzymes control recombination of a single VJ sequence at random from the many possible combinations of 70 V and 4 J sequences on the immunoglobulin light-chain gene. The heavy chain gene has 100 V, 4 D and 6 J sequences. Reproduced with permission from Ref. 106.

P, P-nucleotides

well as lymphocytes that are effective against microorganisms and antigens. Following expression of a mature receptor, continued survival is dependent on antigen stimulation. When an antigen is encountered there is massive proliferation of T- and B-cell clones specific to that antigen.

B-lymphocyte development

B-lymphocyte receptors (BCR) are membrane-bound immunoglobulin molecules with two identical heavy (H) and two identical light (L) chains, joined by disulfide bonds (Fig. 19.3). The variable (V) domain end of the immunoglobulin molecule binds to specific antigen whereas the constant domain at the other end recruits other cells and molecules to immunoglobulin-bound antigen to effect killing and destruction. The constant (C) domain has five main forms (isotypes) that determine the immunoglobulin class (IgM, G, A, E and D). Smaller variations lead to four IgG and two IgA subclasses. Both heavy and light chains have C and V domains. There are two types of functionally identical light chains, lambda (λ) and kappa (κ).

Antibodies are immunoglobulins produced by B lymphocytes and their derivatives, plasma cells, in response to specific protein antigens. Specific serum antibodies may be present without prior exposure to the relevant antigen, so-called “natural” antibodies, resulting from cross-reactivity between antigens, particularly nonprotein (polysaccharide) antigens (e.g., ABO antibodies).

The variable region of the immunoglobulin molecule has a unique amino acid sequence, giving each antibody its unique specificity and ensuring, in principle, that there is

an antibody complementary to every antigen that could be constructed. There are five main classes of immunoglobulin, each with its own structure and functions.

The immunoglobulin class or isotype is determined by the heavy chain. During B-lymphocyte development, rearrangement to bring a particular variable gene combination to lie adjacent to a different heavy chain constant region gene allows the B lymphocyte to switch to another antibody class (isotype) with the same antigen specificity. A μ chain is always produced first; class switching to other isotypes occurs later. Specific antibody diversity is created by the large number of possible combinations of variable region genes that can be selected and is increased further by a very high mutation rate in V genes and the effect of the enzyme TdT (deoxynucleotidyltransferase) during the rearrangement process.

Variable domain gene rearrangement

Variable domains of T- and B-cell antigen receptors are made by recombining segments encoded by genes from two or three “families.” For immunoglobulin light chains, a variable (V) segment joins to a joining (J) segment, which joins to a C (constant) domain. A similar process occurs for the heavy chain, but using a diversity (D) segment as well as V and J segments, all joined to the heavy chain C domain. There are a number of different gene segments in each “family.” Diversity is generated by varying the combination in which the V(D)J segments are arranged. Further diversity is introduced by pairing different combinations of heavy and light chain variable regions. A third way of increasing diversity is created by imprecise splicing and rejoining of different gene segments creating different nucleotides at the joining junction. These recombination events occur in the bone marrow.

T-lymphocyte development

T-lymphocyte receptor (TCR) development is similar to that of B cells, but occurs in the specialized microenvironment of the thymus. Precursor cells migrate to the thymus and undergo TCR chain rearrangements. The TCR consists of α/β or γ/δ heterodimers. Each α , β , γ and δ chain contains a variable and a constant domain. As in the BCR, variable domains are constructed from gene segments from different V, D and J “families.” TCR α and γ variable domains do not contain D segments. A fundamental difference between BCR and TCR is that TCR only recognizes an antigen bound to an MHC complex. During thymic development, T cells that recognize the individual’s own MHC complex are positively selected (self-MHC restricted), while those that do not undergo apoptosis (programmed cell death). Furthermore, those that recognize self antigen–MHC complexes are eliminated (negatively selected), thus preventing autoimmunity. In this way, less than 2% of T-cell precursors entering the thymus leave as mature, naive T cells.

Fig. 19.4 Interactions of CD3 (T-cell receptor complex) and CD8 or CD4 with class I and class II major histocompatibility complex (MHC), respectively.

Antigen presentation and lymphocyte activation

Mature T and B lymphocytes circulate through blood, lymphatics and tissues “looking for” antigen specific for their receptors. Microorganisms taken up and processed by antigen-presenting cells (APCs), such as macrophages, are broken down into small peptide fragments, which are bound in the surface grooves of MHC class I or II molecules and presented at the cell surface as an antigen–MHC complex. Adaptive immune responses are generated in lymphoid tissue, where lymphocytes and APCs are mixed in high densities. Only a few hundred distinct lymphocytes will recognize each specific antigen. Although all cells can present antigens of infecting intracellular pathogens using MHC class I to CD8⁺ cytotoxic T cells, APCs do this very effectively and also present processed antigens from extracellular organisms via MHC class II to CD4 helper T cells (Fig. 19.4). Following this, an APC surface molecule (B7) interacts with CD28 on the T cell to provide a second signal. The synchronous combination of these two signals (TCR/MHC–antigen and B7/CD28) activates the T cell causing replication of T cells bearing the same antigen-specific receptor (clonal expansion). In contrast, delivery of the first signal alone renders the T cell unable to respond to antigen (anergic). B cells express antibody (immunoglobulin) on their surface during development and recognize native (unprocessed) antigen directly. Subsequently, antibodies are secreted in large quantities by the mature B cell (plasma cell). T-cell receptors by contrast are only surface expressed and exist in a complex of coreceptors and signaling molecules. Individual lymphocytes and their progeny do not change the antigen specificity of the receptor they express. However, B cells can change the isotype of the antibody they produce (e.g., from IgM to IgG). This switching process is controlled by interactions between B and T cells via both direct receptor–ligand contact and release of soluble factors (cytokines) (Fig. 19.5). Thus, T cells are vital not only in specific cell-mediated responses but also in the regulation of most specific humoral (antibody-mediated) immune responses. More details about these processes can be found in specific texts.¹

Fig. 19.5 Interactions between T and B cells: T-cell help. L, ligand; MHC, major histocompatibility complex; CD, differentiation cluster; IL, interleukin.

Primary immunodeficiency diseases

Many primary immunodeficiencies were first described as clinical syndromes, usually recognized in children who became unwell with progressive infections of particular organ systems or compartments and with certain characteristic types of pathogen. Careful investigations in such groups led, in some cases to recognition of the defect at the functional cellular level. In recent years, the molecular basis of many of the primary (genetically inherited) immunodeficiencies has been elucidated at the protein and genetic levels.² The identification and clarification of precise molecular mechanisms has not only enhanced understanding of the immune response but also enabled more focused treatment of primary immune deficiencies.

Specific immune defects are described below. Severe and rare conditions have tended to be elucidated first, but it is clear that many milder conditions are variants of more severe disease, and some mild defects only become manifest when other factors simultaneously impair immune function. During the late 1990s and early 21st century several new primary immunodeficiencies have been described by applying new molecular genetic techniques to groups of patients with specific unusual or recurrent infections. It has been surprising to find that defects in these pathways previously thought to have quite general regulatory or signaling roles turn out to cause propensity to infection with narrow spectra of pathogens.

T-cell and “combined” immunodeficiency

Severe combined immunodeficiency

Severe combined immunodeficiency (SCID) describes the severest form of primary immunodeficiency, where failure of both T- and B-lymphocyte function leads inevitably to death from infection within the first year of life. The different forms of SCID result from different blocks to the differentiation of

Table 19.1 Classification of severe combined immunodeficiency.

Defect	Gene defect	Inheritance	T/B/NK cells
Cytokine signaling	cδc	XL	-/+/-
	JAK 3	AR	-/+/-
	IL-7 Rα	AR	-/+/+
Defects associated with the salvage pathway of nucleotide biosynthesis	ADA deficiency	AR	T _{low} /B _{low} /NK _{low}
	PNP deficiency	AR	T _{low} /B _{low} /NK _{low}
Defects affecting signaling through the T-cell antigen receptor	CD45	AR	-/+/-
	CD3 δ	AR	-/+/-
	CD3 ε	AR	-/+/-
	ZAP 70K	AR	+ / + / + (absent CD8)
VDJ recombination defects	RAG 1 and 2	AR	-/-/+
	Artemis	AR	-/-/+
Other	Reticular dysgenesis	AR	-/-/- (+ myeloid dysfunction)
	MHC class II deficiency	AR	+ / + / + (absent CD4)

ADA, adenosine deaminase; AR, autosomal recessive; IL, interleukin; JAK, Janus-associated kinase; PNP, purine nucleoside phosphorylase; RAG, recombination activating gene; XL, X-linked.

T and, in some conditions, B and NK cells.³ The main types of SCID can be broadly classified into five groups (Table 19.1).

Most of the SCID-associated gene mutations have now been identified, providing insight into the role of key molecules involved in lymphocyte precursor differentiation. Identifying the molecular defect in specific patients with SCID is important for prognosis, treatment, genetic counseling and increasing our knowledge about these rare diseases.

While the usual clinical features of this group of diseases are well characterized, atypical presentations and “leaky” forms with an attenuated phenotype are increasingly recognized.^{4–6} Circulating T-lymphocyte numbers are usually low or absent but may be normal in certain forms (Table 19.1). Lymphocyte responses to mitogen are usually absent, but may be present in attenuated forms where immunoglobulin may also be produced. However, tests of antigen-specific T-lymphocyte proliferation and antibody production are consistently defective, and delayed hypersensitivity skin tests are negative. Patients usually have a limited diversity of T-lymphocyte receptor and immunoglobulin gene rearrangements. Thus, diagnosis may be more difficult in atypical patients.

Signaling receptor defects

Common γ-chain deficiency (X-linked SCID)

The most common form of SCID is characterized by severe lymphopenia, absence of mature T and NK lymphocytes, but normal numbers of circulating B lymphocytes. It is caused by a deficiency of the γ-chain common to the interleukin (IL)-2, IL-4, IL-7, IL-9 and IL-15 receptors.⁷ Carriers show nonrandom skewed X inactivation of lymphocytes.

JAK-3 deficiency

This autosomal recessive form of SCID, phenotypically identical to the X-linked common gamma-chain deficiency, is due to mutations in the gene encoding Janus-associated kinase 3,⁸ a protein that binds to the intracellular tail of the common gamma chain, and through which signals are transduced following cytokine binding.

IL-7Ra deficiency

This rarer autosomal recessive form of SCID is characterized by a T⁻/B⁺/NK⁺ phenotype.⁹ The defect lies in the alpha chain of the interleukin 7 receptor and disrupts T cell development.

Lymphocyte metabolism defects

Adenosine deaminase deficiency

Adenosine deaminase (ADA), an enzyme of the purine salvage pathway, catalyzes the irreversible deamination of adenosine and deoxyadenosine to inosine and deoxyinosine, which are reutilized or degraded to uric acid. This pathway is particularly important for lymphocytes and erythrocytes, which have absent or low *de novo* purine synthesis. Autosomal recessive ADA deficiency results in the accumulation of toxic metabolites such as deoxyadenosine, which inhibit DNA synthesis. Gene deletion leads to very little ADA activity and a profound T and B lymphopenia and early-onset SCID. Patients present earlier than with other forms of SCID, with very low numbers of T, B and NK lymphocytes. Skeletal abnormalities (cupping deformities of the ends of the ribs, abnormalities of the transverse vertebral processes and the scapulae) are reported in up to 50% of cases.¹⁰ Neurodevelop-

mental problems occur in some patients.¹¹ The diagnosis is confirmed by finding very low erythrocyte ADA activity and high levels of dATP in the urine. The clinical spectrum is broader than classical SCID; an increasing number of patients are being diagnosed in childhood with features that include sinopulmonary bacterial infections, markedly elevated IgE and/or eosinophilia, variable elevation of IgM and IgG, and autoimmune features including autoimmune hemolytic anemia and thrombocytopenia.⁵

Purine nucleoside phosphorylase deficiency

Like ADA deficiency, this extremely rare form of SCID is caused by an inherited defect in the purine pyrimidine salvage pathway. The metabolites deoxyguanosine and deoxyguanosine triphosphate are particularly toxic for thymocytes, resulting in a T-lymphocyte deficiency with relatively preserved B-lymphocyte function.¹² Recurrent infections usually begin in the first or second year, although some patients are asymptomatic until as late as 6 years of age. Additionally, patients show characteristic neurologic abnormalities, notably spastic diplegia, ataxia and dysarthria, and autoimmune problems, particularly hemolytic anemia.¹³ There is a progressive fall in T-lymphocyte numbers and function, poor *in vitro* mitogen responses and negative delayed hypersensitivity skin tests. Immunoglobulin levels and antibody responses are initially normal but then fall. Serum uric acid levels are very low. The diagnosis is confirmed by demonstrating absent purine nucleoside phosphorylase activity in red cells or fibroblasts and deoxyinosine and deoxyguanosine in the urine. Without corrective treatment the prognosis is poor, with most cases dying in early childhood. Treatment by early bone marrow transplantation, if successful, corrects the immunodeficiency; its effect on the neurologic disease is uncertain.

V(D)J recombination defects

Two phenotypically identical forms of this autosomal recessive disorder have been described with absent T and B lymphocytes, but normal numbers of NK lymphocytes. The first is due to defects in the recombination activating genes (RAG) necessary for the development of T and B lymphocyte antigen receptors.¹⁴ In the second, there is a defect in the artemis gene, necessary for rejoining DNA following V(D)J recombination, leading to *in vitro* radiosensitivity.¹⁵ Bone marrow transplantation results are not as good as in the T⁻/B⁺ forms of SCID. “Leaky” RAG defects have been shown in some patients with Omenn syndrome.

Omenn syndrome

Omenn described 12 infants in six sibships from an inbred Irish-American kindred; all developed an infiltrating skin rash, hepatosplenomegaly and lymphadenopathy, together with diarrhea, failure to thrive and recurrent persistent infections leading to death.¹⁶ Children usually present in early

infancy although atypical cases may be seen after the first year of life. There are normally high numbers of oligoclonal, activated, poorly functional T lymphocytes of the Th2 phenotype but absent B lymphocytes and low levels of IgA, IgG and IgM. Elevated IgE levels and eosinophilia are often present. The syndrome has been called a “leaky” form of SCID in that small numbers of very abnormal T lymphocytes “leak” past the block in T-lymphocyte development. In some cases a RAG mutation is found.¹⁷ T cells in these patients are autologous, although the clinical picture may resemble SCID with maternofetal engraftment (see below). Molecular genetic studies to identify the origin of the dermal infiltrative T lymphocytes can differentiate the two disorders. Activated oligoclonal lymphocytes in skin provoke Langerhans cells (APC) to migrate to lymph nodes, liver and spleen where lymphoid tissue architecture is severely disrupted. Bone marrow transplantation is the only curative treatment.

SCID with maternofetal engraftment

In immunocompetent individuals, lymphocytes passing from mother to fetus are rejected by the fetal immune system. However, sensitive molecular techniques show that circulating T lymphocytes of maternal origin may be found in up to 50% of infants with SCID.¹⁸ Maternally engrafted lymphocytes show a profoundly restricted V β gene usage, suggesting they have a much reduced TCR diversity and come from a small number of lymphocyte clones. They usually bear the phenotype of activated mature T lymphocytes but give markedly diminished or absent proliferative responses to phytohemagglutinin (PHA), allogeneic cells or specific antigens. Such cells may be clinically silent but in some cases can cause severe congenital graft-versus-host disease (GVHD).

Reticular dysgenesis

This rare autosomal recessive form of SCID is characterized by defective lymphoid and myeloid differentiation. Bone marrow examination confirms the absence of myeloid precursors. Platelets and red lymphocytes are formed normally but there is thrombocytopenia. This may not be a discrete entity, but the result of other forms of SCID, complicated by severe maternal engraftment and bone marrow GVHD.¹⁸ The absence of the nonspecific cellular elements of the immune system (including neutrophils) makes the immunodeficiency even more severe than in other forms of SCID. Clinical presentation occurs earlier, as does the inevitable fatal outcome if bone marrow transplant is not performed quickly.

MHC class II deficiency

MHC class II antigens (HLA DR, DP and DQ) are expressed on APCs that present antigen to CD4⁺ T lymphocytes leading to the activation of T-helper lymphocytes specific for that antigen. Expression of MHC II in the thymus is also essential for positive selection of CD4⁺ T lymphocytes. It is therefore not surprising that lack of MHC II expression (“bare lympho-

cyte syndrome") results in a profound susceptibility to viral, bacterial, fungal and protozoal infections.¹⁹

MHC II deficiency, a rare autosomal recessive disease, can result from mutations in several different genes, including *MHC2TA*, *RFX5* and *RFXAP*, which code for a complex of regulatory factors controlling transcription of MHC II genes, rather than defects in the MHC II genes themselves.²⁰ There is little genotype/phenotype correlation.

The clinical picture resembles SCID, although sometimes infections develop slightly later. Intestinal and hepatic complications due to cryptosporidial infections are more common than in other immune defects. Neurologic manifestations caused by a range of viral infections are also well described, including coxsackievirus, adenovirus, poliovirus and meningoencephalitis.

Most patients have CD4 lymphopenia and hypogammaglobulinemia; lymphocyte proliferation responses are usually normal. The diagnosis can be confirmed flow cytometrically by showing absent or significantly reduced levels of class II molecules, for example DR, on cells that constitutively express class II (B lymphocytes and monocytes).

Affected children require treatment with replacement immunoglobulin, co-trimoxazole and antifungal prophylaxis pending bone marrow transplantation, which is the definitive treatment, although this is more difficult than for other forms of SCID.

Idiopathic CD4 lymphocytopenia

A profoundly low CD4⁺ lymphocyte count characterizes this poorly understood condition. Most reports have been in adults, but it occurs in children. It is regarded as a primary immunodeficiency disorder;²¹ a retroviral cause has not been found despite strenuous efforts. There may be defective lymphocyte homeostasis and restricted clonality in lymphoid populations. Immunoglobulin levels and antibody responses may be normal. The CD4 cell count remains stable for a prolonged period rather than progressively declining as seen in human immunodeficiency virus (HIV) infection. Prophylaxis against *Pneumocystis carinii* infection should be given.

Other SCID syndromes

Defects in other lymphocyte surface and signaling molecules have been described in small numbers of patients. Although T and B cells are usually present, the numbers are often low and function is diminished. Such cases are being recognized in increasing numbers as molecular diagnostic testing becomes more widely available. Other atypical or unusual presentations may be due to defects in molecules already described, or to as yet unidentified molecules or mutations. More detailed texts should be consulted for specific details.

Clinical features and diagnosis of SCID

Affected babies appear well at birth, with the exception of infants with reticular dysgenesis. Most are asymptomatic

for the first few weeks of life before developing persistent respiratory tract or gut infection and failure to thrive, falling progressively away from their birth centile.²² Chronic diarrhea caused by persistent, sometimes multiple, gastrointestinal viral infections, often with associated food intolerance, is common, as is persistent respiratory tract infection with respiratory syncytial virus or parainfluenza viruses, with failure to clear virus accompanying a persistent bronchiolitis-like illness. An insidiously progressive persistent interstitial pneumonitis should raise the suspicion of *Pneumocystis carinii* infection, often a copathogen with respiratory viruses. Other presentations include invasive bacterial infections, particularly staphylococcal or *Pseudomonas* septicemia and pneumonia, which may respond poorly to appropriate treatment. Severe invasive fungal infection is rare, but often fatal. Extensive, persistent superficial candidiasis is more common. Occasionally babies present with disseminated BCG (bacille Calmette–Guérin) or vaccine strain poliomyelitis virus. Children presenting within the first 6 months or so of life are more likely to have SCID or a severe T-lymphocyte defect.

Noninfectious manifestations mainly result from GVHD caused by foreign lymphocytes acquired either maternally *in utero* or from unirradiated transfused blood. Engraftment of transplacentally acquired maternal lymphocytes (maternofetal GVHD) sometimes, but not always, provokes GVHD, typically with a mild reticular skin rash and slightly deranged liver function tests. Fatal GVHD can follow transfusion with nonirradiated blood, white cell, lymphocyte or platelet concentrates. In these cases the skin rash is more severe, and lymphadenopathy and hepatosplenomegaly may be present. Cases may be clinically indistinguishable from Omenn syndrome, but identification of maternal cells by karyotype or DNA fingerprinting will distinguish maternofetal GVHD from Omenn syndrome. Epstein–Barr virus (EBV) infection may lead to uncontrolled B lymphoproliferative disorders.

Examination usually reveals a wasted child who has dropped through the growth centiles, with candidiasis and other infections. Skin rashes may be indicative of infection or GVHD. Lymphoid tissue is usually absent. There may be hepatomegaly.

By the time of diagnosis most infants will have several infections. Unfortunately, only interstitial pneumonitis is pathognomonic of immunodeficiency, and so infants with respiratory infection may be severely ill and needing assisted ventilation before immunodeficiency is considered: bone marrow transplantation is less successful when children are diagnosed late with significant organ damage. In a UK series, symptoms developed at a median age of 5 weeks, but diagnosis of SCID was not made until a median age of 7 months (range 4 weeks to 16 months).²³

Lymphopenia is the most useful diagnostic clue but is often overlooked as the absolute lymphocyte count is rarely observed when a full blood count is performed. Lymphocyte counts are higher in infants than adults and the lower limit of

normal can range from $2 \times 10^9/L$ at birth to $4 \times 10^9/L$ at 1 year (see Chapter 37 for reference values). In the UK series of 45 infants with SCID, 44 had a lymphocyte count > 2 standard deviations below the mean for age, compared with 8 in a control group all of whose counts normalized on repeat testing a few days later.²³

Lymphocyte subset analysis demonstrates low or absent T-lymphocyte numbers; B-lymphocyte numbers may be normal. IgG levels may be normal due to transplacentally transferred maternal IgG, and many laboratories cannot distinguish between absent IgA and IgM and the low levels normally seen up to 6 months of age; hence if SCID is suspected, lymphocyte subset analysis should always be performed. Failure of lymphocyte proliferation in response to stimuli such as phytohemagglutinin helps confirm the diagnosis.

Chest radiography may demonstrate an absent thymus, and hyperinflation and/or interstitial pneumonia, if infection is present. Typical cupping and flaring of the costochondral junction is also evident in patients with ADA deficiency.

Once an immunologic diagnosis has been made the nature and extent of infection should be determined. Serology is unhelpful as infants with SCID cannot produce antibody. Viral culture and immunofluorescence studies of nasopharyngeal suction specimens, as well as electron microscopy of stool, and stool and urine viral culture, together with bacterial stool, urine and surface swab cultures are necessary. EBV, cytomegalovirus (CMV) and adenovirus must be looked for assiduously, including polymerase chain reaction (PCR) testing of blood, and in children with a respiratory disease, bronchoalveolar lavage should be performed to look for pathogens such as *Pneumocystis carinii*, bacteria and viruses. Finding a respiratory virus in a nasopharyngeal suction specimen should not preclude performing bronchoalveolar lavage as many infants have dual infections, and *Pneumocystis carinii* is usually found only in respiratory secretions and is treatable. Infants should be nursed in strict isolation to prevent nosocomial viral and fungal infections. Nutritional support is often required.

Without treatment, patients die from infection by about 12 months of age. The diagnosis of SCID is a pediatric emergency; suspected cases should be urgently referred to a designated center for assessment and treatment.

Combined immunodeficiency

Wiskott–Aldrich syndrome

This X-linked recessive condition is characterized by immunodeficiency, thrombocytopenia, eczema, an increased risk of autoimmune disorders and malignancy. It is due to defects in Wiskott–Aldrich syndrome protein (WASP), which regulates the actin skeleton of bone marrow derived cells.²⁴ Mutations in the WASP gene are also found in patients with X-linked thrombocytopenia (XLT),²⁵ and X-linked severe congenital

neutropenia.²⁶ Lack of a proper actin skeleton may lead to failure of polarization of T cells toward antigen-presenting cells and B cells, leading to a failure of cognate immune responses.

The classical features of bruising/bleeding, recurrent infections and eczema can each vary in severity; the eczema can be surprisingly mild. Presentation is usually in early life with bruising, petechiae and bleeding; thrombocytopenia and bleeding episodes may require platelet transfusions. Bacterial and/or viral infections of the upper and lower respiratory tract are common; opportunistic infection, such as *Pneumocystis carinii* may occur. Herpesviruses are poorly handled and may cause severe and recurrent disease. Impetigo, cellulitis and skin abscesses are common whilst molluscum contagiosum and viral warts may be very extensive. Infection exacerbates the bleeding tendency, and early death may result from bleeding. With increasing age, infective problems replace bleeding as the major cause of death. Immunization with polysaccharide vaccines are often ineffective. The median survival is 11 years. Autoimmunity, particularly hemolytic anemia and vasculitis, and lymphoreticular malignancy become more common with increasing age, and many cases are related to persistent EBV infection. Heterozygous female carriers are clinically normal and demonstrate nonrandom X-inactivation in all hematopoietic cells.

Thrombocytopenia with an abnormally small mean platelet volume (< 5 fL) are pathognomonic. The severity of immunodeficiency is variable, but affects cellular and humoral responses. T lymphopenia is progressive with depressed responses to mitogens and antigens and negative delayed hypersensitivity skin tests. Serum immunoglobulins often show a very low IgM, normal IgG, and raised IgA and IgE. Antibody responses to tetanus, *Haemophilus influenzae* type B and pneumococcus are often low, as are isohemagglutinin titers. The direct Coombs test is frequently positive. *In vivo* neutrophil and monocyte chemotaxis may be impaired. Phagocytes migrate poorly to sites of inflammation and do not put out normal filopodia, dendritic cells do not present antigen effectively, lymphocytes show impaired signaling to each other, and platelets form imperfectly from megakaryocytes.^{27,28} Missense mutations in exons 1–3, which lead to normal-sized or truncated protein, result in the milder phenotype of XLT, whereas most other mutations result in the classic Wiskott–Aldrich phenotype.

Acute bleeding episodes may be controlled by platelet transfusions (irradiated to prevent GVHD). Splenectomy and steroid treatment will increase the risk of infection and should be avoided if possible, although topical steroids may be required for the eczema. Intravenous immunoglobulin, with or without prophylactic antibiotics, reduces bacterial sinopulmonary infections and in high doses may help to treat autoimmune phenomena.

Even with supportive intervention, the prognosis remains poor. Immunologic and hematologic correction can be achieved by bone marrow transplantation (BMT) and despite a higher

risk of EBV-driven lymphoproliferative disorders, 5-year survival is 87% after HLA-identical sibling donor BMT and 71% after unrelated donor BMT, although unlike HLA-identical sibling BMT, results for unrelated donor BMT after 5 years of age are poorer.²⁹

X-linked lymphoproliferative disease (Duncan disease)

In this X-linked condition immunity is normal and the patient asymptomatic until EBV or other stimuli³⁰ uncover a defect in T- and B-lymphocyte interaction. There are three common clinical presentations: fulminant infectious mononucleosis (58%), dysgammaglobulinemia, often evolving to common variable immunodeficiency (31%); and EBV-driven B-lymphocyte lymphoma, usually extranodal and affecting the gastrointestinal tract or central nervous system (20%). Less common presentations are vasculitis, aplastic anemia, hemophagocytic lymphohistiocytosis or pulmonary lymphomatoid granulomatosis.³¹ The prognosis is poor, with 45–96% mortality, depending on the clinical presentation; registry data indicate no survivors after 40 years of age. The gene responsible for the disease, *SH2D1A* in the Xq25 region of the X chromosome,³² encodes a small protein, SAP – signaling lymphocyte activation molecule (SLAM)-associated protein – which is crucial for T-lymphocyte and NK cell control of EBV-infected B lymphocytes; why this causes the clinical features is unclear. Confirmation of the diagnosis involves demonstrating EBV genome in blood by PCR, together with the immune defects outlined above and an abnormal serologic response to the virus with absent antibody response to EBV nuclear antigen. The mothers of affected boys also have abnormal EBV serology, with persisting very high titers against viral capsid antigen. Protein analysis reveals absent or abnormal SAP protein in many cases, although a gene mutation is not identifiable in up to 40% of patients. Treatment with intravenous immunoglobulin on a regular basis is recommended in affected patients as passive immunization against EBV, particularly if hypogammaglobulinemia is present. Hemophagocytic lymphohistiocytic episodes require treatment with immune suppression including ciclosporin, antithymocyte globulin, steroids and the HLH-94 protocol.³³ Correction of the disorder by bone marrow transplantation is the only curative treatment.

DiGeorge anomaly

This syndrome results from abnormal cephalic neural crest cell migration into the third and fourth pharyngeal arches in early embryologic development associated with a microdeletion at chromosome 22q11.2; it is also found in velocardiofacial, or Shprintzen, syndrome, which should now be considered as a part of the same spectrum.

Clinical features vary; partial forms are more common than the complete phenotype. Whilst classically recognized

by the triad of congenital heart defects, immunodeficiency secondary to thymic hypoplasia and hypocalcemia secondary to parathyroid gland hypoplasia, an expanded phenotype is increasingly recognized with dysmorphic facies (low-set, abnormally formed ears, hypertelorism and antimongoloid slant, micrognathia, short philtrum to the upper lip and high arched palate), palatal abnormalities (cleft palate, velopharyngeal insufficiency), autoimmune phenomena, learning difficulties (particularly speech delay), renal anomalies, neuropsychiatric disorders and short stature. Conotruncal heart defects are classically associated with the syndrome, but other defects include tetralogy of Fallot, septal defects, pulmonary atresia, and aberrant subclavian vessels. Some patients have normal cardiac anatomy.

Severe T-lymphocyte immunodeficiency presenting with a SCID phenotype is rare, accounting for < 1.5% of cases. Recurrent sinopulmonary infection due to partial humoral immunodeficiency is more common;³⁴ significant lung damage can occur due to repeated infection. Autoimmune features are increasingly recognized, including juvenile chronic arthritis and autoimmune cytopenias. The long-term immunologic outlook is not well defined.

This diagnosis should be considered in infants with heart lesions or hypocalcemic fits. Urgent cardiac surgery is often required; blood products should be irradiated before transfusion to avoid potentially fatal GVHD in the minority of cases with total thymic aplasia. Immunologic investigations should include a lymphocyte subset analysis and a test of mitogen-induced proliferative responses (PHA). CD4⁺ and CD8⁺ T-cell numbers are often modestly reduced while mitogen-induced proliferation is usually normal. Antibody responses, particularly to polysaccharide antigens, are often impaired. Immunoglobulin levels may be normal but hypogammaglobulinemia may develop; occasionally such children need immunoglobulin replacement. Most individuals respond to protein antigen vaccination. It is safe to give live vaccines such as oral polio vaccine, measles, mumps, rubella vaccine, or varicella zoster vaccine as long as the CD4 count exceeds 400/mm³, and T-lymphocyte mitogen responses are normal.³⁵

When there is severe immunodeficiency children should be treated like those with SCID. Surprisingly, given that the defect is thymic, BMT may be successful; thymic transplant has also been advocated.³⁶

X-linked hyper-IgM syndrome (CD40 ligand deficiency)

X-linked hyper-IgM syndrome is a T-lymphocyte immunodeficiency due to a defect in the gene encoding for the CD40 ligand glycopeptide (CD154) expressed on activated T lymphocytes. CD40L binds to CD40, expressed on B lymphocytes and monocyte/macrophage-derived cells (Fig. 19.5). Lack of binding prevents B-lymphocyte immunoglobulin isotype

switching from IgM to IgA, IgG and IgE as well as activation of Kupffer cells and pulmonary macrophages. Lack of IgA and IgG results in a similar clinical picture to X-linked agammaglobulinemia (XLA), with sinopulmonary and invasive bacterial infection, but, in contrast to XLA, opportunistic infections also occur; failure of T lymphocytes to activate macrophages results in *Pneumocystis carinii* pneumonia, and repeated bowel, pancreas and biliary tree infections with *Cryptosporidium parvum* leading to sclerosing cholangitis, cirrhosis, pancreatitis and hepatic malignancy. Neutropenia with oral ulceration is seen in 50% of patients and may be cyclical. A low or absent IgA and IgG, with normal or raised IgM, should suggest the diagnosis. Autoimmune phenomena are relatively common and include hemolytic anemia, thrombocytopenia, hypothyroidism, arthritis and liver disorders.³⁷

Patients should receive co-trimoxazole prophylaxis for *Pneumocystis carinii* pneumonia and immunoglobulin replacement therapy. With adequate replacement the high IgM levels may normalize. The neutropenia sometimes responds to granulocyte colony-stimulating factor (G-CSF) and intravenous immunoglobulin (IVIG). All drinking water should be boiled and filtered to lessen the risk of *Cryptosporidium parvum* infection, for which purpose antimicrobial prophylaxis is given by some practitioners although supportive evidence for this is lacking. Despite conventional treatment, many patients do not survive beyond the third decade of life, largely due to hepatic complications, but a few patients with a common variable immunodeficiency-like clinical course and no biliary or liver disease are relatively well in middle life. Bone marrow transplantation is increasingly being recommended for this condition.³⁸

MHC class I deficiency

Although described before MHC class II deficiency, SCID due to abnormal expression of the A, B and C components of the MHC class I complex is much less common. MHC class I is required for development of CD8⁺ T lymphocytes, and affected children have low numbers of these cells. Mitogen responses are frequently normal. The genetic basis for the disease is mutations in TAP1 or 2,³⁹ proteins required for transport of antigen from the cytoplasm into the endoplasmic reticulum where they associate with MHC class I.

This disease has a milder clinical phenotype than MHC class II deficiency, symptoms often not beginning until late childhood. Recurrent respiratory tract infections leading to bronchiectasis and sinus problems are common. Unusual skin lesions thought to be due to vasculitis have been reported.

Diagnosis is confirmed by showing absent HLA class I expression on peripheral blood cells. Sinopulmonary infections should be promptly treated with antibiotics, physiotherapy and bronchodilators. The value of prophylactic antibiotic treatment is debated. Most cases do not require replacement immunoglobulin therapy or bone marrow transplantation.

Defects of lymphocyte apoptosis (autoimmune lymphoproliferative syndrome)

Apoptosis (programmed cell death) is important for regulating immune responses once an infection has been eliminated. Defects lead to the marked autoimmune and lymphoproliferative features that characterize autoimmune lymphoproliferative syndrome (ALPS).⁴⁰ There are a number of pathways through which apoptosis can be induced; one of the most important is via a cell surface molecule Fas (CD95). Ligation of this molecule initiates a cascade of intracellular reactions culminating in apoptosis induced by proteolytic enzymes including caspases. Mutations in several molecules in this cascade result in molecularly distinct but clinically similar forms of ALPS.

Type Ia is the most frequent form of ALPS. Fas is expressed as a trimeric surface protein. As a consequence heterozygotes with a Fas mutation in one allele develop disease because one abnormal protein chain is sufficient to impair the trimer's function, a so-called dominant-negative effect. Most of the cases described have been heterozygotes although the few homozygous cases seen have had severe disease. The clinical variability and the occurrence of asymptomatic individuals make estimates of incidence very difficult.

Many cases present in early childhood although adult presentation is also described. Symptomatic and asymptomatic cases may occur in the same families. Autoimmune disease most commonly affects the hematopoietic system. Lymphoproliferation often results in characteristically massive asymmetric lymph nodes in the anterior triangle of the neck, with splenomegaly in nearly all cases and hepatomegaly in some. Lymphoid malignancies (both Hodgkin and non-Hodgkin) are reported with increased frequency but have probably been overdiagnosed because the histologic picture of proliferation resembles malignancy: clonality studies distinguish the two.⁴¹

Lymphocyte counts and immunoglobulin levels are often high. Autoantibodies are usually present, a direct Coombs test is usually positive. In almost all cases 5–20% of circulating CD3⁺ T lymphocytes express normal α/β receptors but do not express CD4 or CD8 (so-called double-negative T lymphocytes). Many of these cells also express HLA DR (a marker of T-lymphocyte activation). CD95 is not expressed on lymphocytes even after activation with mitogens. Apoptotic assays, where cell death is measured after artificial ligation of CD95 with an antibody, confirm the ALPS defect. Mutation analysis of Fas, Fas ligand (FasL) and the appropriate caspase genes will confirm the precise molecular diagnosis.

Autoimmune phenomena usually respond to steroids and high-dose IVIG treatment. Where there is marked B-lymphocyte proliferation, administration of anti-CD20 B-cell monoclonal antibody can be very effective. Splenectomy should be avoided, as signs and symptoms often improve

with time, and because of the risk of death from bacterial sepsis; however, when unavoidable, long-term antibiotic prophylaxis is mandatory. The diagnosis of lymphoma should only be made when clonality and molecular markers have confirmed this, because on conventional microscopy benign lymphoproliferation can be mistaken for malignancy and inappropriate chemotherapy given. Bone marrow transplantation has been successful in patients with severe (usually homozygous) Fas deficiency but is not usually needed for heterozygous cases.

Chronic mucocutaneous candidiasis

Chronic mucocutaneous candidiasis (CMC) describes a group of disorders characterized by chronic and recurrent candidal infection of variable severity affecting the mouth, napkin area, skin and nails. Invasive candidal infection rarely occurs. The failure of usually effective antifungal drugs to completely clear *Candida* distinguishes CMC from other conditions that predispose to candida such as secondary immunodeficiency, steroid treatment or systemic antibiotics. Most patients present in the first few months of life with persistent candidiasis of the mouth, perineum and, sometimes, esophagus. When present, esophagitis is often severe and associated with esophageal reflux and failure to thrive. In about half the patients there is an associated endocrinopathy (with, in order of frequency: hypoparathyroidism, Addison disease, pernicious anemia, hypothyroidism and diabetes mellitus), usually not apparent until the second or third decades onward. Less common autoimmune findings include hemolytic anemia, thrombocytopenia and neutropenia, chronic active hepatitis and uveitis. Cases may be familial or sporadic with recessive or dominant patterns of inheritance. Patients may also have evidence of dental enamel hypoplasia and keratopathy associated with autoimmune endocrinopathy. Some patients with CMC have defects in the *AIRE* gene associated with autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy (APECED).⁴² A minority of patients suffer from invasive bacterial sepsis, opportunistic infection, autoimmune hemolytic anemia, malabsorption and chronic active hepatitis. Bronchiectasis and restrictive lung disease can occur.

Candida is often very difficult to eradicate, but can be ameliorated by long-term treatment with fluconazole or itraconazole (unless resistance develops); liver enzymes must be monitored when using these agents, particularly if there is evidence of autoimmune hepatitis. A proportion of cases improve considerably with age.

Immunodeficiency and short-limbed dwarfism

Abnormalities of T- and B-lymphocyte function are seen in a number of osteochondrodysplasias, including Shwachman–Diamond syndrome where there is neutropenia and pancreatic insufficiency, and Schimke immuno-osseous dysplasia,

which features radiographic changes of spondyloepiphyseal dysplasia, nephrotic syndrome and cellular immunodeficiency. Other short-limbed dwarfisms associated with immunodeficiency are less clearly delineated.

Cartilage–hair hypoplasia is the best-described autosomal recessive variant, associated with mutations in the *RMRP* gene, encoding an RNA-editing enzyme. Severe short-limbed short stature (−11.8 SD to 2.1 SD) with radiographic appearances of metaphyseal and spondyloepiphyseal dysplasia are always present, accompanied by sparse light hair in most patients. Severe anemia and Hirschsprung disease are well-recognized associations, as are malignancies, notably lymphoma and skin carcinoma. The immunodeficiency is variable; most have T lymphopenia and impaired *in vitro* mitogen proliferative responses, but only half suffer recurrent infection.⁴³ Patients are excessively vulnerable to viral infections, particularly varicella zoster, EBV and other human herpesvirus infections, and the risk of infective death is 300 times greater than normal.⁴⁴ Severely affected patients should be assessed for bone marrow transplantation, which has successfully corrected the immunodeficiency.

DNA repair defects and immunodeficiency

The immune system has utilized ubiquitous cellular DNA repair mechanisms to generate the diversity of specific immune responses by V(D)J recombination. Without the ability to repair DNA damage, cells may apoptose or undergo malignant proliferation, hence individuals with defective DNA repair mechanisms have a predisposition to neurodegeneration, developmental anomalies and cancer as well as defective immunity.⁴⁵ The mechanisms are complex, with so many single-gene defects able to give rise to distinct clinical entities.

Ataxia telangiectasia

This multisystem autosomal recessive disorder is characterized by progressive cerebellar ataxia, oculocutaneous telangiectasia, variable immunodeficiency and increased risk of lymphoid malignancy. There is chromosomal instability, and cellular radiosensitivity. Diagnosis is chiefly clinical, and gait anomalies lead to referral often before telangiectasia appears. Ataxia and cerebellar signs usually appear in the second year, and although they may be delayed, are always present. Progressive neurologic degeneration usually results in severe disability by late childhood. Telangiectasia usually appears between 2 and 8 years of age, first on the bulbar conjunctivae but later elsewhere, particularly on the nose, the ears and in the antecubital and popliteal fossae. Cutaneous hypopigmentation or hyperpigmentation, atrophy and atopic dermatitis are seen. Gonadal atrophy occurs, and growth failure is also prominent in the later stages. Immunodeficiency affects 60–80% of cases but clinical manifestations are variable.

Recurrent sinopulmonary infection is common and may lead to bronchiectasis and clubbing. Lymphoreticular malignancies and carcinomas occur with increased frequency. Radiosensitivity means that treatment with radiotherapy is toxic and often lethal. Irrespective of the development of malignancy, survival beyond early adult life is unusual.⁴⁶

Immunologic findings vary but there is progressive failure of antibody production, with poor responses to polysaccharide antigens progressing to hypogammaglobulinemia. IgM may be raised; there is lymphopenia, predominantly of CD4⁺ T lymphocytes, with increased numbers of T lymphocytes bearing the γ/δ receptor. Raised α -fetoprotein (abnormal in 90%) and carcinoembryonic antigen support the diagnosis. Increased chromosome breakage on exposure to ionizing radiation is found. Patients have a high incidence of translocations at the sites of the T-lymphocyte receptor and immunoglobulin heavy chain genes, which may explain the immunodeficiency. The *ATM* gene encodes for a phosphatidyl kinase that signals to proteins involved in DNA repair and cell-cycle control;⁴⁷ it is absent or inactive in ataxia telangiectasia patients.

Prophylactic antibiotics or intravenous immunoglobulin ameliorates sinopulmonary infection in some patients. As the immunodeficiency is often progressive, the need for such treatment should be reviewed regularly.

Ataxia telangiectasia-like disorder

Patients with features similar to those of ataxia telangiectasia patients but with no mutation in the *ATM* gene have been described. In some, mutations have recently been found in the *Mre11* gene, part of the complex with which nibrin associates (see below) and which is one of the complexes downstream from *ATM*.⁴⁸

Nijmegen breakage syndrome

Nijmegen breakage syndrome (NBS), an autosomal recessive disorder, is characterized by microcephaly, moderate mental retardation, “bird-like” facies, immunodeficiency, clinical radiation sensitivity and chromosomal instability.⁴⁹ In some cases sensitivity to cross-link damaging agents such as mitomycin C has been described, a phenomenon previously considered to be found only in Fanconi anemia.⁵⁰ Bacterial sinopulmonary infection is common.

Hypogammaglobulinemia is the most common immunologic abnormality. There is a CD4⁺ T lymphopenia, and diminished T-lymphocyte proliferative responses are also found. A defect in the gene encoding nibrin causes NBS.⁵¹ Nibrin is part of a protein signal transduction cascade downstream of the *ATM* protein. Absence of ataxia and telangiectasia, together with normal α -fetoprotein levels distinguishes NBS from ataxia telangiectasia. Treatment with antibiotic prophylaxis or IVIG may help.

Fanconi anemia

Progressive bone marrow failure leading to pancytopenia is the main problem in this condition. There may also be skeletal malformations. Immune deficiency can occur, and selective IgA deficiency and T-lymphocyte abnormalities have been recorded. At least nine genes are implicated in the disorder, encoding for proteins that form a complex involved in sensing cross-link DNA damage, and facilitating repair.⁵² In some variants, radiosensitivity is described, and it is clear that the DNA repair pathways involved in cross-linking and also double-strand break repair are connected.^{50,53}

Bloom syndrome

This rare autosomal recessive disorder is associated with increased sister chromatid exchange, severe growth failure, increased malignancy and immunodeficiency. Affected individuals may develop facial telangiectasia and facial photosensitivity. Recurrent bacterial sinopulmonary infections associated with hypogammaglobulinemia, most often low IgM, may lead to bronchiectasis.⁵⁴

Defects in DNA ligases

DNA ligases function in DNA repair. Defects in DNA ligases I⁵⁵ and IV⁵⁶ have been described in rare individuals with radiosensitive cell lines and combined immunodeficiencies and cytopenias.

Other immunodeficiencies

A number of syndromes have been described that include primary immunodeficiency as part of the phenotype. In some, the syndrome is well described, and in a few the underlying molecular defect has recently been elucidated (Table 19.2).

Anhidrotic ectodermal dysplasia, incontinentia pigmenti and defects in the NEMO signaling pathway

X-linked anhidrotic ectodermal dysplasia is associated with immunodeficiency.⁵⁷ Patients present with sparse scalp hair, conical teeth and absent sweat glands. Some suffer from recurrent sinopulmonary infection and have poor antibody responses to polysaccharide antigens, or frank hypogammaglobulinemia. Incontinentia pigmenti is a rare X-linked dominant condition characterized by developmental abnormalities in skin, hair, teeth and the central nervous system. Rare male infants with a progressive combined immunodeficiency have been described. Hypofunctional mutations in the *NEMO* gene encoding a protein required to activate the transcription factor NF- κ B have been described in male patients with both X-linked anhidrotic ectodermal dysplasia and incontinentia pigmenti.⁵⁸ Defects in *IRAK4*, which acts

Table 19.2 Syndromes with immunodeficiency as part of the phenotype.

Disease	Gene defect	Clinical characteristics
Hoyeraal–Hreidarsson syndrome	XL <i>DKCL</i> (some)	Microcephaly, cerebellar hypoplasia, aplastic anemia, growth retardation, progressive immunodeficiency, hypogammaglobulinemia, lymphopenia
Netherton syndrome	AR <i>SPINK5</i>	Generalized infantile erythroderma, diarrhea, failure to thrive, mild lymphopenia, bamboo hairs (distinguished from Omenn syndrome and SCID with MFE)
Immune dysregulation, polyendocrinopathy, enteropathy X-linked (IPEX) syndrome	XL <i>Foxp3</i> (some AR)	Infantile ichthyosiform dermatitis, protracted diarrhea, IDDM, hemolytic anemia, thyroiditis
Immunodeficiency, centromeric instability, facial dysmorphism (ICF) syndrome	AR <i>DNMT3B</i>	DNA methylation defect, structural abnormalities in chromosomes 1 and 9, agammaglobulinemia, normal T- and B-cell numbers. Opportunistic, viral and fungal infections

AR, autosomal recessive; IDDM, insulin-dependent diabetes mellitus; MFE, maternofetal engraftment; SCID, severe combined immunodeficiency; XL, X-linked.

upstream of *NEMO*, lead to recurrent invasive bacterial infection, particularly due to pneumococci.⁵⁹

NK cell deficiency

NK cells are large granular lymphocytes that bear CD56 instead of B- or T-lymphocyte markers and kill target cells without being previously sensitized. They do not depend on MHC restriction. Isolated complete absence of NK cells is extremely rare, and is associated with severe herpesvirus infections including varicella zoster virus and CMV, together with erythrophagocytosis.⁶⁰ Defective NK function due to absence of CD16 has also been described.⁶¹

Disorders of B-cell function

X-linked agammaglobulinemia (Bruton tyrosine kinase deficiency)

First described by Bruton in 1952, this is caused by a defect in the Bruton tyrosine kinase (BTK) gene, which encodes a cytoplasmic enzyme that is crucial for B-lymphocyte development beyond the pre-B-lymphocyte stage. Affected boys classically show greatly reduced or absent antibody production but cell-mediated immunity is normal. These children contract abnormally severe and frequent upper and lower respiratory bacterial infections and also gastrointestinal infections, pyoderma, septic arthritis, septicemia and meningitis.⁶² These are usually manifest by the second year of life as maternal antibody wanes, and are associated with growth failure. Unfortunately, diagnosis is often delayed resulting in severe chronic lung injury or other complications of invasive infection. These children are also prone to severe infection due to enteroviruses (coxsackievirus and echovirus),⁶³ which can cause chronic meningitis, dermatomyositis and hepatitis. Polioviruses, including the attenuated virus strains in oral

polio vaccine, can cause paralytic poliomyelitis and chronic infection (an issue for the global eradication of polio).⁶⁴

Where there is a family history, diagnosis can be confirmed at birth by the absence or very low numbers of cells expressing the B-cell markers CD19 or CD20 in peripheral blood. Bone marrow aspirate shows pre-B-lymphocytes (containing cytoplasmic μ chains). Lymph nodes show absent follicles and germinal centers. Plasma cells are absent. Molecular genetic analysis of the BTK gene is possible in patients and carrier mothers. Nonrandom X-chromosome inactivation in B cells of carrier mothers is present. Immunoglobulin measurements only become meaningful from 6 months of age as most infants have high levels of transplacentally acquired maternal IgG and low levels of IgA, IgM and IgE before this. After this age, all types of immunoglobulin are low or absent except in mild cases where there is presumably a partial defect in BTK; however, no clear genotype–phenotype correlation has been found. Absent or abnormal BTK has been described in cases of partial antibody deficiency,⁶⁵ so the condition should be considered in such cases in boys, particularly if circulating B-lymphocyte numbers are low, and there is a family history suggesting an X-linked inheritance.

IgG replacement is the mainstay of treatment. Even on adequate therapy, infections may still occur, especially giardiasis and chronic conjunctivitis. Antecedent chronic lung damage and sinus disease may progress after initiation of treatment; respiratory tract infection should be treated with vigorous, early antibiotic therapy. If recurrent infection persists despite increased doses of immunoglobulin, prophylactic antibiotics should be given, and some practitioners use both routinely in this condition. With the widespread use of IVIG, lung disease seems less common, emphasizing the importance of early diagnosis and treatment. There is some evidence that maintaining patients at higher IgG levels reduces the risk of lung disease but not of sinus problems.⁶⁶

Rare associations of X-linked agammaglobulinemia include

growth hormone deficiency, neutropenia, malabsorption and protein-losing enteropathy, although the basis for these problems is unclear and, specifically, it is not known if they are causally linked to BTK mutations. Progressive sensorineural hearing loss has been described with XLA, due to large deletions in the terminal part of the BTK gene that were believed to involve a contiguous gene encoding the deafness, dystonia protein, DDP.

Autosomal recessive forms of agammaglobulinemia

Hypogammaglobulinemia in girls or in children with consanguineous parents suggests the existence of an autosomal recessive genetic defect affecting B-lymphocyte differentiation. Mutations have been described so far in genes coding for μ heavy chain, Ig α (part of the signal transduction complex of the B-lymphocyte antigen receptor), $\lambda 5$ light chain, or BLNK (B-lymphocyte linker protein).⁶⁷ These molecules are required for early B-lymphocyte development from pro-B-lymphocyte to pre-B-lymphocyte stage. In contrast to XLA, pre-B-lymphocytes are not detectable in marrow samples from these patients. Other families have also been described in whom the molecular defect is yet to be identified. In all cases the defect is B-lymphocyte specific. The clinical picture seems to be similar to XLA.

Autosomal recessive hyper-IgM syndrome

Autosomal recessive cases of hyper-IgM syndrome are also described, with defects in isotope class switch recombination and somatic hypermutations due to defects in AID⁶⁸ or UNG genes.⁶⁹

Common variable immunodeficiency

Common variable immunodeficiency (CVID) is a poorly defined entity or group of conditions characterized by the presence of quantitative or qualitative hypogammaglobulinemia. It has an incidence of between 1 in 10 000 and 1 in 50 000. The onset of symptoms is typically seen within the second or third decade of life but is increasingly recognized in childhood.

Familial inheritance is seen in up to 25% of cases, but phenotypic variability within and between families suggests a polygenic inheritance. Selective IgA deficiency may be one end of the spectrum of this disease.⁷⁰ Autoimmune diseases, such as rheumatoid arthritis, are also seen more commonly in these kindreds. A number of patients with CVID have mild phenotypes of other immunodeficiencies such as X-linked agammaglobulinemia, CD40 ligand deficiency or X-linked lymphoproliferative disease.^{71,72}

Patients present with recurrent sinopulmonary and gastrointestinal infections. They are susceptible to *Giardia lamblia* and are at risk from enteroviral infections, causing choriomeningitis in particular; arthritis may result from chronic *Mycoplasma* infection. Other clinical manifestations include

autoimmune disease, particularly autoimmune cytopenias. Nonmalignant granulomatous lymphadenopathy, hepatosplenomegaly and involvement of the gastrointestinal tract is a frequent finding in a subgroup of patients; clinical differentiation from malignancy may be difficult although histologically lesions resemble those seen in sarcoidosis. These granulomas are normally sensitive to steroid treatment. Patients with CVID have a significantly increased risk of lymphoreticular and gastrointestinal malignancies.

Hypogammaglobulinemia may vary from a failure of specific vaccine responses to panhypogammaglobulinemia. B-lymphocyte numbers are frequently normal. A significant proportion of patients have a reversed CD4/8 ratio and a generalized lymphopenia.⁷³ Such abnormalities at presentation should prompt a search for other defined immunodeficiencies.

The aim of treatment is prevention of further infections and end-organ damage such as bronchiectasis. Mild phenotypes may require only prophylactic antibiotics. Significant hypogammaglobulinemia requires immunoglobulin replacement therapy. Patients with significantly abnormal cell-mediated immunity should receive prophylactic co-trimoxazole. Granulomatous lesions and autoimmune phenomena may respond to steroids.

Other humoral immune defects

IgA deficiency

One in every 600–700 healthy Caucasian blood donors have absent serum and salivary IgA; the clinical significance is unclear as most are asymptomatic. However, patients with chronic lung disease and autoimmune disease found to have IgA deficiency have significant morbidity. The pathophysiology of disease in these individuals is probably multifactorial; other factors may include IgG subclass and mannan-binding lectin deficiency. Selective IgA deficiency forms part of the CVID spectrum; in infancy, low IgA may be the last manifestation of transient hypogammaglobulinemia to resolve. Acquired IgA deficiency (usually reversible) may occur as a result of drug therapies (e.g., penicillamine, phenytoin, sodium valproate, captopril). It also occurs in congenital infections and after hepatitis C infection.

If IgA deficiency is found incidentally it is unlikely to be of clinical significance. If recurrent infections are present, IgG subclass levels and specific vaccination responses should be measured. IgG subclass deficiencies are found in approximately 15% of cases.

Recurrent sinopulmonary infections are the commonest symptoms in young children. Middle ear infections can be troublesome, and recurrent lower respiratory tract infections may result in lung damage. In most children the frequency and severity of infections improves with age, regardless of the IgA level. Gastrointestinal infections, in particular with *Giardia lamblia*, are more common than in the general

population. IgA deficiency is strongly associated with autoimmune disease,⁷⁴ whether or not there are recurrent infections; the mechanisms are poorly understood. There is an associated increased risk of celiac disease, a diagnosis that can only be made on intestinal biopsy as the inability to make IgA means that IgA anti-gliadin and anti-endomysial antibodies will be negative. An increased risk of gastrointestinal lymphoma and gastric malignancies has also been reported although the true incidence has not been well defined.

Symptomatic patients may respond to prophylactic antibacterial treatment, replacement Ig is almost never required. Patients with IgA deficiency may have anti-IgA antibodies, which have been reported to cause severe anaphylactoid reactions if IgA-containing preparations are given (including IVIG or blood). The risks can be minimized by choosing an immunoglobulin preparation with the lowest IgA content.

Isotype (IgA, IgM and IgG subclass) deficiency with abnormally frequent or severe infections, and/or atopy and asthma, can be diagnosed if serum levels of one or more of these isotypes repeatedly lie two standard deviations below the mean for age. There is often a poor correlation between serum levels and the severity of infections. The degree of functional antibody impairment must vary widely and other unelucidated factors are likely to be involved. Evaluation is difficult because: (i) different methods are used to measure antibody concentrations; (ii) laboratories often do not prepare age-matched normal ranges using serum from healthy children in their own assays; and (iii) isotype levels change with time in response to infections and with age so that abnormalities are often transient. IgG subclass deficiency (with normal total IgG) is common in pediatric clinics. Levels of IgG2 are low and responsiveness to unconjugated pneumococcal vaccine is often absent in children under 2 years of age. Some children develop this facet of the humoral immune system rather late and so up to the age of 5–6 years such findings may simply represent slow maturation that will resolve with time. Certain combinations of isotype deficiency are well recognized (e.g., low IgA with IgG2).

A small proportion of these children progress to develop CVID in adolescence. The management of such children is not standardized, but should be tailored to the frequency and severity of infections. Some children appear to benefit from antibiotic prophylaxis (see below). Occasional cases require IgG replacement therapy (see below), although very rarely for selective IgA deficiency alone. In our practice such children are offered immunologic review every 6–12 months in order that reassurance can be given as matters improve (as is usually the case) or appropriate treatment can be started and early Ig replacement treatment instituted in the rare cases that progress to CVID.

Specific antibody production defects

Occasionally, children with severe or recurrent infection

have normal IgA, IgM, IgG and IgG subclasses and the only humoral abnormality is an inability to make antibodies to specific antigens (in particular polysaccharides).⁷⁵ It is thus important to check child-specific antibody responses to vaccine antigens as part of the investigation for immunodeficiency. However, specific antibody deficiency can persist despite repeated immunization, whilst some individuals with persistently abnormal IgG subclasses respond well to protein and polysaccharide vaccines. IgG replacement treatment is occasionally needed but only after careful evaluation of the severity of the patients' infections, including a search for evidence of sinopulmonary damage.

Transient hypogammaglobulinemia of infancy

Serum IgG levels are higher at birth due to active transport of IgG across the placenta during the third trimester of pregnancy. Levels fall progressively, reaching a nadir at around 4–5 months and then rise toward adult levels throughout the first decade of life. In a small proportion of infants, immunoglobulin levels of one or more isotypes are low during the second half of the first year of life, later catching up and approaching normal levels.⁷⁶ This is usually uncovered during investigations for frequent infections in a baby who is often well by the time the result comes to light. It is unclear which of these infants form a distinct group as opposed to one extreme of normal. In practice, all that is usually required is reassurance and a repeat test at 18 months of age.

Disorders of phagocytic cells

Chronic granulomatous disease

Chronic granulomatous disease (CGD) is an inherited defect of the phagocyte nicotinamide adenine dinucleotide phosphate (NADPH) oxidase enzyme complex, which generates superoxide and other reactive oxygen species that are required to kill organisms ingested into phagosomes. The commonest gene defect, affecting *CYBA* (which encodes the cytoplasmic protein gp91phox), is inherited in an X-linked manner. Defects in the cytoplasmic components p67phox and p47phox are inherited in an autosomal recessive pattern, as are rare mutations in the second membrane component, p22phox.

The hallmark of the disease is acute, and potentially fatal, bacterial or fungal infection,⁷⁷ commonly acute suppurative lymphadenitis in the neck, axilla or groin. Liver abscesses, osteomyelitis, arthritis, pneumonia, skin sepsis and perianal abscesses are also seen. *Staphylococcus aureus*, *Burkholderia cepacia*, *Aspergillus* species and *Serratia marcescens* are common pathogens. Fungal infection starts with pneumonia, and progresses to pleural and spinal involvement; osteomyelitis and hepatic involvement are also seen. Once established, fungal infection is hard to treat and frequently fatal.

Noninfectious inflammatory granulomas cause bowel

disease, restrictive lung defects, genitourinary and upper gastrointestinal obstruction. Many children have a colitis, which may be clinically and histologically indistinguishable from Crohn disease. These noninfective manifestations may respond to corticosteroid treatment.⁷⁸ Female carriers of the X-linked form have an increased incidence of autoimmune diseases and mouth ulcers.

Prophylactic antibiotics and antifungals, particularly co-trimoxazole and itraconazole, reduce morbidity and mortality from bacterial infections in this disease.⁷⁹ Infections or unexplained fevers should be treated aggressively. Interferon (IFN)- γ is a useful adjunctive treatment in severe bacterial or fungal infections. White-cell infusions may be life-saving in severe infection. Registry data suggest that the outlook in early childhood has improved considerably in recent years, but considerable morbidity and mortality occurs and consideration should be given to bone marrow transplantation when a suitable donor is available.⁸⁰

Other neutrophil disorders

These include neutropenia, Shwachman–Diamond syndrome, other enzymatic deficiencies resulting in neutrophil killing defects, Chédiak–Higashi syndrome, Griscelli syndrome, familial lymphohistiocytosis, and leukocyte adhesion deficiency, and are covered in Chapter 14.

Defects in the IL-12-dependent IFN- γ pathway

Defects in the IL-12-dependent IFN- γ pathway result in persistent, severe, invasive or intractable mycobacterial infections with bone and soft-tissue abscesses complicated by persistent discharging sinuses due to BCG (bacille Calmette–Guérin) or poorly pathogenic environmental nontuberculous mycobacteria; they are often fatal.⁸¹ Invasive non-*Salmonella typhi* infections also occur. There is increased susceptibility to infection with human herpesviruses, respiratory syncytial virus and parainfluenza virus type 3. Infections result from a failure of upregulation of macrophage killing. The clinical picture depends on the precise molecular defect that is present. Defects have been described in a number of constituents of the IL-12-dependent IFN- γ pathway, including complete or partial IFN- γ -R1 deficiency, IL-12 p40 subunit deficiency, and complete IL-12 β 1 subunit deficiency. The outcome for patients with complete IFN- γ -R1 deficiency is poor, whereas the phenotype of IL-12-deficient patients is milder with typically later onset.

Deficiency of plasma proteins

Specific complement component deficiencies (C1–C9)

Complement component deficiency is rare, although patients with defects in virtually all the proteins in the pathways

have been described.⁸² Deficiency is manifest as increased susceptibility to infection, collagen vascular disease or both. Many factors show “autosomal codominant” inheritance so that heterozygote individuals (with one “null” or mutated gene) have half normal levels of the component.⁸³ The commonest deficiency is of C2, with around 1 in 100 of the population carrying one C2 mutation and a frequency of around 1 in 10 000. It exemplifies this group of disorders; affected individuals may be asymptomatic, may suffer from a variety of autoimmune and vasculitic disorders or may develop recurrent bacteremia, particularly with encapsulated organisms such as *Streptococcus pneumoniae* and *Neisseria meningitidis*. Terminal pathway component deficiency is particularly associated with neisserial infection, and in some populations as many as 14% of children with invasive meningococcal infection may have such a deficiency,⁸³ although complement deficiency accounts for less than 1% of cases of meningococcal disease in the UK.⁸⁴

Mannose-binding lectin deficiency

Unlike eukaryotic cells, yeasts such as *Candida* species, mycobacteria and Gram-negative bacteria express high quantities of mannose-rich sugars on their surfaces. Mannose-binding lectin (MBL) is an opsonic protein synthesized in the liver, which recognizes foreign microbes by binding to such sugars, a nonspecific immune response. Low levels of MBL are found in approximately 1 in 100 individuals and most appear well. However, mutations in the MBL gene are found more frequently in individuals with severe or recurrent infections of different types suggesting that this may become important when another immune problem is present.⁸⁵ It may therefore be appropriate to measure serum levels of this protein with other investigations in these patients. Prophylactic antibiotics have been suggested for symptomatic patients.

Interaction of antibody and complement deficiencies

Defects in complement components of the early classical pathway are associated with poor antibody responses, presumably because antigen processing and presentation is impaired. Alternative pathway opsonization is less efficient in the absence of specific antibody to bacterial surfaces. There is evidence that antibody may “neutralize” surface molecules, such as sialic acid, which otherwise inhibit alternative pathway activation.

Management of complement deficiencies

Specific replacement therapies are not available. There is no evidence to support the use of fresh plasma infusions. Lifelong antibiotic prophylaxis is recommended, usually with penicillin, but compliance may be better with amoxicillin,

which covers a wider range of organisms, has a longer dose interval and tastes nicer. Meningococcal, pneumococcal, and *Haemophilus influenzae* type B (Hib) vaccination to maintain protective antibody levels may help. Despite these measures we have seen breakthrough bacterial infections, which highlight the need to respond quickly to the early signs of sepsis and/or meningitis. It is our practice to see patients annually, to look for clinical signs of autoimmune disease, to look for autoantibodies and, more intermittently, to measure levels of antibody to pneumococcus, Hib and meningococcus.

Treatment of primary immunodeficiency disorders

Vaccination of the child with a potentially impaired immune response

Immunocompromised children need protection conferred by vaccination yet are less likely to be vaccinated because of false concerns about potential risks and lack of efficacy in immunodeficiency. Non-live vaccines pose no infectious risk, and live vaccines are sufficiently attenuated to be safe even in children with impaired immune responses. Thus immunodeficient children should be immunized but may require augmented dose regimens and additional vaccines not in routine universal use. BCG vaccine remains a concern in patients with significantly impaired T-cell immunity and with CGD. Measles, mumps and rubella vaccine is remarkably safe, and the balance of risk and benefit often favors use in the immunodeficient patient. Experience with varicella vaccine is growing: it may be better to expose high-risk patients to a two-dose course of attenuated vaccine virus, rather than allow their first encounter to be with the wild-type strain, although the need for passive protection with varicella zoster immunoglobulin following exposure may remain. The vaccine virus is sensitive to aciclovir, which can be used if significant vaccine-induced infection occurs. Children who have undergone bone marrow transplantation are normally re-immunised *de novo* with all antigens from around 12–18 months post BMT (Table 19.3). Conjugate rather than polysaccharide vaccines should be used in children at high risk of pneumococcal or meningococcal infection, such as those with asplenia, hyposplenism, sickle-cell disease, nephrotic syndrome or opsonic defects. Official

published guidelines on immunization of immunodeficient patients tend to be cautious. Expert advice should be sought in formulating immunization advice for a child with compromised immunity.⁸⁶

Supportive care

Children with primary immunodeficiency disorders (PID) require good general pediatric care, with particular attention to growth, nutritional status, secondary dietary intolerances and psychological support. Prevention and early treatment of infections is of paramount importance. Genetic counseling is important, including carrier detection for female relatives of boys with X-linked PID.

Newborns with suspected severe PID should be isolated, and the number of persons involved with care restricted; individuals with respiratory or gastrointestinal symptoms of infection should avoid contact. Breast-feeding should be encouraged. Strict hand-washing procedures are mandatory.

Regular oral co-trimoxazole prophylaxis for *Pneumocystis carinii* is usually given for PID with reduced T-cell function (SCID, CD40L), but dapsone or atovaquone can be used, or inhaled pentamidine in older children. Co-trimoxazole prophylaxis also reduces the incidence of pyogenic infections in patients with phagocytic or humoral immunodeficiencies, in whom it is usually given once daily (30 mg/kg). Antifungal prophylaxis (usually itraconazole) may be used in patients with combined immunodeficiencies and CGD. Where the PID predisposes to infection with relatively few organisms, prophylaxis with a narrow-spectrum antibiotic should be used, for example penicillin for patients with terminal complement defects to prevent neisserial infection. Prophylactic antibiotics are commonly used for patients with minor humoral deficiencies such as symptomatic IgA deficiency. Antiviral prophylaxis with aciclovir is used in patients with cell-mediated immunodeficiency and post-BMT to prevent herpes simplex and CMV reactivation.

Passive immunization is the basis of immunoglobulin replacement therapy (see below), and specific hyperimmune globulins are available for post-exposure prophylaxis in primary or secondary immunodeficiency patients exposed to chickenpox or hepatitis B. After measles exposure, standard immunoglobulin is used. High-titer anti-respiratory syncytial virus (RSV) and monoclonal anti-RSV antibodies protect children with chronic lung disease from infection, and it therefore seems logical to use them in children with severe PIDs during the RSV season, although this has not been formally evaluated.

Recurrent infections cause severe life-limiting and life-threatening damage. Chronic lung disease leading to bronchiectasis is a serious complication, particularly in antibody deficiency states. Regular physiotherapy, sputum cultures to direct appropriate antibiotic therapy and monitoring of pulmonary function are useful. High-resolution computerized tomography may detect early damage or progression of

Table 19.3 Indications for vaccination following bone marrow transplantation (BMT).

12–18 months post BMT
T- and B-cell reconstitution
Ceased immunosuppression ≥ 6 months
Ceased pharmacologic dose of steroids ≥ 6 months

existing lung damage. Breakthrough infections in spite of prophylactic antibiotics may be an indication for starting immunoglobulin therapy even if laboratory studies show only minor abnormalities of humoral immunity.

Treatment of infections

Infections require prompt, vigorous treatment with appropriate antibiotics. Broad-spectrum antimicrobial cover may be needed to cover unusual agents. In neutrophil disorders it is important to cover *Pseudomonas* and other Gram-negative bacilli. Systematic attempts at identification of the causative agent, including invasive diagnostic procedures such as bronchoalveolar lavage or open lung biopsy, should not prevent early treatment. Amphotericin is currently the first line of treatment for systemic fungal infection; promising new agents include voriconazole and caspofungin. Antiviral agents, such as the anticytomegalovirus agents ganciclovir and foscarnet, are particularly useful in the immunocompromised infant.

Blood product support

All blood products except IVIG and fresh frozen plasma contain viable leukocytes; when given to patients with severe T-cell deficiency or those undergoing BMT, all products should be irradiated with 20–30 Gy to prevent possible GVHD. Patients with no evidence of exposure to CMV should be given blood products from CMV antibody-negative donors. White-cell infusions, harvested from GCSF-primed donors, can be life-saving in patients with neutrophil function disorders who are not responding to antibiotics or antifungals.

Support for families and patients

Patient support organizations provide helpful information and advice; they can also arrange contact for families with the same (rare) disorders. In the UK the main one is the Primary Immunodeficiency Association (PIA) (<http://www.pia.org.uk/>). In the USA the main one is the Immune Deficiency Foundation (IDF) (<http://www.primaryimmune.org/>). Abundant information is published on the Internet but this can be confusing as much is produced without reference to expert advice.

Bone marrow transplantation

T-lymphocyte and phagocyte immunodeficiency disorders are potentially correctable by BMT;⁸⁷ patients with immediately life-threatening conditions, mainly SCID, have been treated with BMT for 30 years. An increasing understanding of the basis of PIDs, international registry data on their long-term outcome, together with greatly improved results from BMT, has led to more conditions being treated by BMT, such as Wiskott–Aldrich syndrome,²⁹ CD40L deficiency,³⁸ other

T-cell immunodeficiencies, CGD,⁸⁰ and other phagocyte deficiencies. Matched unrelated donors, particularly for non-SCID immunodeficiencies, peripheral blood and umbilical cord stem cells are being increasingly used.

Complications of bone marrow transplantation

These are covered in Chapter 3.

Matched related donor bone marrow transplantation

Usually only sibling donors can be a perfect HLA-antigen match, but when parents are consanguineous, other family members may be a full match. For SCID, prior immunosuppression (“conditioning”) is not usually required. The risk of GVHD is low. Full and long-lasting immune reconstitution is usually achieved although in a few cases lack of B-lymphocyte engraftment necessitates continuing immunoglobulin therapy. Success rates are now in the order of 90% and failure is usually secondary to preexisting infection. Matched transplants for PID, where conditioning is needed to destroy a residual immune system capable of graft rejection, are also increasingly successful with survival improving from about 70% to 80%.⁸⁷

Mismatched bone marrow transplantation

In an HLA-mismatched situation, GVHD can be prevented by removing T lymphocytes from marrow. T-lymphocyte-depleted stem cells produce precursor T lymphocytes, which are “educated” into a state of tolerance in the host thymus. Successful mismatched BMT is not as easily achieved as matched BMT. Even in SCID, the T-lymphocyte-depleted bone marrow can be rejected (or fail to take), and to prevent this, full conditioning therapy (marrow ablation) is often needed. Immune function develops more slowly, T-cell function taking 3–6 months and full immune reconstitution a year or more. B-lymphocyte function is often good following fully conditioned BMT,⁸⁸ although responses to polysaccharide antigens may remain poor.⁸⁹ The prolonged period of immunoincompetence increases the risk of opportunistic infection. Refinements of the technique over recent years have resulted in continuing improvement in results, with success rates for SCID of around 78% for T-lymphocyte-depleted grafts, and > 90% for matched sibling donors.⁹⁰ Success is dependent on the type of SCID, with better results for B⁺ SCID than the B[−] phenotype.⁹¹ Age at presentation also influences outcome, with very good results for those transplanted in the neonatal period, before they have contracted infections.⁹²

The problems and risks of mismatched BMT together with greater availability and excellent results for unrelated donor umbilical cord stem cells mean that fewer mismatched hematopoietic stem cell (HSC) transplants are now performed.

Matched unrelated donor bone marrow transplantation

National and international registries of tissue-typed volunteers willing to donate bone marrow, as well as storage of screened umbilical cord blood donations, have greatly increased the availability of phenotypically identical HSC for transplantation. Umbilical HSC are particularly useful for infants with SCID,⁹³ where the inevitable delay in obtaining unrelated donor HSC may decrease the chance of successful transplantation. The relatively low stem cell numbers in umbilical donations is less of a problem for infants as their body weight is so much less than adults.

Other replacement therapies

Enzyme replacement

In ADA deficiency, purified bovine ADA conjugated with polyethylene glycol (PEG-ADA), given by regular intramuscular injection, can significantly improve immune function, but regular treatment is needed and the long-term outcome is not known. If a suitable donor is available, BMT seems the best treatment. The role of ADA replacement as an adjunct to transplantation is unclear.

Somatic gene therapy

This has been attempted in adenosine deaminase deficiency using ADA-transfected CD34⁺ autologous cells, and more recently for common γ -chain deficiency.⁹⁴ Unfortunately, insertional mutagenesis was associated with a life-threatening leukemia in 3 of the 11 patients. A number of other conditions may be amenable to gene therapy but at present BMT remains the best treatment except, perhaps, for the sickest patients for whom no matched donor is available.

Replacement of thymus function

Fetal thymus transplants, originally attempted 40 years ago but superseded by HSCT, have recently been again attempted for complete DiGeorge syndrome, with encouraging results.⁹⁵

Replacement immunoglobulin therapy

This is the mainstay of treatment for antibody deficiency and some combined immunodeficiencies. The need for replacement immunoglobulin therapy must be evaluated on an individual patient basis. Absolute indications include quantitative defects (IgG less than the 5th centile for age or < 3 g/L in an older child) and qualitative defects (failure of response to booster vaccinations) in association with clinical features of immunodeficiency. Other indications include failure of antibiotic prophylaxis in a child with quantitatively minor

Ig abnormalities (e.g., IgA and IgG subclass deficiency) and risk of end-organ damage (e.g., bronchiectasis) in a child with any degree of antibody deficiency.

Replacement immunoglobulin must contain the full range of protective antibodies in order to provide effective prophylaxis against infections. Human plasma is used as the source, and to ensure that IVIG contains the full spectrum of protective antibody, preparations are made from pooled (5000–10 000 donors) plasma donations, albeit with an associated very small risk of transmitted infection. Pools are screened for known agents (e.g., hepatitis B and C), and cold ethanol precipitation, universally used in plasma fractionation, kills some viruses, including HIV; a further viral inactivation step such as pasteurization or nanofiltration is employed. There is a theoretical risk of transmission of variant Creutzfeldt–Jakob disease (vCJD), and to minimize this plasma is no longer sourced from the UK. Patients should be evaluated by PCR for hepatitis B and C prior to commencement of therapy, and they require regular monitoring of immunoglobulin levels and liver function tests. Any elevation in liver function tests should prompt reevaluation of their hepatitis status. Batch numbers of all products administered must be recorded to facilitate patient tracing if there is a problem with an individual batch. Switching between different preparations should be avoided unless there are good clinical reasons, to minimize the chance of subsequent problems with hypersensitivity and adverse reactions.

IVIG therapy is given in doses of 0.3–0.5 g/kg every 3 weeks, infused over 2–3 hours. Immediate reactions to IVIG include nausea, vomiting, flushing, rigors and occasionally hypertension, normally controlled by slowing the infusion rate. Severe headaches may occur hours or days later. Anaphylactoid reactions are said to be a risk in IgA-deficient patients with anti-IgA antibodies,⁹⁶ but are very rare. Subcutaneous administration of immunoglobulin is effective in adults,⁹⁷ with far fewer side-effects. Recently this has been licensed for children; the lack of need for venous access and ease of parental training for home therapy make it attractive. Only a limited volume can be given in one site, necessitating two pumps and infusions for larger children. Most families do not find the inconvenience of giving weekly doses (instead of 3-weekly for IVIG) problematic, once established at home.

Acquired (secondary) immunodeficiency diseases

Much human disease is the direct or indirect result of infection (e.g., *Helicobacter pylori* in upper gastrointestinal disease and infectious agents in atheroma). Infectious agents may cause direct or toxin-mediated tissue injury (e.g., gas gangrene, tetanus) but immune/inflammatory responses to infection cause much pathophysiology (e.g., Gram-negative bacterial septicemia, postinfectious arthritis). Many infections induce

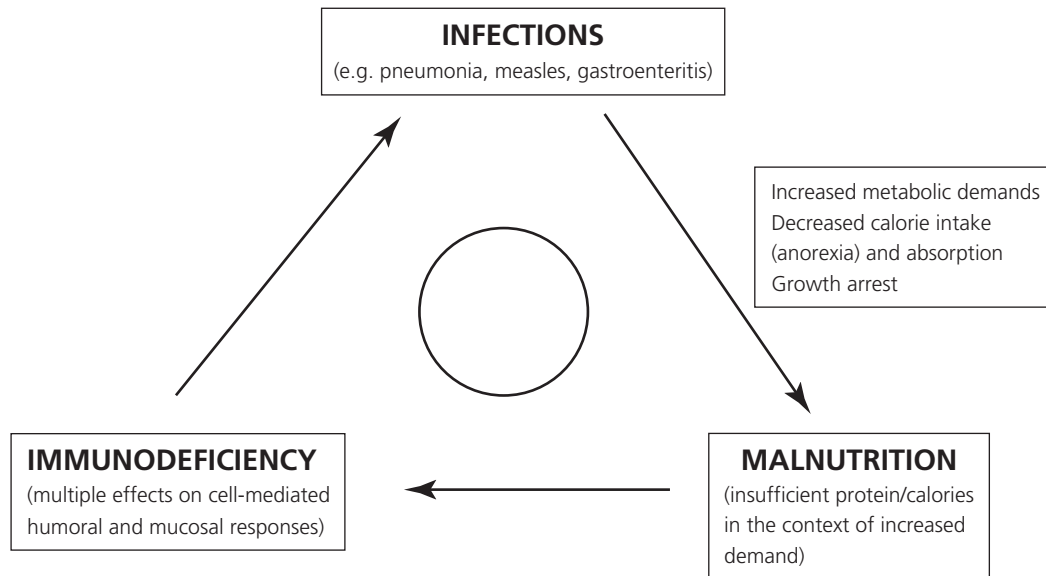

Fig. 19.6 Malnutrition cycle.

an immunodeficient state enhancing the risk of other infectious diseases. This is best exemplified by the vicious spiral of infection and childhood malnutrition (Fig. 19.6).

Even where nutrition is adequate, many childhood infections, such as measles, predispose to further infection. Secondary perioral herpes simplex infection is associated with pneumococcal pneumonia, and bacterial pneumonia may follow a viral upper respiratory prodrome. Epidemiologic studies have revealed a temporal association of outbreaks of meningococcal disease shortly after epidemics of influenza.⁹⁸

Human immunodeficiency virus 1 and 2

The HIV epidemic has been remarkable both for the emergence of large-scale secondary immunodeficiency and the severe and unrelentingly progressive immunodeficiency it causes. HIV, an RNA lentivirus, has high replication rates even early in infection as well as high spontaneous mutation rates permitting rapid acquisition of resistance to antiviral agents.

Transmission and its prevention

In children acquisition is mainly by vertical transmission from an infected mother, either transplacentally, perinatally in the birth canal or postnatally via breast milk. Horizontal transmission from sexual activity, or infected blood products also occurs. Breast-feeding by HIV-positive mothers should be avoided in developed countries but the balance of risk and benefit may be reversed in other settings. Giving anti-retroviral therapy to the mother and baby substantially reduces transmission.⁹⁹ The exact drug regimen depends on

the resistance pattern of the HIV strain infection in the mother (2005 guidelines can be found at <http://www.bhiva.org>). Elective cesarean delivery is widely used but may not be imperative if the mother's viral load is undetectable. Low-cost measures such as vaginal viricides are useful in countries where perinatal infection is common and systemic antiviral agents are unavailable. Use of barrier contraception not only prevents the spread of HIV but also other sexually transmitted diseases, which may act as cofactors in HIV-related illness. Because these forms of intervention have the potential to prevent many cases of pediatric HIV infection there is an urgent need to institute effective programs of antenatal testing, particularly in areas of relatively high prevalence. Such programs were instituted in the UK between 2000 and 2003 and, in the context of rising rates of new HIV diagnoses particularly in heterosexuals, is resulting in prevention of significant numbers of childhood cases (http://www.hpa.org.uk/infections/topics_az/hiv_and_sti/publications/annual2004/annual2004.htm).

Manifestations

Staging of HIV disease has evolved over the years; current definitions are as shown in Table 19.4. The progression of HIV has slowed dramatically since the introduction of highly active antiretroviral therapy (HAART). The clinical features are often distinct from those seen in adults. In some children, particularly with a high viral load due to prenatal infection, there is rapid and often fatal progression during the first year of life, whereas the remainder progress heterogeneously toward severe immunosuppression usually between 5 and 10 years of age. Infections with encapsulated bacteria, in particular *Streptococcus pneumoniae*, including septicemia,

Table 19.4 Clinical staging of HIV-related disease in children.

Category	Features
N	Asymptomatic
A	Mildly symptomatic. At least two of: Lymphadenopathy Hepatomegaly Splenomegaly Parotitis Rash Ear, nose and throat infections
B	Moderately symptomatic Single episode of a severe bacterial infection Lymphocytic interstitial pneumonitis Anemia, neutropenia, thrombocytopenia Cardiomyopathy, nephropathy, hepatitis, diarrhea Candidiasis, severe varicella zoster or herpes simplex virus
C	Severely symptomatic Two serious bacterial infections Encephalopathy (acquired microcephaly, cognitive delay, abnormal neurology) Wasting syndrome (severe failure to thrive or downward-crossing two weight centiles) Opportunistic infections (<i>Pneumocystis carinii</i> pneumonia, cytomegalovirus, toxoplasmosis, disseminated fungal infections) Disseminated mycobacterial disease Cancer (Kaposi sarcoma, lymphomas)

Reproduced with permission from Ref. 107.

pneumonia and otitis media, are a particular problem. As immunosuppression advances, opportunistic infections including *Pneumocystis carinii* pneumonia, mycobacterial infection (both typical and atypical) and cryptosporidial diarrhea can occur, although infections such as CMV and toxoplasmosis, which are common in adults, are seen less often in children.

An insidious progressive lymphocytic intestinal pneumonitis is seen in some cases. Although really a histologic diagnosis, it is usually made in practice on clinical and radiologic evidence alone. Its etiology is obscure but may be due to chronic viral infection. It is associated with significant respiratory morbidity.¹⁰⁰ Neurologic disease is also well described in children with HIV, manifesting variously as developmental delay and regression, paresis and encephalopathy. Malignancies are also a feature, in particular lymphoma,¹⁰¹ and growth failure can be a major problem.

The progression of the immunodeficiency can be followed by monitoring the fall in the peripheral blood count of CD4⁺ T lymphocytes, which are selectively infected and destroyed by HIV. The normal range for CD4 counts varies with age and so must be compared with age-appropriate normal ranges. Quantitative measurement of HIV genomic RNA by PCR in

plasma is now an additional standard for monitoring disease progression and response to therapy.

Specific and adjunctive treatment

Until the mid-1990s medical management of pediatric HIV infection consisted mainly of prophylaxis and treatment of secondary infections with antimicrobial agents combined with the use of one available antiretroviral drug, azidothymidine. Co-trimoxazole is widely used for prophylaxis against *Pneumocystis carinii* pneumonia and bacterial infection, with dapsone being used as an alternative when the former is not well tolerated. The importance of appropriate neurodevelopmental, dietetic, social and psychological support for the children and their families is well established.¹⁰² The years 1996–97 saw the arrival of HAART, when a large number of new antiretroviral agents were used in combination, with dramatic results.

Agents in general use can now be classified into three main groups:

- nucleoside analog reverse transcriptase inhibitors (RTIs), such as azidothymidine or zidovudine, didanosine, lamivudine, and stavudine, and related nucleotide reverse transcriptase inhibitors (e.g., tenofovir);
- nonnucleoside RTIs such as nevirapine and efavirenz;
- protease inhibitors such as nelfinavir and ritonavir, the latter often used in small doses in combination with other protease inhibitors such as lopinavir, promoting their effectiveness by inhibiting their metabolism.

Several other promising classes of drugs are emerging, the most advanced being fusion inhibitors such as enfuvirtide. Despite the immense success of HAART, the emergence of resistance and short- and long-term drug toxicity are major issues, as are convenience of dosing regimens and palatability. HAART is also expensive.

Children with HIV should be followed in a center providing up-to-date management and offering participation in multicenter therapeutic trials, which are essential to evaluate the best form of HAART. Children with HIV usually have parents with HIV, often affected by social deprivation and isolation. Combining medical care with psychological and social support in a family clinic is an excellent way of caring for these families¹⁰² (http://www.medfash.org.uk/publications/documents/Recommended_standards_for_NHS_HIV_services.pdf). It should be remembered that the number of children affected indirectly by HIV, through illness or death in their parents or other family members, greatly exceeds those actually infected with the virus. The main hope for effective control and eradication of HIV infection must be through development of a vaccine.

Hyposplenism

Posttraumatic splenectomy is rare in childhood. However,

primary asplenia or hyposplenia, splenectomy for malignant, hematologic or immunologic indications, or reduced splenic function secondary to hemoglobinopathy, lymphoproliferative diseases, inflammatory bowel disease or following irradiation for BMT are seen more often. Hyposplenism is associated with an enhanced risk of fulminant bacterial infection,¹⁰³ particularly in early childhood. This is because the spleen acts as a filter for bacteria and parasitized erythrocytes. Furthermore, many disorders associated with hyposplenism or requiring splenectomy cause immunodeficiency either directly (e.g., Wiskott–Aldrich syndrome and haematologic malignancy) or through their treatment (e.g., chemotherapy or steroids).

Streptococcus pneumoniae (with a mortality of up to 60%) and *Neisseria meningitidis* cause most infections.¹⁰⁴ The risk of 0.42% per year is significant when viewed over a lifetime, and is four times higher in young children with congenital asplenia, where other aspects of immunity are less effective and pathogens include *Haemophilus influenzae* and Gram-negative organisms. Patients are also at enhanced risk of *Escherichia coli* infection, malaria, babesiosis and DF-2 bacillus (*Capnocytophaga canimorsus*) infection following dog bites.

The immunodeficiency is multifactorial, but largely functional. Failure to clear opsonized bacteria, lack of a B-lymphocyte reservoir, and low activity of the alternative pathway of complement, found in 10% of splenectomized and 16% of sickle-cell patients, all contribute. In older patients, IgG responses to pneumococcal vaccine are close to normal although low serum IgM levels have been reported; antipolysaccharide IgG levels decay more quickly.¹⁰⁵

All children with hyposplenism should receive continuous daily oral antibiotic prophylaxis with phenoxymethylpenicillin, amoxicillin or, in allergic patients, erythromycin. Some experts use co-trimoxazole prophylaxis in children up to the age of 5 years. However, these treatments do not guarantee protection against invasive infection, so urgent medical advice should still be sought when the child is feverish or unwell so that appropriate intravenous antimicrobial therapy can be instituted if necessary.

Hyposplenic children should be immunized routinely. The polysaccharide 23-valent pneumococcal and 2- and 4-valent meningococcal vaccines are poorly immunogenic in children under 2 years of age but can be given to hyposplenic children at age 2 years. Conjugate pneumococcal vaccine is now used in preference in this group of children regardless of age by many practitioners, despite narrower serotype coverage, because of enhanced long-term protection against the commoner serotypes. Immunization should be performed prior to elective splenectomy. Serotype-specific antipneumococcal antibody levels may be measured periodically, and patients revaccinated if levels are low. Influenza vaccine can be given each autumn to reduce the risk of secondary bacterial infection.

Clinical features and therapy of lymphoblastic leukemia

Owen P. Smith and Ian M. Hann

Acute lymphoblastic leukemia (ALL) is the commonest malignancy in children, comprising about 30–35% of all childhood cancers. Only 30 years ago this disease was fatal within 6 months in the vast majority of children.¹ In 1965, less than 1% of children with ALL were expected to be long-term survivors;² however, today, approximately 80% of children and adolescents with ALL are cured.^{3–5} Furthermore, 20–30% of children with leukemic relapse have a long-lasting second remission with the chance of cure with second-line treatment.^{6,7} This success was made possible by a series of carefully designed clinical trials both in the USA and Europe, pioneered by Pinkel and colleagues at St Jude Children's Research Hospital in Memphis, and by several groups in Europe. Despite this progress in treatment outcome, the absolute number of children with ALL who relapse and eventually die of their leukemia still exceeds the absolute number of children with newly diagnosed acute myeloid leukemia (AML). Thus, childhood ALL continues to contribute significantly to the overall mortality of childhood cancer.

Clinical characteristics

The clinical presentation of ALL is determined by the degree

of marrow failure, caused by the infiltration of lymphoblasts and extramedullary organ infiltration. About two-thirds of children with ALL will have had signs and symptoms of disease for less than 4 weeks at the time of diagnosis; however, a history of some months is also compatible with the diagnosis of ALL. The first symptoms are usually nonspecific and include lethargy, unrelenting fatigue, bone pain or loss of appetite. More specific symptoms such as anemia, hemorrhage and infections are a consequence of lymphoblasts occupying the bone marrow and disturbing the residual normal hematopoiesis. Signs and symptoms of childhood ALL are listed in Table 20.1. It is to be noted that there is an association with Down syndrome, where the risk of developing ALL is at least 15-fold greater than usual.^{8–11} Other associations, for example with immunodeficiency disorders, are very rare.

Once leukemia is suspected from the history and clinical symptoms, the evaluation of a blood count and especially microscopic evaluation of a blood smear allows an immediate diagnosis in many cases. However, a normal blood picture and normal blood smear do not exclude ALL. Thus, bone marrow aspiration must be performed immediately if there is any suspicion of ALL. In the past many children with a "rheumatic" presentation were erroneously treated with steroids. This practice is now thankfully far less common, as

Signs of anemia	Lethargy, weariness, fatigue, rapid exhaustion, lack of appetite Laboratory: normochromic, normocytic anemia
Signs of susceptibility to infections	Febrile illness Laboratory: reduced absolute number of neutrophils
Signs of bleeding tendency	Purpura, mucosal bleeding, haematomas and bruising Laboratory: thrombocytopenia and occasional coagulopathy
Signs of organ infiltration	Bone and joint discomfort, hepatomegaly and splenomegaly, generalized lymph node swelling, mediastinal mass and subsequent superior vena cava obstruction
Signs of systemic disease	Fever of unknown origin, weight loss, night sweats

Table 20.1 Signs and symptoms in children with acute leukemias.

Table 20.2 Differential diagnosis of acute leukemia in children and adolescents.

Aplastic anemia and other marrow failure syndromes (e.g., Fanconi disease)	Less common than leukemia, marrow aspiration, trephine biopsy and DEB test
Rheumatic disease (e.g., Still disease, rheumatic fever)	Rare, bone marrow aspiration
Osteomyelitis	Radiography, skeletal scintigraphy, bone marrow aspiration
Bone marrow dissemination of different malignancies (e.g., neuroblastoma, rhabdomyosarcoma)	Tumor markers, immunophenotyping, bone marrow aspiration, immunohistochemistry, trephine biopsy
Myeloproliferative/myelodysplastic syndrome	Bone marrow aspiration, trephine biopsy, marrow cytogenetics, hemoglobin F level
Viral and other infection (e.g., infectious mononucleosis, cytomegalovirus and <i>Leishmania</i>)	Specific serology, bone marrow aspiration
Leukemoid reaction (e.g., in whooping cough, sepsis)	Bone marrow aspiration
Transient erythroblastopenia of childhood	Normal platelet and granulocyte count, bone marrow aspiration
Idiopathic thrombocytopenic purpura	Normal neutrophil and red blood cell count, bone marrow aspiration
DEB, di epoxy butane	

it masks the underlying diagnosis and may lead to temporary remissions and drug resistance.

The differential diagnosis of ALL includes infections, other pediatric malignancies that involve the bone marrow, collagen vascular diseases, and other hematologic diseases such as idiopathic thrombocytopenic purpura (ITP) and aplastic anemia (Table 20.2).

ALL may present as an incidental finding on a routine blood count of an asymptomatic child or as a life-threatening hemorrhage or infection or episode of respiratory distress, especially in children with hyperleukocytosis, e.g., in T-cell ALL (T-ALL). Lymphadenopathy is commonly present and mostly correlates with a high white blood cell count (WBC) (lymphomatous feature). In about 30–60% of children with ALL, marked hepatomegaly and/or splenomegaly is found at diagnosis. Hepatosplenomegaly also correlates with a high WBC at diagnosis.

Although ALL is primarily a disease of the bone marrow and blood, any other organ may be infiltrated by leukemic blasts. Such infiltration may be clearly apparent clinically, such as lymphadenopathy or hepatosplenomegaly. However, leukemic infiltration of other organs may be occult and detectable only by histologic or cytologic examination or diagnostic imaging.

Mediastinal manifestations

Anterior mediastinal masses, mostly within the thymus, are present in about two-thirds of children with T-ALL but are extremely rare in other immunologic subtypes (Table 20.3). Leukemic pleural effusion may be associated with mediastinal masses in some children with T-ALL.¹² Superior vena cava syndrome and severe respiratory distress may occur in these children and may lead to medical emergencies. During

Table 20.3 Basic investigations required at diagnosis of childhood acute lymphoblastic leukemia.

Blood tests

Whole blood count, including platelets, hemoglobin, red cell indices and white cell count
Differential blood count
Lactate dehydrogenase
Electrolytes
Renal function (creatinine, urea, uric acid)
Liver function tests
Coagulation screen
Viral serology (Epstein–Barr virus, varicella zoster virus, cytomegalovirus, measles)

Bone marrow diagnostics

Bone marrow aspiration (if unsuccessful, trephine biopsy)
Morphology
Immunophenotyping
Cytogenetics and DNA content, looking especially for near-haploid and hypodiploid chromosome abnormalities
Molecular genetics, including t(4;11) and t(9;22) translocations and RUNX1 amplification

CNS diagnostics

Cerebrospinal fluid: cell count, cytospin preparation, protein, glucose and culture

Cardiology

Echocardiography

Diagnostic imaging

Chest radiography
Bone radiography if indicated
Abdominal sonography for liver, spleen, kidney size (optional)

Miscellaneous

Alkaline phosphatase and myeloperoxidase are sometimes required as marrow cytochemistry

induction chemotherapy these children may develop pronounced tumor lysis syndrome.

Central nervous system manifestations

Overt central nervous system (CNS) leukemia as defined by the presence of lymphoblasts in the cerebrospinal fluid (CSF) is found in 1.5–10% of children with newly diagnosed ALL, depending on their immunologic subtype (see below). CNS leukemia is more common in children with ALL of the relatively rare mature B-cell subtype, and in T-ALL and children with high WBCs. Children with CNS leukemia at diagnosis may present with diffuse or focal neurologic signs such as increased intracranial pressure (headache, vomiting, papilledema and lethargy), mostly without nuchal rigidity. Cranial nerve involvement, mostly involving nerves III, IV, VI and VII, may be found on careful neurologic evaluation. Occasionally, VI and VII nerve palsies occur without other evidence for CNS disease. CNS leukemia presents rarely with hypothalamic involvement, resulting in excessive weight gain and behavior disturbances.¹³

Leukemic blasts may enter the CNS by hematogenous spread or more rarely by direct extension of involved skull bone marrow through bridging veins to the superficial arachnoid. With progressive CNS leukemia, the blasts eventually infiltrate the deep arachnoid and then the pia/glial membrane and eventually invade brain parenchyma. In a severe combined immunodeficiency (SCID) mouse model, histologically detectable engraftment of leukemic cells in the skull, vertebral bone marrow and meninges preceded engraftment at other sites.¹⁴

Most children with CNS leukemia at presentation have CNS pleocytosis as a result of the presence of leukemic blasts. These blasts can be identified with the use of cyto-centrifugation and May–Grünwald–Giemsa staining. Careful morphologic evaluation is necessary to distinguish leukemic blasts from reactive blood cells, which may be seen after intrathecal chemotherapy or during CNS infection. Contamination of the CNS with blood, as indicated by the presence of red blood cells, often makes the interpretation of morphologic examination difficult or even impossible. The incidence of CNS leukemia at presentation varies considerably depending on the diagnostic criteria used.¹⁵ In 1986, the Rome International Workshop recommended an absolute leukocyte count of $\geq 5 \times 10^6/\text{L}$ with unequivocal blasts in a cytocentrifuge preparation as the definition of cerebromeningeal leukemia.¹⁶ In most trials, patients with CNS-3 overt disease at diagnosis (see below) are treated with 24-Gy cranial radiotherapy, but this has been dropped by some groups such as St Jude's, Memphis.

While some investigators reported that a low number of blasts in the CSF at presentation did not predict later development of overt CNS leukemia or CNS relapse,¹⁷ several other studies have shown an increased risk of CNS relapse in

patients with low levels of blasts (<5 per high-power field) and those in whom the CSF lumbar puncture was traumatic at diagnosis, presumably related to seeding of leukemic.¹⁸

CNS status Classification:

- CNS-1 (no blast cells).
- CNS-2 (leukocyte count $< 5 \times 10^6/\text{L}$ with morphologically detectable blasts).
- CNS-3 (leukocyte count $\geq 5 \times 10^6/\text{L}$ with morphologically detectable blasts and/or cranial nerve involvement).¹⁹

The adverse effect of a CNS-2 classification and a traumatic lumbar puncture appear to be abrogated by the addition of two intrathecal therapies during induction. It should be noted that additional testing for clonality/immunophenotyping does not currently improve the diagnosis.

Leukemic blasts may persist within the CNS throughout induction chemotherapy because most drugs used in the treatment of ALL inadequately penetrate the CNS, thus allowing progressive growth of lymphoblasts or the emergence of resistant clones. Cytogenetic studies and patterns of systemic relapse following the appearance of CNS disease strongly suggest that the hematologic recurrence may be due to reseeding of leukemic blasts from the CNS to the marrow.^{20,21}

Spinal cord involvement due to a localized epidural leukemic infiltrate may lead to spinal cord compression with back pain, weakness of the extremities, paralysis, and bladder or bowel incontinence.²² Gadolinium-enhanced magnetic resonance tomography (MRT) is helpful in localizing the leukemic infiltrate and in differentiating epidural hematoma and vertebral body collapse due to leukemic osteopathy. This feature is more frequently seen with the lymphomatous presentation, and also at relapse.

Genitourinary manifestations

Overt testicular disease, found by careful palpation or sonography, is rare at presentation with ALL. However, leukemic blasts have been found by testicular biopsy in as many as 25% of boys at presentation.²³ Occult testicular involvement occurred only in boys with a WBC $> 25 \times 10^9/\text{L}$. The leukemic infiltration is found mainly in the interstitium.

Clinically overt testicular relapse is usually painless and unilateral. Some boys also show involvement of intraabdominal lymph nodes. Bilateral testicular biopsy often shows an occult leukemic infiltration of the contralateral testis at the time of unilateral testicular relapse. The relatively high incidence of testicular relapse compared with, for example, ovarian relapse may be because the blood–testes barrier is analogous to the blood–brain barrier. However, the wider use of intensified multidrug regimens in recent years, including high-dose chemotherapy with methotrexate, has significantly reduced overt relapse of the testes.³ Thus the use of bilateral testicular biopsies, which was advocated for many years in some trials,²⁴ is no longer recommended.²⁵ Current protocols have also abandoned testicular radiotherapy

for patients with clinically overt testicular involvement at diagnosis, and simply recommend an upgrading of the overall chemotherapy intensity (cf. St Jude's and MRC/NCRI protocols).

Renal infiltrates may lead to oliguria or may be asymptomatic and discovered by their presentation in large kidneys shown by sonography or computed tomography (CT). The incidence of pretherapeutic renal infiltration was 18% in one BFM study but the use of rasburicase in such cases makes the need for dialysis rare nowadays.²⁶ Priapism is very rarely found in boys with T-ALL and the hyperleukocytosis/leukostasis syndrome.²⁷

Skeletal manifestations

About 20–30% of children with ALL present with severe pain, mainly in the lower extremities, leading to a limp or refusal to walk. These children suffer nearly exclusively from B-precursor ALL and often present with a normal blood count and low number or even absence of blood lymphoblasts (aleukemic leukemia), which often results in a delayed diagnosis.²⁸ Up to 20% of children with ALL present with characteristic bony radiographic changes, including transverse radiolucent lines in metaphyses, subperiosteal new bone formation or osteolytic lesions mimicking primary bone tumors, diffuse demineralization (osteopenia) or vertebral collapse, mimicking Langerhans cell histiocytosis.^{29,30} Pathologic fractures and vertebral collapses may occur secondary to severe osteopenia (leukemic osteopathy). Osteonecrosis, especially of the hip and knee, may also produce severe bone pain and is a rare complication of antileukemic therapy, especially with steroids.³¹ Children with these problems rarely need specific orthopedic maneuvers/equipment, which can in fact lead to worsening of osteopenia especially of spinal lesions.

Gastrointestinal manifestations

Specific problems of the oral cavity are common in children with acute leukemia. Infection with *Candida albicans* (oral thrush) is common at diagnosis and during polychemotherapy, and regular mouth care along with antifungal agents is an essential part of supportive care. Petechiae, hemorrhage and gum bleeding occur frequently, especially in children with severe thrombocytopenia. Mucosal ulceration is also common, especially in the presence of profound neutropenia in addition to fungal or bacterial infections, particularly with *Streptococcus viridans* (*S. mitis*, *S. sanguis*, *S. hominis*). Viral infections, mainly due to herpes simplex virus (HSV), can be a problem in neutropenic children. *Candida* or HSV esophagitis characterized by retrosternal pain rarely occurs in neutropenic children with leukemia, because of the use of effective agents such as fluconazole.

Bleeding, as reflected by gross or occult blood in the stool, is the commonest gastrointestinal manifestation of leukemia

and may be due to thrombocytopenia, disseminated intravascular coagulation (DIC), infiltration with leukemic cells, or infection (e.g., with *Candida*). Massive infiltration of intraabdominal lymph nodes, especially in the right lower quadrant, is frequently found in children with mature B-cell ALL.

A characteristic syndrome of right lower quadrant pain with tenderness, abdominal tension, vomiting and sepsis is often seen during profound neutropenia due to intensive polychemotherapy (neutropenic typhlitis or necrotizing enterocolitis).³² Sonography may show a characteristic thickening of the gut wall in the right lower quadrant.³³ Peptic ulcers of the stomach and duodenum may be occasionally seen in children with ALL, especially during steroid treatment.

Severe hemorrhage or necrotizing pancreatitis can be found in children with ALL during asparaginase treatment, and can be extremely troublesome and difficult to diagnose. Amylase is often but not always elevated, when a high lipase may assist diagnosis.³⁴ Management of these conditions includes bowel rest, intravenous fluids and broad-spectrum antibiotics. Surgery is rarely indicated except in rare cases of perforation or peripheral abscess formation, which is usually due to Gram-negative organisms.^{35,36} The differential diagnosis must include common childhood surgical problems, including appendicitis, cholangitis and intussusception.

Impairment of liver function with or without elevated bilirubin levels may be due to liver infiltration by leukemic blasts, chemotherapy-induced hepatotoxicity, especially during treatment with asparaginase, methotrexate and purine analogs, or viral hepatitis, especially with hepatitis B or C virus.³⁷ Rarely, patients can present at diagnosis with severe hepatic dysfunction due to liver infiltration.

Eye manifestations

Occult ocular involvement seen on careful ophthalmologic investigation may be found in up to one-third of newly diagnosed children with ALL.³⁸ Virtually all ocular structures have been found to be involved.³⁹ Retinal hemorrhages are presumably due to thrombocytopenia and may precede intracranial hemorrhage, especially in children with the hyperleukocytosis/leukostasis syndrome.⁴⁰ Overt leukemic infiltration of the eye is uncommon at presentation and is more usually associated with leukemic relapse.⁴¹ About half of children with leukemic eye infiltration present with overt CNS relapse.⁴² Oculomotor palsies and papilledema are frequent signs of meningeal leukemia at presentation or at the time of relapse. Thus, it has been suggested that the eye could be a sanctuary site in ALL, like the CNS and testes.⁴³

Under the conditions of today's intensive polychemotherapy protocols, which include high-dose chemotherapy and CNS-directed treatment, the incidence of ocular manifestations of ALL is lower than in the past, as are the incidences of CNS and testicular manifestations.^{3,44}

Cardiopulmonary manifestations

Leukemic involvement of the lungs and heart is rare. However, these manifestations may cause life-threatening problems in a child with ALL. Pericardial leukemic effusions are found by echocardiographic examination in about one-third of children with T-ALL and are often associated with leukemic pleural effusion and a mediastinal mass. A life-threatening hyperleukocytosis/leukostasis syndrome may cause massive respiratory distress due to infiltration and leukostasis within the lung in patients with high WBCs. Emergency leukapheresis or exchange transfusion can rarely be required as a life-saving emergency measure in this situation but much more commonly patients will respond better to intensive chemotherapy and supportive care.^{45,46}

During polychemotherapy, pulmonary complications in children with leukemia almost always have an infectious origin. Differentiation between bacterial and fungal infections, leukemic infiltrations and hemorrhage is often possible with the help of diagnostic imaging, including high-resolution CT of the lungs.⁴⁷

Severe cardiomyopathy in children with leukemia is seen during severe septicemia or metabolic disturbance in children with high blood counts and rapid lysis of lymphoblasts (tumor lysis syndrome). Late cardiomyopathy is found after extensive treatment with anthracyclines.^{48,49}

The rare ALL subtype with hypereosinophilia⁵⁰ may present with life-threatening involvement of the heart, with mural thrombi of the myocardium or Löffler endocardial fibrosis.⁵¹

Skin manifestations

Skin infiltration is rarely seen in children with ALL in contrast to children with monocytic leukemia. However, lymphoblasts may proliferate within the skin secondary to intradermal bleeding due to thrombocytopenia. In the rare case of congenital leukemia, skin infiltration has been reported in about 50% of neonates.⁵²

Laboratory findings

Laboratory data may show a broad spectrum of abnormal findings at presentation of ALL. Normochromic (normal mean cell hemoglobin), normocytic (normal mean corpuscular volume) anemia is present in about two-thirds of children with ALL and reflects progressive bone marrow failure. The WBC is raised higher than $10 \times 10^9/L$ in about half of children with newly diagnosed ALL, reflecting the proliferative capacity of their lymphoblasts. However, in about 5% of children with ALL, the WBC is less than $2 \times 10^9/L$, often without detectable lymphoblasts in the blood. Rarely, ALL presents with an aplastic blood and marrow profile and in this

situation there is initial marrow recovery followed shortly thereafter by frank leukemia. Hypereosinophilia in the blood is rarely found and is associated with the t(5;14) translocation.⁵⁰ This hypereosinophilia has to be differentiated from AML M4 eosinophilia, where atypical eosinophils are found in the bone marrow.

Blood blasts may not always reflect the bone marrow status of leukemia. In some patients a pathologic shift to the left of the granulocyte series, with increased numbers of promyelocytes or even myeloblasts, can be found as a result of the leukoerythroblastic response to bone marrow infiltration seen in ALL, non-Hodgkin lymphoma (NHL), granulomatous infections, osteopetrosis, and metastatic tumors (e.g., neuroblastoma, Ewing's sarcoma, rhabdomyosarcoma). Thus, the definitive diagnosis of leukemia should not be made from peripheral blood smears alone.

Thrombocytopenia ($<100 \times 10^9/L$) is present in about 80% of children with ALL at diagnosis. The platelets are morphologically normal, and thrombocytopenia is accompanied by other hematologic or physical manifestations of leukemia in the vast majority of children.⁵³

Bone marrow

Inspection of bone marrow smears is essential to establish the diagnosis of leukemia. Whereas a normal bone marrow usually contains $<5\%$ of blast cells (M1 marrow), leukemic marrow generally contains $>40\%$ and in most cases $>80\%$ of blasts. By arbitrary convention, $>25\%$ blasts (M3 marrow) is required to confirm the diagnosis of acute leukemia and to distinguish leukemia from NHL with bone marrow infiltration (stage IV NHL). For cytomorphologic purposes, anterior or posterior iliac crest aspirates smeared in the same way as blood smears are required. The sternum is not used for bone marrow aspiration in children because this procedure may be hazardous, especially to young children. In very young infants, some physicians prefer the tibia, but this can also be dangerous and is rarely necessary. A "dry tap" may be caused by bone infarction, myelofibrosis or bone necrosis,^{54,55} and in such cases a bone marrow trephine biopsy should be performed and the aspirate repeated.

ALL is subclassified according to morphologic, immunologic and genetic features of the leukemic blasts cells. The primary diagnosis is generally based on examination of the bone marrow aspirate; other recommended tests are detailed in Table 20.3. The cytologic appearance of the blast cells in ALL can be highly variable, even in a single specimen, and no completely satisfactory morphologic classification has been devised. The French-American-British (FAB) classification distinguishes three morphologic subtypes (L1, L2 and L3) (Table 20.4).⁵⁶ L1 lymphoblasts are predominantly small with little cytoplasm; L2 cells are larger and pleomorphic with increased cytoplasm and sometimes an irregular nuclear shape and prominent nucleoli; L3 blasts have a deep-blue

cytoplasm with prominent vacuoles and homogeneous nuclear chromatin with prominent nucleoli and immunophenotypic features of immature B-cell ALL.

Granular ALL has been described as a rare variant in about 3% of cases.²⁸ In contrast to myeloblasts, the myeloperoxidase stain is always negative in granular ALL. Immunophenotyping reveals CD10 positivity in nearly all cases

with this morphologic subtype.⁵⁷ The usual patterns of immunophenotypes in B- and T-cell ALL are shown in Tables 20.5 and 20.6 and their relationships to cytomorphologic and cytogenetic classifications are shown in Table 20.7.

In about 10% of children with ALL, morphology alone does not produce a specific diagnosis, even with the use of cytochemical stains,⁵⁸ which can sometimes be useful (e.g., acid phosphatase staining the Golgi region in T-ALL).^{59,60} The introduction of immunophenotyping and genetic classification of acute leukemias has revealed that some blasts show an ambiguous phenotype and genotype that do not allow clear differentiation between ALL and AML.⁶¹ These leukemias have been referred to as mixed lineage,⁶² biphenotypic,⁶³ or acute hybrid leukemias.⁶⁴ They may arise from malignant transformation of a progenitor cell capable of differentiation into more than one lineage (lineage promiscuity).⁶⁵ Alternatively, they may result from aberrant gene regulation not representative of normal hematopoiesis (lineage infidelity).⁶⁶ In B-precursor ALL, coexpression of one or more myeloid markers (e.g., CD13, CD33, CDw65) ranges from 4% to more than 20% depending on the criteria applied.^{67–69} The prognostic significance of coexpression of myeloid markers is now clear: there is no impact of such changes in large modern treatment series.^{68,70,71} ALL defined by morphologic and cytochemical criteria in which blast cells

coexpress myeloid antigens most probably represents phenotypic deviations and should be classified as ALL.⁷² True biphenotypic leukemias with two separate blast cell populations are very rare and have poor prognosis.

Most cases of morphologically and cytochemically undifferentiated acute leukemias can be immunophenotypically classified as either B-precursor ALL or AML M0. However, in about 2% of childhood ALL,³ the cellular origin of blasts remains obscure.⁷³ These leukemias are probably derived from a very immature hematopoietic progenitor cell. In recent years, microarray gene technology has been very helpful in categorizing these cases.⁷⁴

Cytomolecular genetics

Cytogenetic analysis of leukemic blasts provides important information in up to 90% of cases of ALL, and this information is clinically relevant for diagnosis and prognosis of childhood leukemia (Tables 20.7 and 20.8).⁷⁵ There are two major classes of cytogenetic aberrations: those that result in the visible loss or gain of chromosomal material and those that result in a balanced exchange without apparent loss or gain of DNA.⁷⁶ Loss may be characterized as partial (deletion, abbreviated as del) or complete loss of a chromosome (monosomy). Gains may refer to portions of chromosomes (e.g., duplications) or whole chromosomes (trisomy, tetrasomy). Unidentified abnormal chromosomes are labeled as markers (mar). Balanced alterations involve the reciprocal exchange of genetic material either between two or more chromosomes (translocations, t) or between various portions of one chromosome (inversions, inv).

While this type of conventional cytogenetic information (karyotypic analysis) provided information that led to the identification and localization of genes involved in leukemogenesis, there are a number of limitations. Firstly, only a few

cells in metaphase are analyzed. Secondly, analysis is entirely dependent on the production of high-quality metaphase preparations and analysis is significantly restricted for cells that have low mitotic rates or which cannot easily be grown

in culture. It is also very labor-intensive. For these reasons, and because conventional karyotypic analysis may not reveal all cytogenetic abnormalities and gene alterations, molecular cytogenetics in the form of fluorescent *in situ* hybridization (FISH) and polymerase chain reaction (PCR) have been employed to increase the sensitivity level for detection of genetic defects.⁷⁷

Although specific cytogenetic abnormalities in ALL can be related to immunophenotype, with the exception of t(8;14)(q24;q32) and its FAB L3 variants, they do not show a close relationship to the FAB subtype. On the other hand, in AML, chromosomal abnormalities including t(8;21)(q22;q22) FAB M2, t(15;17)(q22;q21) FAB M3, inv(16)(p13;q22) FAB M4 E0, or t(9;11)(q2;q23) FAB M5 have been associated with specific morphologic features.

In terms of numeric changes, hyperdiploidy, the most frequent chromosomal abnormality in ALL, has been identified in over 40% of cases of precursor B-cell disease (Table 20.8). High hyperdiploidy (51–65 chromosomes), which occurs in approximately 27% of cases of ALL, is associated with a particularly favorable response to antimetabolite-based therapy, which translates into an event-free survival (EFS) in excess of 85%.⁷⁸ This karyotype is usually associated with other good risk features: age ≥ 1 and < 10 years, a low WBC and pre-B immunophenotype.⁷⁹ Within the high hyperdiploid group, children with chromosomal numbers between 56 and 67 do better than the subgroup with 51–55, translating into EFS values of 86% and 72% at 5 years respectively. These genes normally involve chromosomes 4, 6, 10, 14, 17, 18, 21 and X. Trisomies involving chromosomes 4, 6, 10 and 17 are associated with good prognosis, whereas trisomy 5, a rare abnormality in childhood ALL, is associated with a poor prognosis.⁸⁰

Gene expression profiles

Recent advances in DNA microarray assay technology in association with bioinformatics has enabled gene expression profiles to be produced that categorize specific leukemias. For example, Golub *et al.*⁸¹ analyzed 27 patients with ALL and 11 with AML and were able to define 50 of 1100 genes that allow ALL to be distinguished from AML but also B-lineage ALL from T-lineage ALL with approximately 100% accuracy. Further studies on larger numbers of ALL samples have been able to identify several prognostic cytogenetic subgroups of B-lineage ALL – hyperdiploid > 50 , t(12;21), t(1;19) and *MLL* – with 95–100% accuracy. This technique may also be able to predict those patients who will do less well with combination chemotherapy regimens and therefore these patients will be candidates for more intense or experimental therapies. This molecular genetic strategy may also be powerful enough to shed further light not only on the genetic drivers of leukemogenesis but also generate a patient-specific gene fingerprint that will warrant individualized treatment approaches.

Biological subsets

Infant leukemias: 11q23

As stated above, infant leukemias tend to have a unique clinical presentation, with high circulating blast counts, massive organomegaly and CNS involvement. After neuroblastoma these are the commonest malignancies seen in infancy and they account for approximately 4% of childhood ALL and about 10% of childhood AML. Unlike older children, where ALL is the predominant leukemia, in infants ALL is only marginally more common. The majority of infant leukemias, both AML and ALL, are associated with a translocation involving 11q23 and its various partners in 50 and 80% of cases respectively. The commonest translocations involving 11q23 in ALL are t(4;11) and t(11;19) and in approximately two-thirds of cases involve the CD10-negative B-lineage precursor cell, with the rest consisting of common/pre-B types. The single most common translocation in AML involving this region occurs at t(9;11)(p22;q23) and is associated with monocytic morphology (AML M5).⁸² Different types of 11q23 translocations are seen in children with ALL who have been treated with the epipodophyllotoxins etoposide and teniposide who develop secondary AML.⁸³

The gene involved in these chromosomal translocations that maps to 11q23 has been cloned by a number of groups, hence the many abbreviations ascribed to it (*HRX*, *ALL-1*, *MLL*).⁸⁴ A 15-kb mRNA is transcribed from 11q23 and translates into a 430-kDa protein. This protein shares sequence homology with the *Drosophila* trithorax regulator, which plays a key role in the embryonic development of the fruit fly. The precise leukemogenic events that result from the expression of this protein have not been fully elucidated, but probably involves impairment of the transcription factor function of *MLL* as a result of which the translocation breaks the gene between the two DNA-binding regions.

B (precursor B⁺ and mature B) ALL: cryptic t(12;21)(p13;q22)

A translocation between the short arm of chromosome 12 and the long arm of chromosome 21 was first reported in 1994 and subsequently shown to be the commonest genetic translocation in childhood ALL, occurring in approximately 25% of patients.⁷⁵ The cryptic translocation results in the *TEL/AML1* fusion gene. The TEL protein is a member of the ETS family of transcription factors. The other target in this translocation is the *AML1* (*CBFA2*) gene, a member of the family of core-binding factor (CBF) genes. AML1 represents one of three CBF α subunits that, together with a common CBF β subunit, comprise functional transcription factors. Both AML1 and CBF β are involved in several translocations in AML. CBF oncoproteins, such as TEL/AML1 fusion product, modulate

endogenous CBF activities, which is most likely to be relevant to leukemia transformation.^{85,86}

The presence of this fusion gene defines a subgroup of children with a better-than-average prognosis and, interestingly, this may be related to sensitivity to L-asparaginase therapy. Because of the prognostic significance of this cryptic translocation, it is essential that molecular screening for the translocation be standard practice in order to improve the understanding of the management of such patients.

t(8;14)(q24;q32) and variants (L3)

The translocation t(8;14)(q24;q11) and the variant forms, t(2;8)(p13;q24) and t(8;22)(q24;q32), are found in Burkitt lymphoma and also occur in mature B-cell or Burkitt-type ALL (FAB L3). The translocation results in the activation of the *c-myc* oncogene through juxtaposition with immunoglobulin heavy-chain loci t(8;14) or light-chain loci t(2;8) or t(8;22), the former occurring more commonly. These cases constitute about 2% of childhood ALL.

The breakpoint on chromosome 8 corresponds to the *c-myc* oncogene while those on chromosome 14, 2 and 22 correspond to heavy chain, κ and λ light chains respectively. Therefore, the translocations are always between the *c-myc* oncogene and an immunoglobulin gene. This translocation results in dysregulation of the *c-myc* gene, which is considered to be the mechanism for the mature B-cell clonal proliferation.⁸⁷ These cytogenetic abnormalities can now be detected not only by karyotyping but also by Southern blotting, PCR and FISH.⁸⁸

Leukemia of mature B cells more frequently involves the testis, ovary, pleura, CSF, peripheral lymph nodes and pharynx, factors that in the past probably contributed to a poorer prognostic group.⁸⁹ However, more recently these patients were found to respond favorably to short-term very intensive chemotherapy compared with typical ALL therapeutic regimens, and hence urgent cytogenetic or molecular confirmation of these genetic lesions is essential to treatment planning.

t(1;19)(q23;p13)

First described in 1984, this translocation is seen in approximately 5% of childhood cases of ALL.⁹⁰ It is associated with a pre-B immunophenotype and the blasts express cytoplasmic immunoglobulin (cyμ) in a high percentage (>90%) of cases.⁹⁰ These children do well on current regimens. The identification of the translocation is sometimes difficult as it can be missed in up to 50% of cases when using conventional cytogenetic analysis. Reverse transcriptase (RT)-PCR looking for the cryptic t(1;19) is the preferred investigational tool.⁹¹ These children more commonly present with high-risk factors such as high WBC and CNS disease.⁹¹ Molecularly, this translocation juxtaposes the *E2A* gene with the *PBX1* gene. *E2A* proteins function as transcriptional activators, which are

essential for normal B-cell development.⁹¹ The translocation creates an *E2A/PBX1* fusion gene on the der(19) chromosome. Cases of t(1;19) ALL without detection of *E2A/PBX1* fusion transcripts have been described, suggesting that this translocation is molecularly heterogeneous.

T-ALL

T-ALL accounts for approximately 12% of cases of childhood ALL and usually presents with a high WBC in males aged 6–8 years with a relatively poor prognosis. These children usually have bulky disease (hepatosplenomegaly with peripheral lymphadenopathy), some having an anterior mediastinal mass, and a WBC in excess of $100 \times 10^9/L$ is not unusual.⁹²

Although, T-ALL and B-ALL share some cytogenetic abnormalities, there are some characteristic changes specific to T-ALL. Numerical abnormalities such as hyperdiploidy are more frequently demonstrated in B-ALL, whereas pseudodiploidy (normal chromosomal number with structural abnormality) or near-tetraploidy (chromosomes > 65) are more frequently seen in T-ALL. These cytogenetic changes such as hyperdiploid near tetraploidy are predictive of better EFS.⁹² Genetic changes in T-ALL involve the T-cell receptor (TCR) genes *TCRα* and *TCRδ*. Rearrangements involving the TCR loci occur in up to 30% of cases.⁹³

Several different protooncogenes are activated by translocations in T-ALL, the commonest being stem cell leukemia (SCL) on *TAL-1* gene, which is aberrantly expressed after translocation from 1p32–33 into *TCRα/δ* or *TCRβ* locus. Most patients with SCL/*TAL-1* dysregulation have one or both *TCRδ* genes deleted and express a CD3-positive, *TCRα/δ*-positive phenotype. The important translocations involve the *TCRα/δ* locus at 14q11 are t(1;14), t(8;14), t(10;14) and t(11;14). Those involving the *TCRβ* locus at 7q3236 include t(1;7), t(7;9), t(7;11) and t(7;19). The prognosis of patients with *SCL/TAL-1* expression is indistinguishable from that of patients without it.

ALL with eosinophilia and t(5;14)(q31;q32)

Eosinophil proliferation is associated with immature B-lineage ALL with t(5;14)(q31;q32).⁹⁴ This translocation joins the interleukin (IL)-3 gene to the immunoglobulin heavy chain gene. The eosinophilia is probably reactive, i.e., through IL-3 gene activation, as the clonal cytogenetic lesion is not seen in the eosinophils themselves and serum IL-3 levels have been found to correlate with disease activity.⁹⁴

Eosinophilia has been demonstrated in association with L1 and L2 blasts. Not all cases of ALL with eosinophilia manifest the t(5;14) chromosome rearrangement. The eosinophils may demonstrate myelodysplastic change. This type of ALL is usually more difficult to manage because of cardiac and pulmonary infiltration of eosinophils and this tends to occur more frequently in males and in older children.⁹⁴

Aplastic/hypoplastic ALL

Transient pancytopenia and hypoplastic/aplastic bone marrow occurs in a small number of children prior to the onset of ALL, but the pathogenesis is poorly understood at present. A transient recovery of normal blood counts is followed by overt leukemia in weeks to months. Dysplastic change is not seen in the blood or marrow and the blasts are usually of L1 FAB subtype and are usually CD10⁺.⁹⁵ The association of a history of fever, usually with an infectious disease prodrome, and a preponderance of girls has also been noted.⁹⁵ Immunophenotype and cytogenetic analysis are not usually helpful and differentiating the marrow findings from bone marrow necrosis can be extremely difficult. It is recommended that the bone marrow should be repeated at a different site or at a later date. However, close follow-up is essential as leukemia will in time become evident.

Prognostic factors

A retrospective analysis of clinical trials established many important prognostic factors, which were subsequently applied prospectively to stratify children into different treatment groups according to their relative risk of treatment failure. Children at higher risk of relapse are treated more intensively,^{3,96,97} whereas in those with a lower risk of relapse the more toxic components of treatment, such as cranial irradiation, anthracyclines, oxazaphorines and epipodophyllotoxins, are reduced or even eliminated.^{96–99} Thus, treatment tailored to the individual risk of relapse is an essential prerequisite for current clinical trials. This approach greatly complicates any comparative analysis of treatment results.¹⁰⁰ A uniform approach to risk classification and the classification of special prognostic factors has been agreed by clinicians in the USA.¹⁹

Since ALL is a heterogeneous disease, there may be multiple populations of patients with different prognosis on

identical treatments. Various clinical and laboratory findings at the time of diagnosis have been correlated with prognosis (Table 20.7). The relative importance of a given prognostic factor varies between different treatment protocols.^{3,97,101} Intensification of treatment can eliminate the prognostic significance of some of the unfavorable features, illustrating that treatment *per se* is probably the most important risk factor in childhood ALL. Although all prognostic factors should be considered treatment-specific, certain features appear to be consistently valuable (Table 20.9).

Clinical phenotype

The initial WBC shows independent significance in most studies (Figs 20.1–20.4), with a linear relationship between the number of leukemic cells and the risk of relapse.^{96,102,103} Organ infiltration is strongly correlated with WBC but has no additional prognostic significance in most trials.¹⁰⁴

Age at presentation is an important prognostic factor (Figs 20.1–20.4). Whereas infants younger than 1 year of age have the worst prognosis of any age group,^{3,83} children aged 2–6 years do best of all.^{3,4,98} Adolescents have fared poorly in many trials and adults with ALL have a poorer outcome compared with children.^{3,4,105} The prognostic importance of age may be due to the fact that, for unknown reasons, specific biologic subtypes of ALL occur more or less frequently in different age groups.

In the past, girls have had a better prognosis than boys, which is not completely explained by testicular relapse or the higher incidence of T-ALL in males. However, some recent trials do not find male sex to be an adverse prognostic factor.^{5,106}

Black children, who account for about 10% of all newly diagnosed children with ALL in the USA, have been reported to have a worse prognosis than white children. This has been attributed to the higher frequency of specific biologic subtypes of ALL with a poorer prognosis in black children.¹⁰⁷ However, a recent trial found race to lack prognostic importance.⁵

Table 20.9 Prognostic factors in the therapy of *de novo* acute lymphoblastic leukemia.

Factor	Favorable	Unfavorable
Age	> 1 to < 6 years	< 1 year
White blood cell count ($\times 10^9/L$)	< 20	> 100
Response to initial 7-day prednisone monotherapy	Slow response*	Good response*
Response to initial induction therapy (bone marrow on day 14)	M1 marrow†	M2, M3 marrow†
Chromosome count	> 50	< 45
DNA index	≥ 1.16	< 1.16
Chromosomal translocations	t(12;21)	t(9;22), t(4;11)
Probability of 5-year event-free survival	> 80%	10–60%, depending on specific constellation

* Blast count of $< 1 \times 10^9/L$ in blood after 1 week is a good response.

† M1 marrow, < 5% blasts and complete regeneration of hematopoiesis; M2 marrow, > 5% to < 25% blasts and/or incomplete regeneration of hematopoiesis; M3 marrow, > 25% blasts in the bone marrow.

Fig. 20.1 Event-free survival by trial.

Fig. 20.2 Overall survival by trial.

Cellular phenotype and genotype

The immunophenotype of lymphoblasts was thought to be the most important factor in childhood ALL. This is still true for mature B-ALL which is now treated differently from B-precursor ALL and T-ALL. However, T-ALL is no longer an unfavorable entity using contemporary risk-adapted polychemotherapy.^{3,97,98}

A pre-B cell phenotype has been reported to confer a worse prognosis compared with the early pre-B phenotype.^{108,109} However, results of a trial using intensive polychemotherapy revealed no difference in outcome between these two immunologic subgroups.³ ALL derived from an even earlier B-cell precursor (CD10⁺CD19⁺) (pro-B ALL) has also been associated with a poor response to therapy.^{110,111} However, in one study the adverse impact of this immune phenotype was

abolished when infants were excluded from the analysis.³ The prognostic importance of coexpression of myeloid antigens has been shown to be insignificant.^{68,70,71}

Children with hyperdiploid leukemia (DNA index ≥ 1.16) were reported to have a better prognosis compared with children without this feature.^{112,113} The translocation t(12;21)(p13;q22) with the *TEL-AML1* fusion transcript found in about 20% of children with ALL confers a favorable outcome with long-term survival exceeding 90%.^{114,115} Children with t(9;22)^{116–120} and t(4;11)^{121,122} have a particularly poor

prognosis irrespective of other chromosomal translocations presenting features or treatment regimens. However, Aric *et al.*¹²³ identified a subset of good responding patients with low WBC and t(9;22) childhood ALL with a lower risk for relapse.

Response to treatment

Response to induction polychemotherapy^{124,125} or monotherapy with steroids,^{3,126,127} as measured by the absolute number of leukemic blasts in the peripheral blood on day 7 or the

Table 20.10 Methods for the detection of minimal residual leukemic cells in childhood acute lymphoblastic leukemia (ALL).

Technique	Detection limit	Applicability
Morphology and cytochemistry	10^{-1} – 10^{-2}	All leukemias
Cytogenetics	10^{-1} – 10^{-2}	Leukemias with microscopically detectable numeric or structural aberrations (only cells in mitosis)
Fluorescence <i>in situ</i> hybridization	10^{-1} – 10^{-2}	Leukemias with known numeric or structural aberrations (interphase cells)
Flow cytometry for DNA content	10^{-1} – 10^{-2}	About 30% of B-precursor ALL; < 5% of T-ALL
Flow cytometry for leukemia-associated immunophenotype	10^{-3} – 10^{-4}	50–90% of ALL
PCR techniques		
DNA level		
Rearranged immunoglobulin and T-cell receptor genes	10^{-3} – 10^{-6}	90% of ALL
Chromosomal aberrations with known breakpoints	10^{-4} – 10^{-6}	10–20% of T-ALL, > 5% of B-ALL
RNA level		
Chromosomal aberrations resulting in leukemia-specific fusion genes and fusion mRNA	10^{-3} – 10^{-5}	10–15% of B-precursor ALL

percentage of bone marrow blasts on days 7 or 14, has been defined as a new important predictor of outcome in many recent trials, again illustrating the importance of treatment response as a prognostic factor. However, the reality is that the majority of children who relapse come from the so-called good or standard risk group(s), i.e., favorable cytogenetics, low count at presentation and rapid early response to corticosteroids, and it is for this reason it is hoped that minimal residual disease monitoring will enhance response prognostic classification.¹²⁸

Minimal residual disease and its detection

Molecular and cellular biological assays have defined the concept of minimal residual disease (MRD) where detection of “leukemia-specific” DNA or RNA or “leukemia-associated” antigens is achievable at levels of sensitivity that are much greater than those for morphologic or karyotypic analysis (Table 20.10).¹²⁹ The two most common methods used for MRD assessment are the detection of cells expressing abnormal immunophenotypes by flow cytometry, and of leukemia-associated molecular targets, e.g., fusion transcripts such as *BCR-ABL*, *TEL/AML1* and clone-specific immunoglobulin and TCR gene rearrangements.¹³⁰ The sensitivities of these two methodologies differ: flow cytometry can routinely detect as few as 0.01% leukemia cells in the blood or marrow, whereas PCR-based assays usually detect one leukemia cell in 10^4 – 10^6 normal cells and hence most investigators have used the latter technique.^{131–133}

The majority of clinical MRD studies to date have been in childhood ALL both during and after treatment. Low levels or absence of MRD after completion of induction therapy appears to predict good outcome both by immunophenotyp-

ing and PCR clonality studies. However, it is important to note that quantitation of levels of MRD can differ in particular types of leukemia. A steady decrease of MRD levels during treatment is associated with a good prognosis whereas persistent high levels or increases in MRD positivity generally lead to clinical relapse. Several prospective studies have indicated that sequential sampling, preferably using a quantitative approach, allows stratification of patient risk of relapse. However, it is important to note that although this technique is a powerful and independent prognostic indicator in certain types of childhood leukemia, it has not been proven that planning treatment according to MRD results will improve outcome or decrease toxicity. Current studies such as the UK-ALL 2003 randomized protocol are addressing this very point.

Treatment of newly diagnosed ALL

Table 20.3 gives an overview of the diagnostic work-up that should be carried out in a newly diagnosed child with ALL prior to commencing therapy. Levels of lactate dehydrogenase (LDH), liver enzymes and serum uric acid are often abnormal at presentation due to leukemic cell turnover or kidney infiltration. In children with hyperleukocytosis and a high leukemic cell burden, metabolic abnormalities such as hypercalcemia, hyperphosphatemia or hyperkalemia may not preclude the immediate start of antileukemic treatment. Renal dialysis may be required in the occasional patient with B-ALL.¹³⁴ Most children with ALL and hyperleukocytosis can be managed by careful steroid-based cytoreductive treatment and preventive measures for hyperuricemia including rasburicase.

In addition to a careful history recording previous infections, recent contact with infections and immunizations as well as baseline viral serologies are recommended, especially for measles, varicella zoster virus, cytomegalovirus and herpes simplex virus. A diagnostic lumbar puncture in most modern treatment protocols combined with intrathecal injection of methotrexate for CSF examination (cell count including the number of red cells because of possible contamination with blood) and a cytospin is required at the beginning of treatment.

Chest radiography or sonography of the mediastinum may reveal a mediastinal mass, which may lead to severe obstruction of the airways and/or the superior vena cava. Sonography of the abdomen is recommended for the deter-

mination of liver, spleen and kidney size. Before the start of treatment with potential cardiotoxic drugs, most protocols recommend echocardiography.

Antileukemic drugs

The ability of a cytotoxic drug to induce complete remission of ALL was first reported in 1948,¹³⁵ and since then a multitude of effective agents has been discovered. Despite the fact that single-agent therapy has no place in the curative treatment of ALL, knowledge of the administration and action of each of the available cytotoxic drugs is necessary so that optimal combinations and a sequential strategy can be determined. Figures 20.5 and 20.6 show the steady improvement

Fig. 20.5 Survival by trial: standard risk
(age 1–9 years and white cell count < 50).

Fig. 20.6 Survival by trial: high risk
(age ≥ 10 years and white cell count > 50).

in EFS and overall survival in successive MRC UK-ALL trial protocols over the past quarter of a decade.

Steroids

Of all agents currently used in ALL treatment, the adrenocorticosteroids are of utmost importance in remission induction treatment. Steroids are lympholytic via a mechanism that is as yet poorly understood but which probably involves the activation of nucleases leading to DNA fragmentation (apoptosis). The particular susceptibility of lymphoblasts to steroids permits rapid reduction of leukemic cell number with minimal myelosuppression. The steroid most often used in polychemotherapy protocols is prednisone in oral doses of 60–80 mg/m²/day or its soluble analog prednisolone. Other steroids have essentially identical remission induction capability, although dexamethasone may provide greater control of leukemia in the CNS and other extramedullary sites.¹³⁶

Vinca alkaloids

Vinca alkaloids, together with steroids, are the most important agents for remission induction in ALL. Vincristine in a weekly dose of 1.5 mg/m² (maximal dose 2.0 mg/m²) is by far the most frequently used vinca alkaloid in ALL. Using this schedule, only mild myelosuppression is to be expected; however, neurotoxicity with paresthesia or paralytic ileus may occur, especially in older children. More frequent injections and continuous infusion increase the efficacy of vincristine but also increase the neurotoxicity considerably. Other vinca alkaloids such as vinblastine and vindesine appear to be less effective than vincristine in ALL.

L-Asparaginase

L-Asparaginase, an enzyme that cleaves asparagine into aspartic acid and ammonia, has a restricted activity against lymphoblasts. Asparaginases of two different origins are in current use, namely from *Escherichia coli* and *Erwinia carotovora* (renamed *Erwinia chrysanthemis*), and have different pharmacokinetics.¹³⁷ Side-effects result from the inhibition of protein synthesis, especially of clotting and fibrinolytic factors,¹³⁸ and anaphylactoid reactions. With polyethylene glycol (PEG)-bound asparaginase, the risk of the latter may be reduced; however, PEG binding alters the pharmacokinetics.¹³⁷ L-Asparaginase is given at various doses and schedules in modern polychemotherapy protocols.

Anthracyclines

Daunorubicin was the first anthracycline antibiotic to show significant antileukemic activity. It is a highly myelosuppressive drug and its cardiotoxicity is cumulative. Cumulative doses should not exceed 300–400 mg/m² in children with AL and

most current schedules aim for total doses of less than 240 mg/m². Doxorubicin (Adriamycin) has been less extensively tested in childhood ALL but may have a similar activity and at least the same toxicity compared with daunorubicin. Of the newer anthracyclines, idarubicin has substantial antileukemic efficacy, although its relative value in comparison with daunorubicin has not been established in childhood ALL.

Folic acid antimetabolites

Folic acid antagonists initiated the revolution in treatment of childhood ALL.¹³⁵ Methotrexate, the only compound in current use, together with mercaptopurine is the basis of maintenance chemotherapy in ALL. Given intrathecally, methotrexate is the key component in CNS-directed chemotherapy. High-dose methotrexate, introduced in the 1960s, may provide effective antileukemic methotrexate concentrations in extramedullary sites, especially the CNS and testes, although its use is currently controversial.¹³⁹

Purine antagonists

Mercaptopurine is the traditional purine antagonist in childhood ALL, whereas thioguanine is preferred in AML. Mercaptopurine remains the drug most often combined with methotrexate in virtually all continuation chemotherapy protocols in childhood ALL. Drug dosage, patient compliance and route of administration determine the antileukemic efficacy during maintenance treatment. Several pharmacologic studies show that bioavailability following oral administration of mercaptopurine is highly variable.^{140,141} Large randomized trials have now shown equivalent efficacy of thioguanine and mercaptopurine but thioguanine causes more liver veno occlusive disease and thus mercaptopurine is the preferred drug.¹⁴² Information on the new purine analogs, such as 2-deoxycoformicin, 2-chlorodeoxyadenosine and fludarabine, are scarce in childhood ALL.

Pyrimidine antagonists

Cytarabine arabinoside is the only pyrimidine antagonist used in childhood ALL. *In vitro* studies suggest that T lymphoblasts may be especially sensitive to cytarabine. High-dose cytarabine is a potent inducer of remissions in refractory and relapsed ALL, in both children and adults, and is now included in most protocols for high-risk patients.

Alkylating agents

Cyclophosphamide is the most commonly used alkylating drug for the treatment of childhood ALL. It is effective in both T-ALL and B-ALL.^{44,143,144} Ifosfamide may be as effective as cyclophosphamide and is included in most modern intensive polychemotherapy protocols for B-ALL.^{44,144}

Epipodophyllotoxin

The two most important epipodophyllotoxins are teniposide (VM-26) and etoposide (VP-16). These compounds interact with topoisomerase-II to prevent the reannealing of DNA after it has been disrupted by the enzyme. This in turn leads to apoptosis. VP-16 particularly is included in some polychemotherapy protocols for high-risk patients. However, there is some concern about the development of secondary AML but usually only when used in schedules other than short-intensive blocks.¹⁴⁵

Intensive polychemotherapy approach

The major advances achieved during the past three decades in the treatment of ALL in children and adolescents have dramatically changed the prognosis for this disease, which was always fatal in the past. While treatment was purely palliative until the 1960s, the aim of current treatment protocols is cure; 70–75% of all children and adolescents with ALL can be expected to be cured of their leukemia. This altered prognosis of ALL is mainly the result of very intensive chemotherapy associated with severe suppression of both the normal hematopoietic stem cells and the immune system. Thus, the improvement of supportive measures such as packed red blood cells, effective platelet support and highly effective antimicrobial agents, including broad-spectrum antibiotics, antifungal agents and antiviral drugs, has been a prerequisite for the use of increasingly intensive polychemotherapy protocols (see below).

The aim of treatment is the elimination of the neoplastic cell clone and the restoration of normal hematopoiesis. The different phases of antileukemic treatment are delivered usually in four separate phases or blocks, called remission induction, intensification, CNS directed and continuation treatments.

Remission induction

After stabilization of the clinical status in a child with ALL (treatment of metabolic changes, infections, bleeding complications), remission induction polychemotherapy should be started without delay. The initial phase of treatment is designed to reduce the leukemic cell burden to a clinically and hematologically undetectable level. Complete remission is achieved when the marrow cellularity has returned to normal with < 5% of blasts, the blood values are within the normal range, and all clinical signs and symptoms of the disease have disappeared.

Clinical trials in the 1960s demonstrated that the combination of two antileukemic agents gives superior remission rates compared with single agents. The combination of vincristine and prednisone led to complete remission in about 90% of children with ALL.¹⁴⁶ The addition of a third drug, namely an anthracycline or asparaginase, increased the com-

plete remission rate to > 95%. This increased remission rate was later shown to translate into an increased long-term relapse-free survival,^{96,147} thus demonstrating the importance of maximal early cell kill for the overall effectiveness of treatment. Current induction regimens therefore consist of three or more drugs. A large Children's Cancer Study Group (CCSG) report has demonstrated similar EFS in intermediate-risk ALL treated with a four- and three-drug induction if intensive reintensification was given.¹⁰⁵

CNS-directed treatment is integrated in most current remission induction regimens, most often in the form of intrathecally given methotrexate or triple drug (methotrexate, cytarabine and hydrocortisone) intrathecal therapy.

Current polychemotherapy treatment protocols give a remission rate of > 95%.^{3–5} Induction failures are divided equally between children with refractory leukemia and those dying from complications of leukemia or toxicity of treatment. Thus, intensive induction polychemotherapy can increase long-term survival but may result in increased short-term morbidity and mortality, especially if supportive care is suboptimal, which illustrates the delicate balance required between intensive polychemotherapy and sometimes life-threatening toxicity.

Intensification

Remission induction treatment is followed by intensification (reinduction treatment) early in remission in most current polychemotherapy regimens in order to maximize early leukemic cell kill. Intensification therapy is less standardized compared with remission induction treatment. While some regimens use single agents in high dosages, such as asparaginase, methotrexate or cytarabine, other trials rely on reinduction with the same drug combinations or related drugs to those administered during remission induction. In most trials, children with a presumed higher risk for relapse are treated with more intensive polychemotherapy compared to those with presumed standard risk. However, reintensification therapy is an important phase of therapy for all children with B-precursor ALL.^{96,105}

In standard-risk patients the improvement in treatment outcome by addition of reinduction treatment early in remission was first demonstrated in the 1980s. In this randomized trial, children receiving reinduction did significantly better compared with those who did not receive re-induction therapy [probability of complete continuous remission after 5 years 84% (SD 5%) vs. 62% (SD 7%)].^{3,96} The importance of reinduction treatment was also confirmed by the CCSG demonstration of 7-year EFS of 63% for standard-risk children receiving BFM-type intensification compared with 42% for children not given such treatment.¹⁰⁵

The importance of intensification therapy in children with high-risk features has been confirmed in many trials.^{4,5,96,148–151} In children with very high-risk features as defined by slow

early response, prednisone nonresponse, or unique biologic features such as t(9;22) or t(4;11), an improved outcome could not be demonstrated with further treatment intensification.^{3,152} However, a recent CCSSG trial demonstrated that further prolongation and intensification of therapy (augmented protocol) improved the outcome of children with high-risk features and slow response to induction therapy as defined by an M3 marrow on day 7.¹⁵³

CNS-directed treatment

The use of CNS-directed treatment (CNS irradiation, intrathecal chemotherapy and high-dose chemotherapy) has been considered a prerequisite for long-term leukemia-free survival. Before its introduction more than 50% of children with ALL developed overt CNS disease while in systemic remission. The concept of CNS preventive therapy is based on the premise that the CNS is a sanctuary site in which leukemic cells are protected by the blood–brain barrier from therapeutic concentrations of systemically administered antileukemic drugs.

The use of CNS irradiation as preventive therapy was first demonstrated in a series of studies at St Jude Children's Hospital in Memphis, USA.¹⁵⁴ Relatively low doses of craniospinal irradiation (5 or 12 Gy) demonstrated no preventive effect, whereas 24 Gy of cranial irradiation together with five doses of intrathecal methotrexate or 24 Gy of craniospinal irradiation reduced the incidence of CNS relapse from >50% to approximately 10%.¹⁵⁴ Because craniospinal irradiation was associated with excessive myelosuppression due to irradiation of large parts of the bone marrow and retardation of spinal growth, cranial irradiation (24 Gy) together with intrathecal methotrexate became the standard form of CNS preventive therapy during the 1970s. The identification of brain abnormalities on CT,¹⁵⁵ altered intellectual and psychometric functions, and neuroendocrine dysfunction in children treated with 24 Gy of cranial irradiation and intrathecal chemotherapy prompted a reappraisal of CNS preventive treatment strategies and stimulated the search for alternative less toxic treatments.¹⁵⁶

Alternatives include intrathecal chemotherapy with one or more cytotoxic drugs such as methotrexate, cytarabine with or without hydrocortisone, as well as high doses of intravenous methotrexate to overcome the blood–brain barrier. With intermediate (500 mg/m²) or high (>1 g/m²) doses of methotrexate, some trials reported a higher CNS relapse rate than that observed with inclusion of cranial irradiation. The CNS relapse rate was found to depend on pretherapy risk factors, the response to treatment and the intensity of systemic chemotherapy. Thus, in the context of more intensive systemic therapy, patients at lower risk of CNS relapse may require less intensive CNS-directed therapy with lower doses of cranial irradiation or nowadays no cranial irradiation at

all. The BFM Group demonstrated that the use of 12 Gy administered in a protocol with high-dose methotrexate and intensive reinduction/consolidation therapy was as effective in the prevention of CNS disease as 18 Gy in a selected group of standard-risk patients.^{3,96,104}

The optimal choice of CNS-directed therapy in childhood ALL is controversial, mostly because of the potential for adverse effects. Extensive metaanalysis of randomized trials of CNS-directed therapy have failed to demonstrate a substantial additional effect of radiotherapy, which has been dropped from therapy in all patients in the St Jude's protocols and for all but those CNS-positive at diagnosis or relapse in the UK series, with a consequent very satisfactory extremely low CNS relapse rate.¹⁵⁷

CNS preventive treatment may be associated with acute neurotoxic sequelae such as headache, nausea and vomiting, and other signs of increased intracranial pressure. In addition, 5–7 weeks after cranial irradiation some children develop a characteristic subacute neurotoxic reaction, with somnolence, lethargy, anorexia, fever and irritability. This somnolence syndrome, which may be accompanied by EEG abnormalities and CSF pleocytosis, usually resolves within 1–3 weeks.¹⁵⁸

Continuation treatment

Unlike most other childhood malignancies, childhood ALL requires the continuation of therapy for a long time. Early studies in which no continuation therapy was given after remission induction were associated with the rapid relapse of almost all children.¹⁵⁹ Furthermore, early studies demonstrated that interrupted treatment resulted in inferior results compared with continued maintenance therapy in childhood ALL.¹⁶⁰ In early clinical studies a variety of single agents were evaluated as maintenance agents. Drugs particularly effective as induction agents were surprisingly not useful for continuation therapy. The combination of methotrexate and mercaptopurine administered continuously is now used most widely and is a principal constituent of nearly all maintenance regimens.

Pharmacologic studies have demonstrated that the bioavailability of oral mercaptopurine and oral methotrexate is highly variable. However, a randomized trial demonstrated that for continuation therapy oral methotrexate is as effective as intramuscular methotrexate.¹⁶¹ In most trials, the interindividual variation in bioavailability of mercaptopurine and methotrexate is compensated for by adjusting the dose of both drugs according to the actual WBC. The addition of vincristine and prednisone or dexamethasone to mercaptopurine and methotrexate during maintenance therapy was found to be effective in some trials^{99,162} but not in others.⁹⁶ The most recent studies suggest no value to the vincristine/steroid pulses and thus further meta analysis is required.

Duration of treatment

The use of intensive induction polychemotherapy has significantly decreased the proportion of children suffering relapse after the cessation of treatment.¹⁶³ The BFM trials using very intensive induction polychemotherapy clearly demonstrated that the frequency of relapse after cessation of treatment could be reduced by further intensifying induction and reinduction polychemotherapy.⁹⁶ The relapse frequency after cessation of therapy is in the range of 15% for all children at risk in most trials.^{5,164} Most of those children eventually relapsing did so within the first year off therapy.¹⁶⁴ In the second, third and fourth years after cessation of treatment, the risk of relapse was only about 2–3% per year. Relapses after the fourth year off therapy are extremely rare. However, very late relapses can occur. In an MRC study, 11 of 1000 long-term survivors (older than 10 years in their first remission) relapsed very late (10–24 years after diagnosis).¹⁶⁵ Molecular studies showed that in five patients the second presentation of ALL revealed an identical clonal immunoglobulin heavy chain or TCR gene rearrangement, thus confirming that these second presentations were true relapses rather than a second or secondary ALL. The current practice of treating children for 2–3 years with continuation chemotherapy derives from older studies in which patients were treated with less intensive polychemotherapy than in current use. For this reason, conclusions drawn from these studies on the duration of continuation may not be applicable to current treatment protocols. In an attempt to address this question, the BFM Group randomized patients to receive 18 or 24 months of treatment. A significant advantage was observed for children receiving longer treatment.⁹⁶ The MRC UKALL-VIII trial using less intensive induction polychemotherapy reported similar results between patients randomized to receive 2 or 3 years of maintenance therapy.¹⁶⁶

The optimal duration of therapy may be different for boys and girls. Boys with standard-risk features of ALL demonstrated a significant relapse cascade after cessation of therapy in both BFM '86 and '90 studies (unpublished results). This confirms treatment results from CCSG 141¹⁶⁷ and MRC UKALL-X,¹⁰⁶ which both demonstrated a higher incidence of relapse after cessation of therapy in males, even after excluding boys with occult testicular disease. Thus, in the ongoing British, American and German protocols, boys with standard-risk features are treated for a total of 36 months, whereas girls receive treatment for 24 months.

Closer monitoring of early response parameters, including the assessment of MRD at regular intervals, may provide new guidelines for the optimal duration of therapy in the individual child with ALL which can be used for further stratification of therapy intensity and duration.^{168,169}

However, differences in rearrangement patterns at the time of diagnosis and relapse, most probably due to clonal

evaluation, have been described.^{170–172} Thus, two or more junctional regions of different genes need to be monitored for detection of MRD.^{170,173–175}

ALL of mature B-cell type

The lymphoblasts of about 4% of all children with ALL demonstrate features of more mature lymphocytes, a unique immunophenotype with the expression of surface immunoglobulin with light chain restriction (either κ or λ chains), and specific chromosomal translocations t(8;14), t(2;8) and t(8;22).

Clinically, mature B-ALL is characterized by a high tumor burden, especially within the abdomen, a high LDH and a high propensity to invade the CNS.⁴⁴ Differentiation between mature B-ALL (>25% B lymphoblasts in the bone marrow) and B-NHL (stage IV) (<25% lymphoblasts in the bone marrow) is arbitrary. Thus, most protocols recommend identical treatment for mature B-ALL and B-NHL stage IV.^{44,144} Children with B-ALL had a poor outcome when treated with the regimen used for B-precursor ALL. Using a very intensive therapy approach, including high-dose methotrexate, cytarabine and cyclophosphamide, as well as intensive intrathecal chemotherapy, the EFS of children with mature B-ALL has increased up to greater than 80%.^{44,144} The duration of treatment for B-ALL is short, usually no more than 4–6 months. Nearly all relapses, often with involvement of the CNS, occur within the first year after initial presentation.^{44,144}

Infant leukemia

About 3–5% of children with ALL are infants (<12 months of age). ALL in infancy differs from that in older children with respect to clinical and biologic features and outcome of therapy (see above). At presentation, infants demonstrate a high tumor burden, including a high WBC, hepatosplenomegaly and a higher incidence of CNS leukemia compared with older children. The lymphoblasts appear to arise from a very early stage of commitment to B-cell differentiation, with an immunophenotype of CD19⁺CD10[−], HLA-DR⁺ and frequent coexpression of myeloid markers such as CD13, CD33 or CD65.

Infants with ALL have an increased incidence of chromosomal abnormalities associated with a poor prognosis. Structural abnormalities of chromosome 11, especially rearrangement of band 11q23 within the *MLL* gene, are frequently observed. The t(4;11) abnormality is particularly common in infants with hyperleukocytosis. Hyperdiploidy, a common finding in ALL of older age groups, is extremely rare in infant ALL.^{176,177}

Although the complete response rate of infants appears to be no different from that for older children, the eventual outcome is much poorer. The 5-year EFS in infant ALL ranges from 25 to 50% in most trials.³ This is especially true for infants under 6 months of age.¹⁷⁸

Because the pharmacokinetics of cytotoxic drugs may differ between infants and older children, the optimal dosage of polychemotherapy in infants with ALL is unclear. Most protocols recommend a reduced dosage or calculation according to body weight instead of body surface area.³ Although polychemotherapy is generally well tolerated by infants and cranial irradiation is deferred until the second year of life, late effects of therapy are more often seen in this age group compared with older children.^{179,180}

Congenital ALL, i.e., ALL diagnosed within the first 4 weeks of life, is especially rare and has to be differentiated from transient myeloproliferative disorders, which are mostly seen in children with Down syndrome.¹⁸¹

Treatment of relapsed ALL

Despite progress in treatment outcome of childhood ALL, 15–20% of children with ALL do suffer from relapse. Most relapses occur within the bone marrow, followed by the CNS, testes and other rare sites such as the eye, ovary or skin. Combined relapses may occur within bone marrow and CNS, followed by bone marrow and testes in boys. However, a leukemic relapse at any site should always be considered as a localized manifestation of a systemic disease, thus leading to careful staging procedures for other occult disease manifestations and to reinduction of systemic polychemotherapy in addition to local treatment including CNS-directed therapy.^{7,182,183}

Since most, if not all, effective antileukemic drugs have already been delivered during primary polychemotherapy, treatment of relapse has to rely on combinations of the same drugs. Such an approach has been used by most groups since the early 1980s using cytotoxic drugs in intermittent blocks of polychemotherapy followed by continuation treatment for 24 months.

Careful documentation of relapse sites is of great importance in the individual child, including examination of extramedullary sites such as the CNS (lumbar puncture and diagnostic imaging of the neuroaxis), testes and eye. Bone marrow relapse is diagnosed if > 25% unequivocal lymphoblasts are found. In some patients, the immunophenotype may be different from that found at presentation (phenotypic shift).¹⁸⁴ Similarly, there can be differences in chromosomal aberration and in gene rearrangement patterns at the time of diagnosis and relapse due to clonal evolution.^{170,171,184} In most children with CNS relapse, lymphoblast counts in the CSF are > 5×10^6 /L. In rare cases, the differentiation between reactive CSF pleocytosis and true CNS relapse may be difficult and further immunologic and cytogenetic/molecular genetic studies are warranted. In doubtful cases, another lumbar puncture is indicated after a couple of days, or several weeks if intrathecal therapy has been given. Testicular relapse is documented by biopsy or fine-needle aspiration. However, the latter technique may give false-positive results

if lymphoblasts are present in the blood. A combined relapse is diagnosed if in addition to extramedullary relapse, > 5% unequivocal lymphoblasts are present in the bone marrow.⁷

Different mechanisms may be responsible for the occurrence of relapse of childhood ALL. One reason for treatment failure may be the existence of an anatomic barrier that prevents antileukemic drugs from reaching their target at therapeutically effective concentrations. This may be the reason for most CNS and testicular relapses (sanctuary sites). Another reason for relapse is drug resistance, either primary or secondary, resulting in nonresponse to treatment of early systemic relapse. Clinical resistance to antileukemic drugs is multifactorial and the cellular mechanisms are still poorly understood. Multiple drug resistance is partly due to the overexpression of p-glycoprotein, which acts as a drug-transport protein.¹⁸⁵ The third reason for relapse might be that cells are hidden in metabolic sanctuaries, thus being prevented from recruitment into the cell cycle (G_0 phase) and therefore not accessible to the cytotoxic drug. This may be due to either intrinsic properties of the leukemic cell or altered metabolic environmental conditions that may exist in the CNS or the testes, resulting in much lower proliferative activity. In the individual child with relapsing ALL, one or more of these possible reasons may be responsible and have different treatment implications.⁷

As in the primary treatment of childhood ALL, a number of prognostic factors have emerged from long-term observation of multicenter ALL relapse trials (Table 20.11), implying that different relapse situations should be treated differently.^{7,186–188}

Very early relapse

Children relapsing at any site within the first 18 months after presentation (very early relapse) and children with any relapse of T-ALL have a dismal prognosis with chemotherapy alone.^{7,189,190} Thus, if the relapsing leukemia again responds to intensive polychemotherapy, allogeneic bone marrow transplantation (BMT) in second complete remission from a related or unrelated donor is the treatment of choice in such patients.^{191–194}

Early isolated bone marrow relapse

Most children with isolated bone marrow relapse within the first 6 months after cessation of therapy (early relapse) initially respond to second-line polychemotherapy. However, since prognosis is also dismal in this group,^{7,195} allogeneic BMT from a related or unrelated donor is indicated in this subgroup of relapsing patients as well, preferably on a clinical trial.

CNS relapse

The CNS is the second commonest site for relapse in child-

Table 20.11 Prognostic factors in the therapy of relapsed acute lymphoblastic leukemia.

Factor	Favorable	Unfavorable
Duration of first complete remission	Late (> 6–12 months after cessation of treatment)	Early
Site of relapse	Extramedullary relapse	Bone marrow relapse
Peripheral blasts at relapse ($\times 10^9/L$)	< 10	> 10
Immunophenotype	B-precursor ALL	T-ALL, B-ALL
Cytogenetics/molecular genetics	t(12;21)	t(4;11), t(9;22)
Response to relapse treatment	Complete remission within 6 weeks	Complete remission after 6 weeks

hood ALL. The incidence of CNS relapses depends largely on the CNS-directed treatment applied in first-line treatment.¹⁰⁰ With adequate CNS-directed treatment, isolated and combined CNS relapses occur in < 5% of children in first remission.^{3–5,101,196} As in other presumed isolated extramedullary relapses of ALL, CNS relapses should be considered a localized manifestation of systemic leukemia and thus treatment should always include intensive systemic polychemotherapy as well as local therapy. Most successful treatment regimens use intensive polychemotherapy together with extended intrathecal therapy and cranial or craniospinal irradiation at a dose dependent on the dose given during first-line treatment.^{7,197,198}

A study from St Jude Children's Hospital reported a 5-year disease-free survival in second remission of > 70% in children with isolated CNS relapse. About half of all children with CNS relapse with or without concomitant bone marrow involvement have achieved long-term (>5 years) second remission and possible cure in the ongoing ALL-BFM relapse trials.¹⁹⁹

Testicular relapse

Testicular relapse probably arises in a sanctuary area. In early ALL trials with less intensive polychemotherapy, up to 50% of males exhibited testicular relapse, either with or without concomitant bone marrow involvement.^{200–203} The incidence of testicular relapse has been dramatically decreased after intensification of front-line regimens. In recent trials, < 5% of boys with ALL developed overt testicular relapse with or without bone marrow involvement.^{3–5,196}

Treatment of testicular relapse with or without bone marrow involvement must include intensive polychemotherapy including CNS-directed therapy together with local therapy. Most trials recommend second remission radiotherapy to the scrotum and iliac region, usually with a dose of 24 Gy. Using this approach, boys with late isolated testicular relapse occurring later than 6 months after cessation of therapy may have a 70% or greater probability of cure.^{7,204,205} Routine testicular biopsy at the end of first-line therapy has proved to be of no value.²⁰⁶

Late bone marrow relapse

Children with B-precursor ALL relapsing more than 6 months after cessation of therapy may experience extended second remission or even cure with a second course of intensive polychemotherapy.^{7,189,207,208} A second remission can be induced by intensive polychemotherapy in > 90% of children with late bone marrow relapse,^{7,207} with a second EFS of > 5 years in about 35%.^{209,210} Duration of first remission^{6,7,211} is the most important predictive factor for the length of second remission. In addition, a blood lymphoblast count of $< 10 \times 10^9/L$ ²⁰⁹ and a low WBC²¹¹ at the time of relapse have been associated with a high second EFS rate. Furthermore, the presence of t(12;21) at relapse predicts a favorable outcome.²¹² Most relapse trials demonstrate a superior outcome in children with combined rather than isolated bone marrow relapse.^{7,208}

Relapse at other sites

Leukemia may very rarely reoccur at other sites (e.g., eye, ovary, tonsils and skin). As in other extramedullary relapses, intensive polychemotherapy including CNS-directed treatment together with appropriate local therapy is recommended in these rare situations.

Role of bone marrow transplantation

Over the past three decades, BMT has evolved as an effective treatment modality for hematologic malignancies.^{213,214} In the past, much progress has been made in reducing treatment-related problems, which occur especially in older patients. However, BMT is still burdened by distinct toxic side-effects and infectious complications, resulting in a treatment-related mortality of up to 30%, depending on the source of hematopoietic stem cells.^{191,213}

Graft-versus-host disease (GVHD), which is mediated by cytotoxic T lymphocytes, may cause severe morbidity and even mortality, but may also provide additional antileukemic

efficacy via a graft-versus-leukemia (GVL) reaction. Attempts to separate GVHD and GVL reaction are ongoing. T-cell depletion of donor marrow results in a significant reduction in GVHD, but also in some situations an increased graft failure rate and an increased leukemic relapse rate.¹⁹¹

Matched related sibling or family donor transplantation is limited by the availability of a matched HLA-identical family member (available in $\leq 30\%$ of children with leukemia).^{191,213} This limitation may be overcome with increasing numbers of volunteer bone marrow donors on worldwide registries for matched unrelated donor transplantation. However, transplantation-related mortality after matched unrelated donor transplantation is significantly higher compared with matched sibling transplantation in the majority of published trials.^{193,194} Another alternative source of hematopoietic stem cells may be cord blood; long-term results are not yet available after cord blood stem cell transplantation.²¹⁵

Predictive factors for the outcome after allogeneic BMT may be similar, at least in part, to those seen in polychemotherapy, e.g., high-risk features at diagnosis and the duration of first remission.^{192,216}

The most commonly used preparatory regimen consists of total body irradiation (TBI) and cyclophosphamide, the original Seattle regimen,²¹⁷ or TBI and etoposide.^{218–220} Myeloablative chemotherapy with high-dose cytarabine followed by TBI²²¹ or a preparative regimen without TBI such as busulfan/cyclophosphamide²²² did not decrease relapse rates or improve overall survival.

The high cure rate of ALL in children and adolescents implies that BMT is generally reserved for children who relapse. However, under the conditions of recent risk-adapted polychemotherapy, some patients with very poor risk factors may benefit from allogeneic transplantation in first remission.

Although BMT is widely accepted as an appropriate form of therapy in second remission, the exact impact of BMT for the different subsets of children in second remission, the possible use of matched unrelated donors, and the possible impact of cord transplantation²²³ are matters of intensive debate. The role of BMT has to be measured against the efficacy of polychemotherapy within controlled trials. In the absence of randomized trials, matched-pair analyses were used to try to answer some of the most important questions.²²⁴

In early bone marrow relapse (≤ 6 months after cessation of treatment), BMT increases the probability of EFS in second complete remission compared with chemotherapy.^{219,225} This is especially true for T-ALL relapses and for relapses of Philadelphia-positive ALL. In these situations, the prognosis after conventional chemotherapy is dismal. Therefore, allogeneic BMT from a matched unrelated donor should be considered if no matched related donor is available.

In late bone marrow relapse (> 6 months after cessation of therapy), about 35% of children with non-T-ALL may be cured by intensive polychemotherapy alone; thus allogeneic BMT is not recommended by most investigators in this

Table 20.12 Possible indications for bone marrow transplantation (BMT) in childhood acute lymphoblastic leukemia (ALL).

BMT in first complete remission

Philadelphia chromosome-positive (*BCR/ABL*-positive) ALL
t(4;11), near haploid, *AML1* amplification
Poor response to treatment (e.g., no complete remission after 4 weeks of induction therapy)

BMT in second complete remission

Early (< 6 months after cessation of therapy) bone marrow relapse
Late bone marrow relapse with unfavorable features (*BCR/ABL*-positive ALL; *TEL/AML*-negative ALL; poor response to relapse therapy after 6 weeks)
All relapses of T-ALL

BMT in greater than second complete remission

All patients

situation.²²⁵ It is expected that new technologies such as monitoring response to polychemotherapy for relapse, including monitoring of MRD, will help with the difficult decision of which child should receive allogeneic BMT in second complete remission and these tests are indeed the basis of current international relapse protocols.

The possible indications for BMT using hematopoietic stem cells are summarized in Table 20.12. Autologous stem cell transplantation has the advantage of applicability to all patients in the absence of GVHD. However, there exists a risk of reinfusing residual leukemic blasts.^{226,227} In a recent matched-pair analysis, the outcome after autotransplantation was no different from intensive chemotherapy.²²⁴ At this time there is no defined role for this procedure in therapy of ALL.

Complications of treatment

Early complications

Major complications can be expected in children who present with a high leukemic cell burden and a high proliferation capacity, such as T-ALL, B-ALL and c-ALL with hyperleukocytosis ($\text{WBC} > 10 \times 10^9/\text{L}$). Life-threatening metabolic complications can result from spontaneous leukemic cell turnover and chemotherapeutically induced leukemic cell death (tumor lysis syndrome), presenting with hyperuricemia, hyperkalemia and hyperphosphatemia.^{228,229} Massive release of cellular nucleic acids and their conversion to uric acid may result in the precipitation of uric acid in the renal collecting system and ureters.^{230,231} Careful hydration, together with the administration of allopurinol prior to chemotherapy^{232–234} or application of rasburicase, help avert these metabolic complications. Potassium is released from lysed lymphoblasts and requires dialysis in some children with decreased renal function due to leukemic infiltration.²³³

In children with hyperleukocytosis ($\text{WBC} > 10 \times 10^9/\text{L}$) the microcirculation may be impaired by intravascular clumping of leukemic blasts, resulting in local hypoxemia, endothelial damage, hemorrhage and infarction, especially within the CNS and lungs (hyperleukocytosis/leukostasis syndrome).⁴⁵ This syndrome is seen more often in children with AML but has been reported in children with ALL. Packed red blood cell transfusion should not be given in this situation to avoid further increasing blood viscosity and thus worsening the symptoms of hyperleukocytosis/leukostasis syndrome.^{45,46}

In children with T-ALL and an enlarged mediastinal mass, life-threatening bronchial and/or cardiovascular (superior vena cava syndrome) compression may occur. Immediate application of systemic chemotherapy is necessary in this oncologic emergency.

Signs and symptoms of meningeal or intracranial involvement, such as headache, vomiting, meningism and cranial nerve palsies, are rare at presentation. Differentiation between intracranial bleeding and leukemic infiltration of the CNS is sometimes impossible even with the help of diagnostic imaging (cranial CT, MRT), especially in children with the hyperleukocytosis/leukostasis syndrome. Immediate lumbar puncture may be dangerous in this situation. Prompt administration of systemic chemotherapy should be considered.

Leukemic infiltration of the optic nerve and/or the retina is extremely rare.^{235,236} Immediate systemic chemotherapy including high doses of steroids together with local radiotherapy and intrathecal therapy should be given to prevent blindness.

Supportive care

Optimal treatment of children with ALL requires appropriate supportive care, including the rational use of blood products, an aggressive approach to detection and treatment of bleeding and infectious complications, and continuous psychosocial support for the patient and family. Some of these topics are addressed elsewhere, and only the most important issues, namely the diagnosis, treatment and prophylaxis of bleeding and infectious complications, are discussed here.

Bleeding

Bleeding in children with leukemia is usually due to thrombocytopenia, the differential diagnosis including decreased production due to marrow infiltration and/or chemotherapy-induced marrow aplasia, disseminated intravascular coagulation and septicemia. In rare cases, heparin-induced thrombocytopenia has also to be considered.²³⁷

Thrombosis

Venous thrombosis (e.g., intracranial sinus vein thrombosis) may occur during treatment of childhood ALL, especially when asparaginase is given.^{238,239} Nowak Göttl *et al.*²⁴⁰ described 15 thromboembolic episodes in 243 consecutive children with

ALL. Most of these children had central venous catheters, and at least one of the following thrombophilic defects were found in all children: factor V Leiden mutation, protein C deficiency, protein S deficiency, antithrombin III deficiency and increased level of lipoprotein (a). Prophylaxis with antithrombin III and avoidance of central venous catheters during asparaginase therapy may be useful in children with defined thrombophilic disorders.¹³⁸ However, other series have failed to confirm these findings.

Infections

Infections during granulocytopenia are an important complication of intensive polychemotherapy. Most are presumably bacterial, but a significant microorganism can often not be found by standard methods. Therefore, any febrile child with leukemia and an absolute neutrophil count $< 0.5 \times 10^9/\text{L}$ should be considered bacteremic and treated with broad-spectrum antibiotics covering Gram-positive and Gram-negative organisms.

A variety of nonbacterial opportunistic microorganisms can invade the immunocompromised host. Fungal infections, especially *Candida* and *Aspergillus* species, are increasingly observed during prolonged periods of neutropenia and immunosuppression.⁴⁷

The administration of the hematopoietic growth factor granulocyte colony-stimulating factor (G-CSF) to intensively treated children with high-risk ALL may reduce febrile neutropenia and culture-confirmed infections.²⁴¹ However, the evidence for regular use is weak at present.

Viral infections, especially due to varicella zoster virus (VZV), complicated by pneumonia, hepatitis and cerebral infection had a high morbidity and mortality in earlier studies.^{242,243} Prophylaxis with VZV hyperimmunoglobulin²⁴⁴ and treatment with aciclovir in overt VZV infection^{245,246} have significantly reduced the frequency of disease. Rare cases of measles in severely compromised children with leukemia still have a high mortality and emphasize the importance of vaccination in the general population.^{247–249}

In early trials, *Pneumocystis carinii*, now believed to be a fungus, was the cause of severe, often fatal interstitial pneumonia in children with leukemia receiving polychemotherapy, especially with steroids.²⁵⁰ Prophylaxis with co-trimoxazole almost completely abolished the incidence of severe infection with this organism.²⁵¹

Late complications

The improved survival of childhood ALL has focused attention on the late effects of antileukemic therapy (Table 20.13).

Gonadal

Normal sexual development can be expected in most girls regardless of the form of CNS-directed treatment.^{252,253}

Table 20.13 Late sequelae of leukemia treatment.

Organ	Etiology
<i>Gonads</i>	
Infertility	Alkylating agents, radiotherapy
<i>Liver</i>	
Fibrosis/cirrhosis	Methotrexate, mercaptopurine, hepatitis B, C virus
Hepatocellular carcinoma	Hepatitis B virus
Venoocclusive disease	Busulfan, bone marrow transplantation
<i>Lung</i>	
Fibrosis/pneumonitis	Busulfan, radiotherapy
<i>Kidney</i>	
Tubulopathy (Fanconi syndrome)	Ifosfamide
<i>Thyroid</i>	
Tumors, hypothyroidism	Radiotherapy
<i>Spleen</i>	
Overwhelming sepsis	Splenectomy/radiotherapy
<i>Bone</i>	
Osteonecrosis	Steroids
<i>Heart</i>	
Cardiomyopathy	Anthracyclines, radiotherapy
<i>Central nervous system</i>	
Leukoencephalopathy	Radiotherapy, intrathecal chemotherapy
↓IQ, ↓cognition	Radiotherapy, intrathecal chemotherapy
↓Psychomotor skills	Radiotherapy, intrathecal chemotherapy
↓Growth	Radiotherapy, intrathecal chemotherapy
Second malignancies	Genetic predisposition; radiotherapy; alkylating agents, epipodophyllotoxins

Sexual maturation is also normal in most boys,^{254,255} although gonadal dysfunction is common following testicular irradiation.²⁵⁶ Testosterone replacement is recommended in this situation. Currently, there is no evidence that the progeny of survivors of childhood ALL are at increased risk of congenital abnormalities.²⁵⁷

Liver

Children receiving continuation treatment with methotrexate frequently have elevated liver function tests. After cessation of therapy these tests return to normal. Chronic liver diseases may occur in children with a history of hepatitis B or C infection.²⁵⁸

Cardiac

Anthracyclines are known to exhibit cumulative dose-related cardiotoxicity. Children receiving a cumulative anthracycline dose of 200–260 mg/m² are usually asymptomatic,

although in some reduced contractility has been measured after cessation of therapy.⁴⁸ Younger age, female sex and a greater cumulative dose of anthracyclines were found to be risk factors for late cardiotoxicity.⁴⁹ Additional cardiotoxicity may be caused by other cytotoxic drugs, such as high-dose cyclophosphamide and spinal or mediastinal irradiation.²⁵⁹

Central nervous system

A number of CNS sequelae have been described after different modalities of CNS-directed treatment.¹⁸⁰ The incidence of neuroradiologically observed structural abnormalities varies greatly between different trials and may be as high as 75%.^{260–263} Four radiologically distinct forms have been identified in children with ALL: subacute leukoencephalopathy, mineralizing angiopathy, subacute necrotizing leukomyelopathy, and cortical atrophy.²⁶⁴ Although a higher incidence of structural pathology was observed after more intensive CNS-directed treatment, the role of the different components of this treatment (namely high-dose systemic chemotherapy, intrathecal drug application and cranial irradiation) remains to be determined. Several trials revealed no difference in the CT abnormalities between patients receiving cranial irradiation and those who did not.^{265,266}

Often a discrepancy between neurologic findings and clinical measurements of neurologic or neurocognitive function is found.^{267,268} Children who receive cranial irradiation at a younger age tend to show greater neurologic decrements.^{269,270} While most children in these studies had received cranial irradiation, the potential adverse sequelae with intensive intrathecal and systemic high-dose chemotherapy must also be appreciated.^{271,272}

Children with CNS relapse who receive a second course of CNS-directed treatment are at particular risk of significant cerebral dysfunction, in addition to neuropsychologic deficits, seizures and leukoencephalopathy.^{273,274}

Growth

Cranial irradiation with doses of 18–24 Gy may have a negative impact on final growth, depending on age at radiation, fraction schedule, type of systemic chemotherapy, and pubertal status at radiation. In general, the slowing of growth during treatment of ALL is followed by catch-up growth.^{275,276} The effects of cranial irradiation on final growth are more marked in children treated at a young age^{277,278} and in female patients.²⁷⁹ Endocrine studies revealed growth hormone deficiencies in some of these children and treatment with growth hormone has been evaluated in some of the most severely affected children.²⁸⁰

Others

Hypothyroidism is relatively common after radiation

treatment.²⁸¹ Avascular osteonecrosis has been reported during and after treatment with high doses of corticosteroids.^{282,283} The reader is directed to recent excellent reviews of the complex problem of late effects of therapy.^{284,285}

Second malignancies

The risk of developing second malignancy after successful treatment of ALL is low. Two large cohort studies from the Nordic countries and the USA estimated a cumulative risk of 2.9% by 20 years²⁸⁶ and 2.5% by 15 years²⁸⁷ respectively. The majority of second malignancies were brain tumors, mostly gliomas, developing in the radiation field. Exposure to radiotherapy appears to be associated with a continuous risk of second neoplasm, especially within the thyroid gland.^{288,289}

The use of epipodophyllotoxins has been found to be associated with a risk of secondary AML if used in schedules other than short intensive blocks,⁸³ a complication not observed in treatment protocols that do not contain these drugs.²⁹⁰

Lymphomas

O.B. Eden and Ross Pinkerton

Non-Hodgkin lymphoma

Childhood non-Hodgkin lymphoma (NHL) represents a heterogeneous group of disorders that are different from adult NHL in that they are commonly disseminated; diffuse not nodular; high grade; of mature and immature T- or B-cell lineage; and have frequent extranodal disease, marrow and central nervous system (CNS) involvement. Over the last three decades, empirical chemotherapeutic management has transformed survival, and more recently greater understanding of the biology is offering hope for improved management of resistant disease.

Epidemiology

Age-standardized incidence rates for NHL vary from 6.1 per million children (0–15 years) in the UK and Japan to 90.1 per million reported from Ibadan, Nigeria.¹ Hidden within these statistics are very different patterns of disease, particularly the incidence of B-cell lymphomas. Of all childhood cancers reported from Ibadan between 1960 and 1984, 47% were Burkitt lymphoma (BL) with an age-standardized incidence rate of 80 per million. Even higher rates have been reported from Uganda.

In endemic malarial areas of Africa, especially where BL is common, the peak age incidence is between 5 and 9 years, with a ratio of up to three boys to each girl affected. The primary tumor is most frequently in the jaw. Other areas with an NHL incidence intermediate between the African and UK experience also report high BL rates (e.g., Middle East, Latin America, Mediterranean area and North Africa), but in these regions the tumors occur more commonly in the abdomen and over a wider age range (0–9 years). The age-standardized incidence for BL in the USA it is 3.6 per million in white males, 0.4 per million in white females, 0.7 per million in black males and of a very low incidence in black girls.¹

In western Europe, the male to female ratio for all NHL is

approximately 2 : 1 and NHL constitutes 5–6% of all childhood cancers, although the relative and absolute incidence rises southwards toward the Mediterranean. In the UK the peak age incidence is between 7 and 10 years, but all ages can be affected. Over the last 30 years there appears to have been a steady increase in the overall incidence of NHL for reasons that are unclear.

Etiology and cell biology

The childhood immune system consists of many different mature functional cells as well as a wide array of precursor and stem cells. Malignancy can occur at any stage of lymphocyte ontogeny, and monoclonal antibodies have helped to define the differentiation process of both normal and malignant lymphocytes (Fig. 21.1).

Young children are constantly exposed to antigens, but unlike adults they do not have a large immune memory bank to help them recognize and repel such antigens. As a result, a large proportion of lymphoid cells during childhood are in a very active state, undergoing molecular rearrangements to produce specific immunoglobulins and other factors required for the normal immune response. For B cells to function, the genes that regulate the different components of immunoglobulin production have to be brought together or rearranged in an ordered sequence. In T cells, the genes that control T-cell antigen receptor molecules similarly need to be organized. The immunoglobulin heavy chain genes are on chromosome 14q32, the λ light chain genes on chromosome 22q11 and the κ light chain genes on chromosome 2p12.

The human T-cell receptor α -chain gene maps to chromosome 14q11–q12 and harbors the T-cell receptor δ genes between its V and J region gene sequences. The T-cell receptor β -chain locus is on chromosome 7q35. A complete product molecule requires two chains, an α from chromosome 14 and a β from chromosome 7. In normal health the rearrangement process producing the product of the receptor gene is very similar to that for immunoglobulin gene rearrangements.

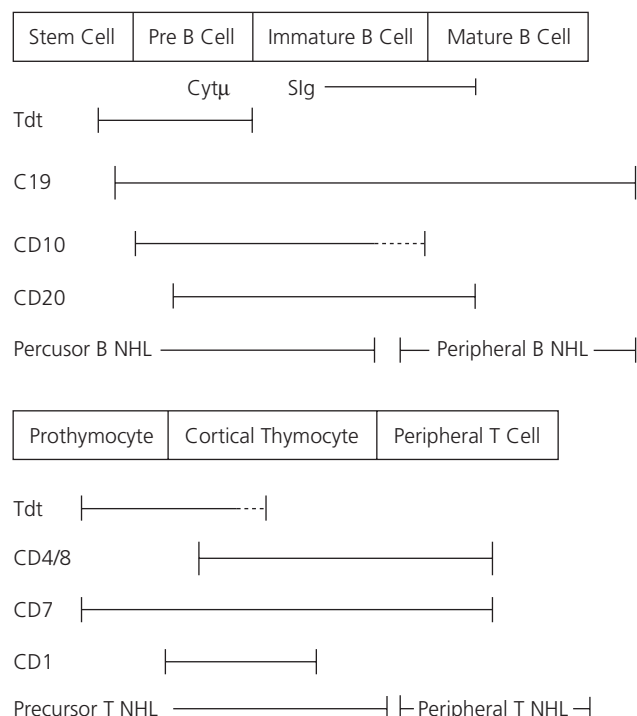

Fig. 21.1 Phenotypic features of lymphoma in relation to normal lymphocyte differentiation: T and B cells differentiate in parallel with malignant lymphoma. Cytψ, cytoplasmic immunoglobulin; NHL, non-Hodgkin lymphoma; Slg, surface immunoglobulin; Tdt, terminal deoxynucleotidyl transferase.

The enzyme terminal deoxynucleotidyl transferase is intimately involved in T-cell rearrangements but is not found in mature B-cell acute lymphoid leukemia (ALL) or lymphoma and can be used as a distinguishing marker.

Malignant change can occur when genetic defects arise secondary to deletion, mutation or translocation. This can interrupt the normal orderly rearrangement, but what actually initiates the disorganization is not clear in most instances. Accumulating evidence incriminates viruses, at least in the pathogenesis of some lymphomas. The products from the retroviruses human T-cell leukemia/lymphoma virus (HTLV)-1 and HTLV-2 rearrange genes within the host cell, thus stimulating production of interleukin (IL)-2 and its receptor, which can activate T-cell proliferation. Clonal or polyclonal proliferation provides the opportunity for a second strike, which may be necessary to produce a malignant clone. HTLV-1 is thought to play a role in the genesis of a particular form of adult T-cell leukemia/lymphoma, particularly in Japan. No viral inclusions have yet been found in childhood T-cell NHL.

More directly relevant to pediatric practice was the discovery of Epstein-Barr virus (EBV) particles in the nuclei of endemic African BL cells.² The finding of such viral inclusion and high antibody titers (especially to the viral capsid antigen)

to EBV in the vast majority of cases (95%) from tropical regions contrasts with those in temperate regions, where the incidence of raised titers and/or viral inclusions is only about 15–20%.^{3,4} However, there is increasing evidence of aberrant expression in sporadic cases. In very high incidence regions, malaria is endemic and is thought to cause a continuous antigenic stimulus that alters responses to EBV infections, which are also endemic (nearly 100% of children have been exposed by age 3 years). EBV infection early in life is thought to enlarge the size of certain pre-B and B-cell populations and maintain them in a proliferative state, thereby rendering them more likely to genetic change. Alternatively, it has been postulated that EBV produces an immortal cell clone with genetic translocations already present, perhaps induced by another infection. The product of the *EBER* locus of the EBV genome has been implicated in oncogenesis by its antiapoptotic activity. The promoter region of this locus is a binding site for *c-myc*, which could upregulate *EBER* transcription.⁵

Repeated infections, especially of malaria (a T-cell suppressor and B-cell mutagen), malnutrition and other cofactors (e.g., use of phorbol esters as herbal medicine) result in T-cell immunosuppression (reduced CD4 : CD8 ratio and decreased number and function of EBV-specific T cells) and B-cell hyperplasia that can potentiate the effects of EBV infection. A consequent increase in number of EBV genome-positive cells during acute malaria is postulated to increase the chance of genetic changes, including the characteristic translocation involving the long arm of chromosome 8 (q23–24), usually as part of a t(8;14)(q24;q32) rearrangement, although variants including t(2;8)(p12;q24) and t(8;22)(q24;q11) are seen in about 15% of cases. The *c-myc* oncogene lies at the chromosome 8 breakpoint, while the immunoglobulin heavy chain locus and κ and λ light chain loci are at 14q32, 2p12 and 22q11, respectively. In all cases, an immunoglobulin gene enhancer is placed close to *c-myc* and induces its expression. Of great interest has been the finding that the chromosome 8 breakpoint is upstream of *c-myc* in endemic cases, whereas in the sporadic form it occurs within *c-myc* or immediately upstream. However, in all forms, the *c-myc* coding region appears to be left intact so that deregulation of the oncogene rather than mutation seems to be the consequence of the translocation. The myc-encoded protein appears to regulate the expression of target genes required for cell cycle progression through G₁ into S phase. If it is dysregulated, it leads to progression through the cell cycle and lymphoproliferation. On chromosome 14 the breakpoints involve limited D and J segments, regions prone to physiologic rearrangements during the normal sequence of VDJ recombination. Endemic cases of BL usually have low levels of surface immunoglobulin, while sporadic cases have high levels and the cells also secrete immunoglobulin. It is thought that in sporadic cases the translocations are at a later stage of B-cell differentiation. These endemic cases have a more homogeneous immunophenotype and fewer genetic abnormalities.⁶ This

ever-increasing knowledge of the biology of NHL has been applied to the detection of minimal residual disease using polymerase chain reaction techniques to detect specific patterns of immunoglobulin gene rearrangements.⁷

8q24 is a fragile site but what specifically initiates the translocation is not clear. A multiple-hit model is postulated for the initiation of BL. Some have speculated that genetic factors might also be involved, since familial clusters of BL have been reported,⁸ and genetic factors including inherited mutations of the *c-myc* oncogene or p53, and the finding of an excess of HLA-DR7 phenotype, raise the possibility of inherent DNA repair defects or abnormal responsiveness to infection. The intriguing effect of extracts from *Euphorbia triucalli* (used as a herbal medicine) in inducing *c-myc* activation⁹ further suggests that a complex interaction of environmental and genetic factors is likely.

Human immunodeficiency virus (HIV) infection as a result of profound T-helper cell depression predisposes to a variety of tumors, including intermediate- to high-grade B-cell lymphomas, Hodgkin disease, T-cell NHL and some pre-T and pre-B tumors, especially Kaposi sarcoma. Some of the resultant lymphomas appear to be polyclonal B-cell proliferations similar to those seen after intense iatrogenic immunosuppression. The characteristic feature of HIV-associated lymphomas is extranodal disease, especially of the skin, and a high incidence of EBV positivity, raising the possibility that HIV may predispose to EBV-driven proliferation.¹⁰

For T-cell ALL and NHL, chromosomal abnormalities are more heterogeneous. About 25% of cases of T-cell ALL involve a small deletion of the *TAL1* gene on chromosome 1 and this is sometimes associated with a t(1;14) translocation. Also, translocations can involve the locus for the α chain of the T-cell receptor gene on chromosome 14 or for the β chain on chromosome 7.¹¹ No clear-cut association between these changes and etiologic factors has been made but the changes can be used to detect minimal residual disease.

In anaplastic large-cell lymphoma (ALCL), a t(2;5)(p23;q35) translocation has been described.¹² This is found in occasional cases of Hodgkin disease, and current interest exists in exploring the overlap between these two conditions, and also the association of chromosome 2 anomalies in ALCL with more advanced disease and with a poorer prognosis. To date, no clear etiologic link has been made. The translocation produces a fused gene (nucleophosmin, *NPM*, from chromosome 5 and AL kinase gene, *ALK*, from chromosome 2) and a product that is primarily cytoplasmic in location. Its precise function has not been defined. Inhibitors of antiapoptotic mechanisms such as BCL-6 have been implicated in a range of lymphomas.¹³ Overexpression has been described in pre-T NHL.¹⁴

Genetic factors may be important in NHL development, not just given the occasional familial clustering with BL but also because a number of inherited or congenital immunodeficiency syndromes are associated with NHL. These

include ataxia telangiectasia (including a number of variants, especially with T-cell malignancies), Wiskott–Aldrich syndrome, Bruton agammaglobulinemia, severe combined immunodeficiency and IgA deficiency. Post-organ transplantation lymphomas representing either monoclonal or polyclonal B-cell proliferation have been referred to already. The X-linked syndrome described by Grierson and Purtillo,¹⁵ characterized by undue sensitivity to EBV and leading to uncontrolled EBV proliferation, comprising hepatitis, encephalopathy, aplasia and malignant lymphomas, has similar features. Other chromosomal or genetic disorders associated with NHL include Klinefelter syndrome¹⁶ and neurofibromatosis type 1.

Apart from postnatal long-term exposure to phenytoin (which can produce a benign lymphadenopathy, a self-limiting pseudolymphoma and, rarely, a true lymphoma), EBV infection for BL and the intense immunosuppression following transplantation or chemotherapy, no other environmental factors have been firmly incriminated in the causation of NHL. Although still the subject of intense investigation, prenatal or postnatal exposure to irradiation, chemicals, electromagnetic fields and electricity have not been firmly associated with NHL.

Classification

A confusing array of classifications exists for NHL. For pediatric practice there is a concerted effort to use the REAL (Revised European American Lymphoma) classification, which is an update of the Kiel scheme, incorporating immunophenotyping and dividing NHL into T- and B-cell neoplasms, and further classifying them as of high- or low-grade malignancy (Table 21.1). Virtually all childhood NHL are diffuse, with three types, namely BL (42%), T lymphoblastic (20%) and ALCL (15%), predominating.

Clinical presentation

Abdominal primary

Lymphadenopathy is a common referral to GP, general pediatrician and oncologist. The vast majority of cases are

Table 21.1 REAL classification scheme for childhood non-Hodgkin lymphoma (relative incidence in parentheses).

Burkitt (42%)
Burkitt like (4%)
Precursor B lymphoblastic (5%)
Precursor T lymphoblastic (20%)
Diffuse large B cell (3%) (primary sclerosing mediastinal 0.4%)
Peripheral T cell unspecified (1%)
Anaplastic large-cell T or "null" types (15%)

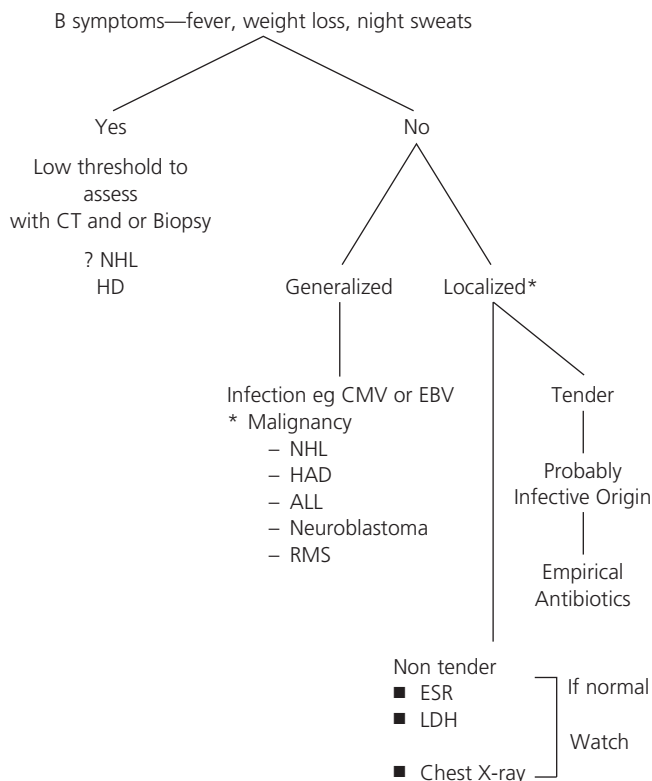

Fig. 21.2 Assessment of child with lymphadenopathy. Asterisk indicates that biopsy should only be considered if swelling is very large or rapidly increasing in size. ALL, acute lymphoid leukemia; CMV, cytomegalovirus; CT, computed tomography; EBV, Epstein-Barr virus; ESR, erythrocyte sedimentation rate; HD, Hodgkin disease; LDH, lactate dehydrogenase; NHL, non-Hodgkin lymphoma; RMS, rhabdomyosarcoma.

nonmalignant and self-remitting; with malignancies, the primary site will give a clue to likely tumor type (Fig. 21.2).

In Europe, the commonest presentation of high-grade B-cell NHL (BL or non-BL type) is an abdominal mass (30–45% of all NHL cases). There are two commonly recognized types. The first is the diffuse abdominal tumor with involvement throughout the omentum and mesentery, often including infiltration into the kidney, liver and spleen. With this type, bone marrow and CNS involvement is more common. Only a few cases present with jaw involvement, whereas in African BL this is almost universal. Abdominal involvement is also present in up to 50% of African patients presenting with jaw primaries. There is a lower incidence of bone marrow involvement in African compared with non-African BL.

The second type comprises localized tumors of the bowel wall, most commonly the terminal ileum (thought to arise in Peyer's patches), which can lead to intussusception or bleeding with or without perforation of the bowel. Patients most often present with a right iliac fossa mass and are sometimes thought to have appendicitis or an appendix mass. This type of presentation is much rarer than the rapidly growing diffuse abdominal form.

Mediastinal primary

Up to two-thirds of patients with precursor T-lymphoblastic NHL and 25–30% of all NHL present with mediastinal masses, with or without pleural effusions. Frequently, there are signs of superior vena cava obstruction, with dysphagia, dyspnea and pericardial effusion. Lymphadenopathy is usually confined to the neck and axillae. Abdominal node enlargement is uncommon. Hepatosplenomegaly is common and bone marrow and CNS infiltration may occur. Patients with mediastinal disease are at especially high risk of developing respiratory obstruction and/or distress if general anesthesia is instigated for investigations. Parenchymal lung disease is very rare except in ALCL.

Localized disease

Lymphoid swelling can occur anywhere but most commonly arises in the head and neck, including Waldeyer's ring and the facial bones (10–20%). Neck nodal tumors apparently have a lower risk of CNS spread. Some 5–10% of tumors arise in nodes or lymphoid tissue at other sites, including pharyngeal masses which are usually of B-cell origin. Rarer sites for primary tumors include bone, skin, thyroid, testis (usually lymphoblastic), orbit, eyelid, kidney (can mimic Wilms tumor) and epidural space. Bony NHL can be localized or more generalized, and is sometimes associated with hypercalcemia. Lymphoblastic lymphoma can present peripherally with skin and/or bone disease, and these tumors are usually of more mature T-cell phenotype. Subcutaneous lymphoma, often seen in very young children, is usually of precursor B-cell type. Skin involvement, either alone or combined with nodal disease, is a feature of ALCL.

CNS involvement

Primary CNS lymphomas are rare except after organ transplantation, but CNS involvement as secondary spread from disease elsewhere is quite common, particularly in lymphoblastic and advanced BL. It leads to headache, vomiting, papilledema, cranial nerve dysfunction and seizures. It is much more common at diagnosis if the bone marrow is also infiltrated, but is occasionally seen in patients with localized disease and those with large-cell histology.

Diagnostic investigations and staging

Following a full history and an extensive clinical examination, the aim of subsequent investigations is to confirm the diagnosis as accurately and as quickly as possible, and to determine the extent of disease so that appropriate therapy is started immediately. All patients should have a preliminary chest radiograph to exclude mediastinal mass and/or

Table 21.2 Characteristic features of main subgroups of non-Hodgkin lymphoma.

	B cell	Lymphoblastic	Anaplastic large cell
Primary site	Most frequently abdominal primary	Most frequently mediastinal but also nodal	Nodal ± skin
Histology	Burkitt (small noncleaved) centroblastic or B-cell immunoblastic	Lymphoblastic	Large cell
Cytomorphology	L3	L1/L2 characteristics (focal capped acid phosphatase positivity in T cell)	–
Immunomarkers	Cells display SIg ⁺ B-cell markers (CD19 ⁺ , CD22 ⁺ , CD24 ⁺), Tdt negative	CD1–CD8 T-cell markers (SIg [–] but occasionally Cylg ⁺) (CD10 ⁺ in precursor B)	CD30 ⁺
Cytogenetics	t(8;14), t(2;8), t(8;22)	Heterogeneous	t(2;5)

L1, L2, L3, French–American–British (FAB) classification; SIg, surface immunoglobulin; Cylg, cytoplasmic immunoglobulin; Tdt, terminal deoxynucleotidyl transferase.

pericardial/pleural effusions, and this should certainly be done prior to any anesthetic procedure.

Biopsy

Unless the diagnosis can be made from cytologic examination of tapped pleural fluid or bone marrow, biopsy is indicated in the presence of accessible localized disease and if there is peripheral lymphadenopathy associated with a mediastinal mass. If there is truly isolated mediastinal disease, material should be obtained by percutaneous needle or mediastinoscopy. For abdominal primaries, diagnosis should be attempted by cytologic examination of ascitic fluid or by percutaneous needle biopsy. Unless there is an acute abdominal emergency (e.g., gastrointestinal obstruction or intussusception) or the primary tumor is small and resectable, laparotomy should be avoided in order to prevent the common sequelae of prolonged ileus and even ruptured abdominal wounds. In extensive disease, the most accessible tumor deposits, not necessarily the primary, should be biopsied. All tumor material should be submitted for routine histology diagnosis, full immunophenotyping profile and cytogenetics. Table 21.2 shows the characteristic diagnostic features that help to distinguish subtypes of NHL.

Bone marrow studies

The marrow should be examined from at least two, and preferably four, sites (ideally from two aspirates and two trephines). The specimens should routinely be sent for cytogenetic analysis and immunophenotyping as well as standard cytomorphology.

Lumbar puncture

Provided there is no clinical evidence of raised intracranial pressure, cerebrospinal fluid should be examined. If there are signs of raised intracranial pressure, either computed

tomography (CT) or magnetic resonance imaging (MRI) should be carried out before lumbar puncture to exclude any focal deposit with consequent risk of brain shift.

Imaging

Abdominal ultrasonography is often the quickest way to define liver, spleen and kidney involvement and the extent of abdominal primaries and is adequate to stage advanced disease. It can also be carried out without sedation, whereas general anesthesia is frequently required in young children when using MRI or CT. These modalities can be reserved for confirmation of localized disease and definition if there is complete response after chemotherapy. In experienced hands ultrasound is very effective for guiding needle biopsies, especially of abdominal masses. Bone scans are only indicated if there is focal bone pain.

Blood tests

Initial investigation should include a full blood count, liver and renal function studies, serum lactate dehydrogenase (LDH) levels, and urate, calcium, phosphate and urea levels.

Staging

Table 21.3 shows the most commonly used staging system for childhood NHL. All primary mediastinal and diffuse abdominal tumors are considered to be at least stage III. Spread in NHL, unlike Hodgkin disease, is not orderly or contiguous from node to node. Therefore, there is no place for routine staging laparotomy or lymphangiography in childhood NHL.

Role of gallium and positron emission tomography

Both Ga-67 uptake and fluorodeoxyglucose (FDG) positron emission tomography (PET) are indicators of tumor viability.

Table 21.3 St Jude modified staging system for non-Hodgkin lymphoma.

Stage		Approximate percent seen in UK
I	Single tumor (extranodal) or single anatomic area (nodal). Not mediastinum or abdomen	5
II	Single tumor (extranodal) with regional node involvement. Primary gastrointestinal tumor with or without involvement of associated mesenteric nodes only On the same side of diaphragm: (i) two or more nodal areas; (ii) two single (extranodal) tumors with or without regional node involvement	20
III	On both sides of the diaphragm: (i) two single tumors (extranodal); (ii) two or more nodal areas All primary intrathoracic tumors (mediastinal, pleural, thymic), all extensive primary intraabdominal disease; all primary paraspinal or epidural tumors regardless of other sites	50
IV	Any of the above with initial CNS* or bone marrow involvement (<25%)†	25

* CNS disease: unequivocal blasts > 5/mm³ in a cytocentrifuged cerebrospinal fluid specimen with or without neurologic deficits, e.g., cranial nerve pulses plus intracerebral nodal deposits.

† Distinction is arbitrarily made at 25% to distinguish between acute lymphoid leukemia and non-Hodgkin lymphoma (NHL). This may not be useful for all, e.g., in B-cell NHL there is no difference in outcome between stage III and IV disease up to a marrow infiltration of 70%.

Specificity and sensitivity of Ga-67 are only around 75%¹⁷ but are higher with FDG-PET.¹⁸ Only rarely does Ga-67 imaging add to initial staging in a manner that would influence therapy, i.e., upstage the patient. No large prospective study in childhood NHL has evaluated either Ga-67 imaging or FDG-PET. In adult NHL, PET appears to be a useful tool in the assessment of response, and residual positivity may predict recurrence. No such studies have been done in children. At the present time, neither Ga-67 imaging nor PET are part of standard evaluation but may be of help in determining whether residual abnormalities require biopsy. In general it would be unwise to either upstage or introduce additional therapy on the basis of such scans alone.

Prognostic factors

Therapy

With modern aggressive intensive chemotherapy regimens, the overall cure rates are 70–75% for T-cell NHL, 80–85% for B-cell NHL (ranging from 100% for stage I and II disease to 60–70% for stage IV with CNS involvement), and 60% for anaplastic large-cell tumors. Each type requires very specific treatment (see below) and the most significant prognostic factor now appears to be the choice of the right therapy, based on meticulous initial work-up and definition of tumor type. There remains doubt as to the optimal therapy for ALCL and peripheral T-cell lymphoma and even more so for the rare low-grade follicular tumors. The speed of response may be significant, especially in T-cell NHL. In a UK T-cell NHL study, Shepherd *et al.*¹⁹ reported that for the 25% of patients in full radiologic remission at day 60, 5-year disease-free survival (DFS) was 84% compared with only 56% for patients who had some radiologic evidence of residual mediastinal thickening.

Stage

In general, the higher the stage, the worse the prognosis, although effective therapy is reducing the differential. In T-cell disease, very few relapses occur in stage I and II tumors, whereas 5-year DFS for stage III and stage IV tumors is expected to be 70% and 60% respectively.

In B-cell NHL, the figures are 95–100% for stage I and II tumors, and have greatly improved for stage III and IV tumors. The previously defined adverse prognostic features of extensive abdominal organ involvement, pleural effusions, extraabdominal disease, poor nutritional status and bulky disease no longer appear significant. The only remaining adverse clinical features in B-cell NHL are the presence of marrow infiltration of > 70% and CNS-positive disease, but even in the latter more aggressive treatment has increased survival to nearly 70% (see below). Elevated serum LDH levels in patients with stage III B-cell NHL remains an indicator of prognosis, but is of less significance with improved therapy.

Site

Patients with stage I disease with orbital or Waldeyer's ring tumors appear to fare worse than those with other localized nodal NHL, partly due to a higher CNS relapse rate. Stage II localized abdominal tumors have a better prognosis than a similarly staged nasopharyngeal tumor extending to the skull base.

Cytogenetics

Recent studies have suggested that in B-cell NHL, karyotype may be of prognostic significance.²⁰ In ALCL, a t(2;5)

translocation was originally thought to influence outcome, but with better methods of detection this is no longer apparent.

Treatment

General principles

Frequently, patients with lymphomas present with poor nutrition, concomitant infection and metabolic problems. Of the latter, spontaneous tumor lysis, especially in stage IV T- and B-cell disease, is the commonest.²¹ Hypercalcaemia has been described.²² The features of tumor lysis syndrome are hyperphosphatemia, hypocalcemia, hyperuricemia and azotemia. In order to avoid this complication, it is essential to provide high fluid intake (3 L/m² daily) to induce diuresis, with intravenous or oral allopurinol or urate oxidase. Policy varies regarding alkalinization of urine to keep urate and phosphate in solution (if used, it should only maintain urinary pH at about 6.5; above this level, phosphate will precipitate). With established tumor lysis syndrome, aluminum hydroxide or calcium carbonate to lower serum phosphate levels, and slow intravenous or intramuscular magnesium (intravenous calcium tends to be tissue deposited) to reverse any symptomatic tetany are usually adequate. Maintenance of adequate diuresis is essential, and if necessary furosemide may be required; although this drug raises serum urate levels, it prevents urate from being deposited within the renal tubules. However, lysis prior to therapy or signs of renal failure progression (rapidly rising urea, creatinine and, most significantly, sustained serum potassium levels > 6.5 mmol/L) warrants early instigation of dialysis to facilitate antilymphoma therapy, since the lysis will only really cease when tumor bulk has been reduced.

The use of urate oxidase revolutionized the management of tumor lysis syndrome and significantly reduced morbidity and the need for dialysis. Recombinant urate oxidase (rasburicase) has been shown to be more effective than allopurinol, although in the absence of bulk disease is probably not necessary.^{23–25}

Provided patients can be acutely supported using nasogastric feeding, malnutrition at diagnosis is not now considered an adverse prognostic feature in European and North American studies, although it may still adversely affect outcome in patients with extensive disease presenting in developing countries.

Surgery should generally be reserved for taking biopsies and repeat biopsies in the presence of residual masses after intensive therapy, and sometimes for the resection of residual tumor. Extensive initial surgery is strongly contraindicated, especially in mediastinal and extensive abdominal disease. Radiotherapy probably has a place in the local control of refractory disease, in primary CNS lymphoma and for tumors in unusual primary sites (e.g., bone). It is frequently used

although its value in the setting of intensive chemotherapy is unclear. CNS-positive B-cell NHL is now curable without irradiation.

Chemotherapeutic strategies

Wollner *et al.*²⁶ observed that lymphoblastic disease (T and precursor B) responded optimally to an intensive leukemia-type regimen (LSA2L2). In a key randomized trial, the Children's Cancer Study Group (CCSG) confirmed that LSA2L2 was better for lymphoblastic disease, whereas a shorter pulsed cyclophosphamide-based regimen (COMP; cyclophosphamide, vincristine, methotrexate, prednisolone) produced superior results in diffuse undifferentiated lymphoma (especially in extensive abdominal disease).^{27,28} The latter approach has been applied successfully in large B-cell lymphomas. In ALCL, the situation is less clear and no randomized trial has shown whether T-cell leukemia regimens are inferior to more aggressive B-cell protocols.

Localized NHL (stage I and II)

For low-stage peripheral B-cell NHL, both the CCSG and Pediatric Oncology Group have reported short-course therapy (approximately 6 months) using COMP or CHOP (cyclophosphamide, doxorubicin, vincristine, prednisolone) protocols to be extremely effective.^{29,30} For stage I and abdominal stage II disease, there is no need for CNS-directed therapy. All groups have attempted to reduce the risks of late cardiotoxicity by limiting or omitting anthracyclines, of infertility by omitting alkylators, or of oncogenesis by limiting exposure to anthracyclines and/or alkylators.^{31–35}

The Pediatric Oncology Group³⁰ reported inferior results for localized precursor B or T lymphoblastic disease, and thus all other collaborative groups have excluded such disease from short-course chemotherapy protocols and instead treated them with a longer duration leukemia-type regimen, as they would for more advanced disease

Advanced-stage B-cell lymphomas

Progressively more intensive protocols introduced in the early 1980s by the Société Française d'Oncologie Pédiatrique (SFOP) have achieved 60–70% cure rates for stage IV disease. Both the LMB and BFM (Berlin–Frankfurt–Münster) protocols use initial relatively low-dose cytoreductive therapy, in particular cyclophosphamide, vincristine and prednisolone (COP) before the more intensive induction regimen, which in the case of the LMB protocol consists of two courses of high-dose methotrexate, fractionated high-dose cyclophosphamide, vincristine, prednisolone and doxorubicin (COPAdM), followed by further high-dose methotrexate and continuous-infusion cytarabine. Since the first LMB study in 1981, event-free survival (EFS) has progressively increased, and therapy and duration reduced from 12 to 4–6 months

Table 21.4 Chemotherapy regimens in FAB LMB trial.

Group A (localized resected disease): COPAd × 2

Group B (stage II unresected, stage III, stage IV < 25% marrow, CNS negative)

Arm B1: COP, COPAdM, COPAdM, CYM × 2, COPAdM

Arm B2: COP, COPAdM, reduced-dose COPAdM, CYM × 2

Arm B3: COP, COPAdM, COPAdM, CYM × 2

Arm B4: COP, COPAdM, reduced-dose COPAdM, CYM × 2, COPAdM

Arm C: COP, COPAdM × 2, full-dose CYVE vs. reduced-dose CYVE + continuation

COP, low-dose cyclophosphamide, vincristine, prednisolone; COPAdM, cyclophosphamide, vincristine, prednisolone, doxorubicin, high-dose methotrexate; CYM, cytarabine, high-dose methotrexate; CYVE, high-dose cytarabine, etoposide; continuation, lower-dose COPAdM, CYM.

depending on risk stratification. Identified high-risk groups include those with bone marrow involvement of > 70% (essentially B-ALL) and those with CNS involvement at diagnosis, who now receive the most intensive regimen (i.e., 8 g/m² of systemic methotrexate per dose) along with triple intrathecal therapy and consolidation with continuous-infusion high-dose cytarabine and etoposide (CYVE). The LMB '89 protocol yielded an EFS of 87% in patients with B-ALL without CNS involvement and 81% in those with CNS disease at presentation, which contrasts with only 19% for such patients on the LMB '81 protocol. Inevitably, there is morbidity and some mortality associated with such intensive therapy.³⁶ A similar progressive improvement in EFS was seen in the BFM studies, especially for patients with stage IV disease and those with B-ALL (increase in EFS from 50 to 80%), and for stage III patients with raised LDH levels who seem to benefit from an increase in consolidation methotrexate dosage from 0.5 to 5 g/m² per dose.³³

The UKCCSG also adopted the short intensive course based on the French LMB '86 regimen for patients with stage IV disease and those with B-ALL.³⁷ At a median follow-up of 3.1 years, 68% of patients were alive in complete first remission. There was a relapse rate of 16% and a death rate due to toxicity of 11%, with five deaths from sepsis and two from sepsis with renal failure. CNS toxicity was also notable.³⁸ Subsequent experience with this regimen and the use of urate oxidase during induction has significantly reduced morbidity. Various other regimens have been reported but the precise duration and dose intensity required for cure remains unclear.^{39–47} The recent combined COG, UKCCSG and SFOP study (FAB LMB '96) addressed the issues of whether the total dose of cyclophosphamide given, duration of therapy or both can be reduced in standard-risk disease. For high-risk disease the high dose of cytarabine was reduced.⁴⁸ (Table 21.4)

Speed of response to initial therapy is of prognostic significance; for example, where there is no tumor reduction fol-

lowing the initial COP in the LMB protocol or there is failure to remit by 3 months, intensification of therapy is indicated. However, any residual mass should be biopsied or resected since many are fully necrotic. Relapses in advanced B-cell NHL tend to occur early, within the first 1–2 years after diagnosis, and relapses beyond 3 years appear quite rare.

Although intensive second-line treatment may be effective in relapse after localized disease where minimal chemotherapy has been used, in previously heavily treated patients the outcome is bleak.⁴⁹ There may be some longterm survivors where a high-dose regimen achieves complete response and is followed by myeloablative therapy.⁵⁰ There is some evidence of graft-versus-leukemia effect in NHL, supporting the use of allogeneic transplant.^{51,52} High-dose methylprednisolone may play a useful role in palliation of symptoms.⁵³

The role of antibody therapy is currently under evaluation both in combination with front-line chemotherapy and as antibody-guided radiation therapy in relapsed disease. Anti-CD20 (rituximab) has been reported to produce responses in relapsed disease.⁵⁴

Advanced-stage T-lymphoblastic NHL

Since the mid-1970s, T-cell and precursor B-cell lymphoblastic disease has been treated using sustained, progressively more intensive leukemia-type protocols; this approach was verified in the randomized CCSG trial, which demonstrated superiority of LSA2L2 over CHOP regimens.²⁷ The BFM group pioneered such therapy with induction, reinduction, four courses of high-dose methotrexate as CNS-directed therapy, plus cranial irradiation. The basic protocols have been proven by the test of time; systemic methotrexate dosages have been increased from 0.5 to 5 g/m² and the cranial irradiation dose reduced from 18 to 12 Gy. The BFM '86 study³³ reported an EFS of 79% (±5%) for 71 patients treated with a modified LSA2L2 protocol in which 10 pulses of 3 g/m² of methotrexate infused over 3 hours was used as CNS-directed therapy. EFS was 79% for those with stage III disease and 72% for those with stage IV disease.³⁴ CNS control was excellent. In the UK, a protocol identical to the Medical Research Council ALL protocol (UKALLX) has been used, consisting of a standard four-drug induction, early (week 5) and late (week 20) six-drug consolidation modules, cranial irradiation (18 Gy) plus six intrathecal methotrexate injections, plus 2 years of standard continuing therapy (including four weekly pulses of vincristine and prednisolone). The 4-year EFS for 95 patients with stage III and IV disease was 65% (±15%). Subsequently, in protocol 9004, cranial irradiation was been replaced by three pulses of high-dose methotrexate (6–8 g/m² depending on age), with ongoing intrathecal methotrexate every 3 months during the 2 years of treatment; in 1995, a third intensification module was introduced at week 35. No increase in CNS relapses was seen in a series of over 100 patients treated using this protocol.^{55,56}

Comparable results have been reported from most unselected series, with single-center studies reporting 5-year EFS of 70–75% and collaborative unselected series 65–70%, with little difference between patients with stage III and IV disease. The BFM '90 study reported a 90% 5-year EFS and this remains the benchmark protocol.⁵⁷ The addition of high-dose cytarabine to the BFM regimen was of no value in one randomized trial.⁵⁸

Failure to remit by day 60 with complete resolution of a mediastinal primary is an adverse prognostic sign.¹⁹ Instigation of more intensive therapy, including high-dose chemotherapy and autologous stem cell rescue, may be justified in the presence of such residual disease. In the BFM '90 strategy, if there was < 70% tumor regression at day 33 or residual viable tumor at the end of induction, an intensified high-risk ALL regimen was used. An early UKCCSG study suggested a useful role for localized mediastinal irradiation. Although incorporated into a modified pulsed LSA2L2-like protocol with overall worse results than now seen, this randomized study showed significantly improved results in patients who received 15-Gy irradiation to the mediastinum compared with those who did not.⁵⁹ In the presence of persistent mediastinal widening, the local use of irradiation may improve results from the rather stubbornly fixed level of 65–70% now seen.

It is important to remember that in lymphoblastic disease relapses continue to occur up to 5 years from diagnosis. Greater understanding of the cell biology involved in T-cell NHL and ALL may assist in the future application of novel strategies.

Anaplastic large-cell lymphoma

Since clinicians recognized this as an entity and improved immunohistochemical and cytogenetic techniques became available, its incidence has progressively risen. What defines the prognostic features is unclear, as is how to treat its variable forms. Indeed, it is not known whether it is a single entity or a group of disorders awaiting further classification. Rashes, which are common in this condition, may resolve spontaneously, whereas other patients progress rapidly to requiring aggressive chemotherapy.^{60,61} In view of these ambiguities, both sustained leukemia-type regimens, as employed for lymphoblastic disease, and B-cell lymphoma protocols have been utilized.^{62–68} Using the latter approach, an overall EFS of 76% at 5 years has been achieved.⁶³ Less good results have been reported by the UKCCSG using the LMB regimen (65% EFS at 5 years).⁶⁶

A collaborative retrospective European analysis has defined four prognostic groups, although one limitation is that it was based on a range of treatment protocols (Table 21.5). As the results with BFM B-NHL regimens have been the best reported, this provides the backbone of the current European trial ALCL '97. Treatment is based on the new risk grouping

Table 21.5 Risk groups in anaplastic large cell lymphoma.

<i>Low risk</i>
Localized disease, completely resected
<i>Standard risk</i>
No skin involvement
No mediastinal involvement
No liver, spleen or lung involvement
<i>High risk</i>
Presence of biopsy-proven skin lesions (except skin overlying an involved or isolated skin disease)
Presence of mediastinal involvement
Presence of liver, spleen or lung involvement
<i>Patients with CNS involvement</i>

and the study asks questions about the schedule of high-dose methotrexate and the value of continuation therapy with single-agent vinblastine. There remains controversy about the need for such aggressive therapy being given for the disease. Results with simpler COMP-based regimens appear encouraging but there are difficulties in comparing regimens due to differences in pathologic classification and the combining of disease types.

Relapsed ALCL is unusual in that prolonged remissions may be achieved with weekly vinblastine regimens, either alone or in combination.⁶⁹ High-dose therapy with autologous or allogeneic rescue has been used but its value remains unproven.

ALCL is the third largest subgroup of childhood NHL and more needs to be learned about how to stage and treat it successfully. Resources need to be pooled internationally so that the group of patients requiring more, or less, intensive approaches can be identified.

Large B-cell lymphoma

It is important that all large-cell lymphomas are not grouped together, as ALCL and large B-cell NHL are clearly distinct entities.^{67,68} The tumor is generally treated with the same approach as for BL and to date results appear to be very similar. Current studies are attempting to define distinct clinical and pathologic features.⁷⁰

Peripheral T-cell lymphoma

There are a small number of CD30-negative patients with peripheral T-cell lymphoma for whom the optimal therapy is not known.^{71,72} It is probably logical to treat them in the same way as for ALCL, although T-ALL regimens have been used.

Primary mediastinal B-cell NHL

This is mostly seen in adolescents and young adults, where it mimics T-cell NHL. Bone marrow and CNS involvement are

rare.^{73–75} Recommended treatment is as the same as for stage III B-cell NHL. The possibility that a mediastinal lymphoma may be of B-cell rather than T-cell origin, and so may not respond to standard lymphoblastic therapy, emphasizes the need in all childhood NHLs for full pathologic confirmation plus immunophenotyping of diagnostic material.

Follicular lymphomas

These are extremely rare in childhood and are usually stage I/II.⁷⁶ Localized disease should be treated conservatively as dissemination is very rare.^{77,78} With advanced disease, CHOP regimens are effective in adults, although long-term outcome is poor.

NHL following intense immunosuppression

Over the last decade an increasing incidence of lymphoproliferative disorders has been seen in organ-transplant recipients (especially in those receiving multiple immunosuppressant drugs such as ciclosporin, FK506 or mycophenolate) and in others receiving intense immunosuppression, including patients with a diverse range of diseases (e.g., chronic inflammatory bowel disease). Although many are polyclonal, EBV-driven proliferations that recede with withdrawal of the immunosuppression, others behave more aggressively or become true malignant lymphomas. Almost all appear to be B-cell disorders, although a range of pathologies is seen. These can be divided into polymorphous (usually polyclonal, EBV-driven, good prognosis) and monomorphous (variable clonality, less clear EBV association, poorer outcome). In contrast to BL, the EBV expression patterns in these proliferations consist of a mixture of cells, with latency type 1, latency type 2 or cells expressing lytic genes.⁷⁹

In the UK a graded therapeutic response is recommended, starting wherever possible with withdrawal or drastic reduction of the immunosuppressives followed, if there is no early response, by weekly pulses of low-dose cyclophosphamide, vincristine and prednisolone (Fig. 21.3).⁸⁰ If COP therapy does not produce resolution, then standard intensive B-cell NHL therapy is initiated. Alternative strategies have been proposed, including the use of anti-B-cell monoclonal antibodies such as rituximab^{81,82} and *in vitro* production of cytotoxic T lymphocytes against EBV-infected cells.^{83,84}

Indications for high-dose chemotherapy with stem cell support

There are now few indications for high-dose therapy in childhood NHL. Dose intensification appears to be of value where only partial remission is achieved after induction therapy in B-cell NHL. Dose escalation with CYVE may be sufficient where complete response is not achieved with surgery.⁸⁵ Regimens such as BEAM BCNU, etoposide, cytarabine,

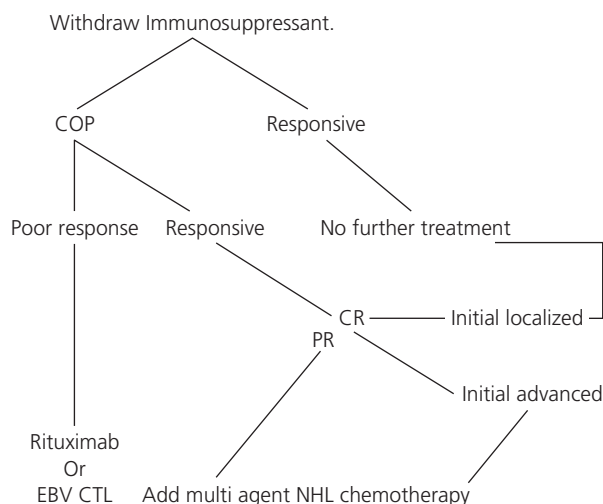

Fig. 21.3 Treatment strategy in posttransplant lymphoproliferative disorders. COP, cyclophosphamide, vincristine, prednisolone; EBV CTL, Epstein-Barr virus-specific cytotoxic T lymphocytes; CR, complete response; PR, < 50% response.

melphalan with autograft have been recommended. Relapse after localized B-cell NHL may be curable with the full LMB regimen C.

Relapse of either B- or T-cell NHL is an indication to consider allogeneic transplantation. In adults there are also suggestions of a graft-versus-lymphoma effect. The management of relapsed T-cell NHL is essentially the same as for relapsed T-ALL.

Future approaches

The evolution of humanized monoclonal antibodies and the demonstration of significant benefit using rituximab in low- and high-grade NHL in adults has encouraged their use in childhood peripheral B-cell NHL.^{86,87} Current trials are evaluating both rituximab and radiolabeled anti-CD20 in relapsed and front-line regimens. Rituximab not only has a direct antitumor effect but may also chemosensitize by downregulation of BCL2. Evidence of activity in childhood NHL is limited to case reports and series of PTLPD post transplant lymphoproliferative disorders. Current trials are attempting to clarify whether rituximab should be used as part of induction or subsequent therapy. Radio-labeled anti-CD20 is also under evaluation after encouraging phase 2 studies in adults. Antisense oligonucleotide therapy has been proposed and tested in adult tumors.⁸⁸

Hodgkin disease

It is now widely accepted that Hodgkin disease (HD) is a malignancy of uncertain cellular origin. The mononuclear HD cell and the polynucleated Reed-Sternberg cell represent

the malignant cells and are derived from immature lymphoid elements. Evidence suggests that there is an EBV association in some, if not all, childhood HD.

Epidemiology

Age-standardized incidence rates for children (0–15 years) vary considerably around the world, from 0.6 per million in Japan to 10.3 per million in the Middle East, with European rates ranging from 3.3 per million (Sweden) to 6.9 per million (Italy). The UK rate is 4.1 per million.^{89,90} In western industrialized countries, incidence increases with age, whereas in developing countries an earlier onset (even peaking in the first decade) is seen, as well as a much higher relative proportion of mixed cellularity cases. Incidence appears to be lower in colder latitudes where nodular sclerosis is more frequent. Genetic factors may be relevant: for example, UK children of South Asian origin have a higher incidence of early-onset mixed cellularity disease compared with those of north European Caucasian origin. In the USA there is a higher rate for black children under 10 years but for white children during adolescence. Lymphocyte predominance is more common in black than white children in North America. In northern Europe there is a bimodal pattern, with a peak at 15–30 years of age of predominantly nodular sclerotic type and a second at 45–55 years with mixed cellularity and other subtypes predominating. Boys predominate in the first decade (ratio 10 : 1) but by adolescence there is no sex difference.

Etiology

Case clusters, patterns of seasonal variation and an increased risk of developing HD in early life for children living in poor socioeconomic circumstances and among large sibships has long raised the suggestion that HD is of infectious etiology.^{91–93} The bimodal peak seen in northern Europe and North America strongly resembles the epidemiology of, for example, poliovirus. The identification of EBV inclusions, especially in the early-onset mixed cellularity subtype and in cases from developing countries, has fueled speculation of a causative relationship, at least in some circumstances.^{94,95} Rather like BL, other antigens and cofactors may be involved, but for at least some cases the response to such viral infection, including genetic rearrangements and initiation of inflammatory and cytokine responses, could explain the mixed pathologic pattern. There have been occasional reports of familial clusters,⁹⁶ as well as association with immunodeficiency disorders, suggesting genetic factors may be relevant for some children at least.

Cell biology and pathology

The principal malignant cell is considered to be the Reed–Sternberg (RS) cell, a large multinucleated giant cell with

Table 21.6 Rye histopathologic classification of Hodgkin disease.*

Lymphocyte predominance (7–14%)
Nodular sclerosis (17–68%)
Mixed cellularity (17–68%)
Lymphocyte depletion (0.5–20%)

* Percentages represent ranges of relative incidence reported by different pathologists in childhood series.

inclusion-like nucleoli surrounded by a clear halo. The mononuclear cells and the lacunar RS cell seen especially in the nodular sclerosing subtype are also considered to be malignant cells. However, the mere presence of these cells is not diagnostic, since on occasion they can be found in a variety of other conditions, including infectious mononucleosis and graft-versus-host disease. “Malignant” cells in the midst of a reactive collection of lymphocytes, histiocytes, plasma cells, eosinophils and fibroblasts is the characteristic pattern of HD. The cellular origin of the atypical cells in HD has been a topic of controversy for many years. Results of clonality and gene rearrangement studies on involved cells have produced conflicting results. However, it seems probable that RS cells are clonal and of B-cell origin. The absence of B-cell antigen expression may reflect defective immunoglobulin transcription.⁹⁷

Table 21.6 shows the Rye histopathologic classification scheme in universal use for HD.⁹⁸ The categories are determined by the relative proportions of RS cells, lymphocytes, sclerosis and fibrosis. There is variability in reported series of different proportions of subtypes, but mixed cellularity is seen much more commonly in younger patients and in those from developing countries.^{94,99} Lymphocyte depletion is rare in the UK and northern European children, while nodular sclerosis and mixed cellularity are seen in roughly equal proportions. Nonrandom cytogenetic changes have been reported (involving chromosomes 1, 2, 7, 11, 14, 15 and 21) as well as the presence of a t(2;5) translocation in occasional cases. Whether these represent true HD or denote ALCL remains unclear.¹⁰⁰

There does appear to be some correlation between patterns of presentation and histopathology. Mixed cellularity and lymphocyte-depleted forms usually present with more disseminated disease, nodular sclerosis classically with mediastinal disease in adolescents, and lymphocyte-predominant disease with focal nodal disease (characteristically in the neck or groin). Recurrence at distant sites is more common in mixed cellularity disease treated with local irradiation as sole therapy.¹⁰¹ The lymphocyte-predominant nodular variety is probably best regarded as a separate entity (i.e., a variant of B-cell lymphoma) due to its unique behavior.¹⁰²

Clinical presentation

The commonest presentation is painless cervical lymphadenopathy with or without a mediastinal mass. The cervical

nodes quite characteristically fluctuate in size, often over a considerable time, giving long latent periods between first symptom/sign and diagnosis. The presence of "B symptoms" confers a less favorable prognosis, and are seen with increasing frequency in more advanced-stage disease. These symptoms comprise fever, night sweats and loss of 10% or more of body weight over the preceding 6 months, without another clear-cut explanation. Isolated disease of the spleen, liver and lung pose particular diagnostic difficulties.

Diagnostic investigations and staging

Biopsy

Adequate biopsy from the most accessible, preferably primary, tumor mass is essential. Open rather than needle biopsies are optimal, since reactive surrounding lymphadenopathy can lead to false negativity in HD and the full pattern of cellularity within the tumor needs to be reviewed in order to classify the patient properly. Careful clinical examination to detect nodal disease and organomegaly is essential as distant nodal involvement will alter the stage of disease and therefore determine therapy. Confirmation of disease extent by appropriate imaging and/or biopsy is mandatory.

Imaging

The mere size of nodes especially in the neck is no guarantee of involvement. Mediastinal disease, which is usually clinically silent, is seen in about 60% of children (proportion rises with age) and should be evaluated using posterior/anterior and lateral radiography. CT of the chest is essential to identify nodal, pleural and pulmonary disease, and will identify nodal and pulmonary deposits not seen with conventional radiography. MRI is being employed increasingly to visualize abdominal organs and nodal disease, but the gold standard imaging for HD at diagnosis remains plain chest radiography and CT of chest and abdomen. Ultrasound can be used to monitor nodal, hepatic and splenic shrinkage with therapy. Lymphangiography, a technically difficult procedure and at one time the mainstay of abdominal node detection, is now very rarely performed. Lymphangiography does enable both size and architecture of nodes to be examined but CT or MRI are as efficient as lymphangiography and much less invasive. Lymphangiography may occasionally be of value where CT/MRI are equivocal and if therapy depends on precise definition of abdominal disease. Gallium imaging, and more recently FDG-PET, have been used both to identify initial disease extent and, more importantly, to try to define disease activity at the end of treatment.¹⁰³ Abnormalities may persist on CT/MRI but subsequent clinical behavior shows that this is inactive "scarring". Residual gallium positivity, especially in the mediastinum, is highly suggestive of disease. FDG-PET is the most accurate method of defining

residual disease¹⁰³ but like gallium imaging is not free of false-positive or false-negative results. If the treatment strategy involves omission of radiation therapy on the basis of complete response after chemotherapy, then PET may be useful to decide whether to biopsy residual CT/MRI abnormalities. Current paediatric studies should clarify if PET positivity alone is an indication for radiotherapy or to determine the dose administered.

Laparotomy

There is now little or no indication for primary staging laparotomy in children. Once the only truly reliable method of determining subdiaphragmatic disease and hence in formulating appropriate therapy options, especially radiation fields, it is a procedure associated with morbidity (intestinal obstruction) and even mortality (especially the lifelong risk of septic death after splenectomy). Preoperative vaccination with pneumococcal and *Haemophilus influenzae* vaccines plus lifelong prophylactic oral penicillin are essential. Death can occur up to 20 years after splenectomy from a wide range of infective agents, not just the pneumococcus. The use of combined modality therapy or chemotherapy alone for the majority of patients obviates the need for such primary staging laparotomy, especially as CT or MRI and imaging-guided biopsies can be performed if abdominal organ involvement is in doubt. With modern intensive therapy, isolated liver, spleen or other organ relapses are rare.

Bone marrow studies

Bone marrow aspirates (×2) and trephines (×2) should be performed in all patients except those with stage IA disease. Although bone marrow disease is much more common in advanced disease, an occasional patient with apparently localized disease is found to have marrow infiltration and failure to treat this appropriately leads to early recurrence. Those with B symptoms, an altered blood picture, or the rare bony disease are at higher risk of bone marrow infiltration.

Blood tests

Once the diagnosis is confirmed, useful laboratory investigations include a full blood count, erythrocyte sedimentation rate (ESR), viral titers for EBV, cytomegalovirus, measles, chickenpox and rubella status, and biochemical assessment of renal and liver function. Markers that have been reported to be useful include IL-2 receptor, soluble CD30 antigen and IL-10 levels.^{104–106} However, routine use of any of these is not yet recommended. A number of risk grouping have been devised based on outcome analysis in individual studies (Table 21.7). It is important to emphasize that these relate to the specific treatment strategy applied, which may differ widely with regard to intensity of chemotherapy and irradiation.

Table 21.7 Examples of risk groupings based on multiple clinical parameters.

<i>Stanford</i> ¹⁰⁵
Poor risk = three factors, event-free survival < 70%
Male
Stage IIB, IIIB, IV
Bulky mediastinum
White cell count > 13.5
Hemoglobin < 11.0 g/dL
<i>SFOP</i> ¹¹¹
Poor risk score = 3, event-free survival < 65%
Score 1: hemoglobin < 10.5 g/dL
Score 2: two or more of following:
Erythrocyte sedimentation rate > 40 mm/hr
White cell count > 12 × 10 ⁹ /L
Fibrinogen > 5 g/L
α ₂ -Globulin > 10 g/L
Albumin < 35 g/L
Score 2: nodular sclerosis

Staging

Table 21.8 shows the Ann Arbor staging scheme employed universally in HD. In most reported series low-stage disease (I and II) accounts for 50–70% of cases, while stage IV is seen in < 10% of childhood patients, and stage III in 20–40%. The variation in percentages reported in different series depends on the methods used in staging, and the rigor of clinical and imaging procedures employed.

Prognostic features

Bulky disease and poor response to initial chemotherapy remain key factors. Advanced stage in the presence of B symptoms confers adverse prognostic significance.¹⁰⁷ Pathologic subtype used to be more significant in predicting relapse but with modern aggressive therapy is less so, although patients with the rare lymphocyte-depleted form do fare worse than all other types. Lukes and Butler originally described two forms of lymphocyte-predominant type, a diffuse and a nodular form. The latter is a very slowly progressive disease

that may with time evolve into a more aggressive high-grade B-cell NHL.¹⁰⁸

Lymphopenia is a sign of advanced disease and is consequently a less favorable feature. Neutrophilia and eosinophilia are not thought to be of prognostic significance. An elevated ESR predicts more advanced-stage disease and if found in stage I disease, unless in the presence of clearly defined and confirmed infection, should lead to a much more extensive search for occult disease. Patients with B symptoms usually have a markedly elevated ESR.

Treatment

Since Kaplan’s report in 1970 of the effectiveness of 40–44 Gy in curing HD, a number of controversies have dogged the management of childhood disease.

- If irradiation is to be used, how large should the field be and what is the optimal dosage and scheduling?
- Is chemotherapy as effective as irradiation?
- Which group of patients requires combined modality therapy?
- Which combination of drugs is both efficacious and least likely to cause long-term toxicity, either alone or in combination with radiation?
- How is high-risk disease defined and treated?

In deciding treatment strategies, therapeutic groups have tried to balance the beneficial and adverse effects of each treatment modality and of individual drug toxicities.

Neck, mantle and total nodal irradiation may produce compensated or full-blown hypothyroidism, risk of thyroid malignancy, soft tissue thinning, chest and spinal deformities (short clavicles and high spinal kyphosis), and impaired spinal growth. This will depend on total dose, fraction size, field and patient’s age (the younger the patient, the more likely that tissue damage will be long term). Reactive pleural and pericardial effusions, long-term fibrosis and even restrictive pericarditis have been described, as has an increased risk of coronary artery disease. Chronic radiation enteritis and retroperitoneal fibrosis are reported following abdominal radiation in HD.

Chemotherapy regimens such as MOPP (mustine, vincristine, prednisolone, procarbazine) or ABVD (Adriamycin,

Table 21.8 Ann Arbor staging system for Hodgkin disease.

Stage I	Involvement of one lymph node region (I) or a single extralymphatic organ or site (IE)
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or solitary involvement of an extralymphatic organ or site and of one or more lymph node regions on the same side of the diaphragm (IIE)
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III) which may be accompanied by localized involvement of extralymphatic organ or site (IIIE) or by involvement of the spleen (IIIS) or both of these (IIISE)
Stage IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues with or without associated lymph node enlargement

bleomycin, vinblastine, dacarbazine) are highly effective but also carry specific hazards. Azoospermia is to be expected following the dose of alkylators (mustine, procarbazine, chlorambucil or cyclophosphamide) that are generally given to cure HD. Whether there is a safe alkylator dosage is unclear. MOPP and other derivative regimens appear to have less impact on female fertility, especially in young girls, but loss of follicles may be associated with subsequent premature menopause. The ABVD regimen has much less impact on the gonads, but greater impact on pulmonary and cardiac function. The risks are compounded by the use of radiotherapy to the mediastinal region. Chemotherapy-induced second-tumor induction is a major worry in this disease where long-term survival is over 80%. This risk appears to be lower in the UKCCSG series where chlorambucil replaced mustine (ChlVPP) and most patients did not receive radiotherapy. Although ABVD was previously reported to be at low risk of inducing such tumors, anthracyclines are increasingly implicated in the causation of leukemia. Consequently, in planning any therapeutic strategy these effects and benefits must be weighed carefully. Hybrid regimens are designed to reduce the total dose of any single agent, thus reducing the incidence of infertility or cardiac problems associated with MOPP or ABVD alone.

Radiation therapy has played a major role in curative treatment of HD. With the advent of effective chemotherapy the role of radiation therapy, either combined with chemotherapy or on its own, has been reviewed and is the subject of a number of randomized trials. The dose of radiation and the field to which radiation is administered have been progressively reduced with no adverse influence on efficacies. Extended field radiation is now rarely used and total dose has been reduced to 20–30 Gy. Radiotherapy alone has been used by the UKCCSG for stage IA high cervical disease in order to avoid the effects of chemotherapy.¹⁰⁹

In the HD2 II series, children with stage IA disease received involved field radiation therapy at a dose of 35 Gy as sole therapy.¹⁰¹ Progression-free survival was 70%, i.e., there was a high local relapse rate. Patients with mixed cellularity disease appeared to do particularly poorly, with a

progression-free survival of only 48%, although the salvage rate was very high with subsequent chemotherapy. Current practice in the UK group is that all but mixed cellularity cases still receive limited radiation therapy although an exception may be the younger child (i.e., <5 years of age) in whom the late sequelae of radiation therapy may be more marked, and in this situation the option of chemotherapy alone may be discussed with the family. In a small study using VEEP (vincristine, etoposide, epirubicin and prednisolone) as sole therapy, there was a comparatively high initial failure or relapse rate and it was concluded that this approach was not suitable particularly in patients with more advanced disease.¹¹⁰

An alternative strategy to reduce the extent of radiation is that followed by the French SFOP group, where risk stratification is based on the initial response to a nonalkylating combination of vinblastine, bleomycin and etoposide. In those patients who have a rapid response to this low-intensity treatment, radiation therapy dose is reduced.¹¹¹ This strategy is now increasingly applied (Tables 21.9 and 21.10).^{112–115}

Where alkylating agent-based chemotherapy is combined with radiation, attempts have been made to reduce the total number of cycles of MOPP or the hybrid regimen MOPP/ABVD. Follow-up of these shorter regimens is insufficient to be clear about the precise risk of infertility or cardiac dysfunction but it is likely that these are significantly lower than with previous protocols. In the UKCCSG HD1 study, patients with all stages of disease apart from stage IA received ChlVPP chemotherapy, radiation therapy being confined to those with bulky mediastinal disease (where it exceeded one-third of maximal transthoracic diameter). Using this approach the 10-year progression-free survival (and overall survival) was 85% (92%) for stage II, 73% (84%) for stage III, and 38% (71%) for stage IV. In the subsequent HD2 study, radiation therapy was omitted completely unless there was biopsy-proven residual disease following chemotherapy alone. This did not adversely affect the outcome of patients with stage II and III disease. The ChlVPP protocol appears to be associated with a lower incidence of second tumors than MOPP, with an overall risk of 3.4% at 10 years, of which 2.7% are leukemia/NHL and 0.7% solid tumor. The low risk of late second solid

Table 21.9 Examples of regimens designed to reduce late sequelae by the omission of radiotherapy.

tumors almost certainly reflects the omission of radiation therapy for the majority of patients. A randomized Pediatric Oncology Group study has demonstrated that after delivery of eight cycles of MOPP/ABVD, the addition of radiotherapy has no beneficial effect. Other studies where chemotherapy alone or reduced radiation strategies have been applied are shown in Tables 21.9 and 21.10.^{116–120}

Patients with stage IV disease continue to have relatively high relapse rates, although subgroups such as those with only pulmonary involvement do better.^{121,122} The best published data come from the BFM group. Using the same intensive approach with OPPA/COPP and extensive radiation therapy administered to all sites of disease,¹¹⁶ the SFOP group has replicated the encouraging outcome although late sequelae are inevitable. The comparatively high salvage rate in the

UKCCSG series has led this group to persist with the current strategy of ChlVPP alone, with dose intensification, including in some cases high-dose melphalan, in the event of a poor response (Table 21.11).

Relapsed disease

The management of relapsed HD depends on the initial extent of the disease, the nature of chemotherapy, prior use of radiation therapy and time of relapse.^{123,124} In the case of early-relapse high-stage disease previously treated with multimodal therapy, the outcome with second-line chemotherapy alone is poor. This is in contrast to a late relapse of localized disease treated with low-dose therapy or single-modality strategies. In the former group the use of very high-

dose therapy requiring stem cell rescue has been explored but not tested in a randomized study. In single-center or national series the benefit remains unproven.^{125–127}

Summary

- *Stage IA*: patients appear to be highly curable with involved field irradiation only (dosages 30–35 Gy) (although some will require salvage chemotherapy) but will develop hypothyroidism and some soft tissue thinning of the neck. Chemotherapy with or without low-dose involved field radiotherapy can be equally effective, but the number of cycles needed for cure is unclear, and exposure to alkylators and anthracyclines should be restricted.
- *Stages II and IIIA*: both short-course hybrid chemotherapy (three cycles of MOPP or ChlVPP/AVBD or VEBP) with involved field irradiation (20 Gy), and chemotherapy alone (six cycles of therapy) can be curative. However, without irradiation more chemotherapy appears to be required (i.e., six rather than three cycles) and there is probably an increased risk of sterility with therapy including alkylators, or cardiopulmonary dysfunction for that including anthracyclines and/or bleomycin. The long-term safety of the short course of chemotherapy with involved field irradiation has not been fully evaluated. The strategy of response-adapted therapy has now been adopted by groups including the COG and seems the most logical way to minimize treatment for those who do not need aggressive therapy while maintaining high cure rates in those who do. A philosophy of accepting high relapse rates on the assumption that salvage rates are high is accompanied by a high overall burden of therapy and later sequelae. This approach is unacceptable unless the initial treatment is minimal.
- *Advanced stage IIIB and IV*: hybrid chemotherapy and radiotherapy to involved sites appears to be most efficacious, but the total duration of therapy required is not clear.

Long-term sequelae of lymphoma therapy

Table 21.12 shows some of the potential sequelae of lymphoma therapy. These risks must be taken into consideration

Table 21.12 Potential long-term sequelae in children treated for lymphoma.

Secondary neoplasia
Growth impairment
Endocrine dysfunction
Infertility
Educational and psychologic dysfunction
Other organ toxicity, e.g., cardiac with anthracyclines, pulmonary with bleomycin
Problems with obtaining jobs and insurance, and acceptance as adopters

for both childhood NHL and HD because of the high overall cure rates now possible.

Second tumors

Hawkins *et al.*¹²⁸ reported a 1.4% rate of leukemias in patients treated for NHL within the first 6 years from diagnosis compared with 0.5% for all other tumors. This increased risk appears to be associated with a specific era of treatment, when high doses of epipodophyllotoxins were used in schedules that did not allow for adequate DNA repair and which allowed total doses in excess of 1.2 g/m². These second leukemias characteristically have a short latency and are associated with chromosomal translocations involving 11q23 (*MLL* gene). It is also important to note that the anthracyclines included in many lymphoma protocols are also inhibitors of topoisomerase II and are linked with therapeutically induced acute leukemia. The leukemia risk is reduced by the omission of mechlorethamine from combination regimens.¹²⁹

Irradiation to the thyroid, especially if compensated hypothyroidism is not treated early, is associated with an increased risk of thyroid cancer.¹³⁰ The Late Effects Study Group in a follow-up study of 1380 childhood HD survivors reported an 18-fold overall increase in tumors, principally leukemias, but also a remarkable 75-fold increased risk of young women developing breast cancer at 20 years from diagnosis (17 cases compared with an expected 0.2 cases).¹³¹ With extended follow-up of this cohort treated between 1955 and 1986, the cumulative incidence of any malignancy was 26% at 30 years. The standardized incidence ratios for breast and thyroid cancer were 56% and 36%, respectively. A significance increase in bone, colorectal, lung and gastric cancers were also documented.¹³² In a recent study from Boston, the standardized incidence rates in over 6000 women diagnosed between 1970 and 1986 was 25%. Age of diagnosis was not an independent risk factor.¹³³

It has been suggested that DNA repair mechanism polymorphisms (e.g., XRCCI and GSTTI) may be associated with risk of second cancers.¹³⁴

Growth impairment

Although now rarely used, CNS-directed radiotherapy will cause the well-documented risk of induced growth hormone insufficiency.¹³⁵ Age at treatment and total plus fraction dose of radiation determine the extent of impairment. Modern protocols that omit irradiation probably avoid the risk, although high-dose intensity chemotherapy may have some direct effect on bone growth,¹³⁶ although not as great as that from irradiation of the hypothalamic-pituitary axis.

Endocrine dysfunction

Irradiation to the neck even at very low dosages (0.1 Gy) can

induce thyroid dysfunction, initially with a rise in thyroid-stimulating hormone and only subsequently a fall in thyroxine.¹³⁷ Replacement therapy is almost universally required in HD patients treated with bilateral neck or mantle fields. Although many drugs used for lymphomas, especially alkylating agents, are gonadotoxic and usually disproportionately affect fertility in boys, they are not steroidogenic (secondary sexual characteristics and potency are preserved). There is much less direct effect of chemotherapy on ovarian function, although follicle numbers may be reduced (inducing premature menopause). Conversely, irradiation, especially total nodal irradiation, has a major effect on ovarian function with a requirement for lifelong hormonal replacement.¹³⁸

Fertility

Male long-term survivors exposed to alkylating agents have a very low fertility rate, whereas females do not appear to be as severely affected, but abdominal irradiation affects fertility in both sexes,¹³⁹ depending on the dose received by the gonads. Risk of male infertility is low in the absence of alkylators.¹⁴⁰ As mentioned above, premature menopause is a significant risk for adolescent lymphoma survivors and is associated with exposure to alkylating agents (nine times the risk) and/or abdominal irradiation (four times the risk), even in the third decade of life.¹⁴¹ The prospects for any specific pregnancy are good provided extensive irradiation involving the pelvis (specifically uterine vasculature) has not been required. In the postpubertal male, it is important that sperm cryopreservation is discussed and performed prior to chemotherapy. Recently a number of centers have considered more novel and often experimental approaches such as testicular aspiration and ovarian slice cryopreservation. It seems likely that such techniques will become more widely used as data on effectiveness emerges.¹⁴²

Educational and psychologic functioning

The well-documented impact of cranial irradiation (in dosages of 18–24 Gy) on neuropsychologic functioning includes impairment of attention span and cognitive processing skills. Verbal IQ is frequently well preserved. Age at treatment, and possibly gender, influence the degree of impairment. The adverse impact of high-dose methotrexate remains to be clearly defined.

Apart from the physical effects of CNS-directed therapy, patients who do not adjust well to the diagnosis, its treatment and survival may have long-term schooling problems (especially attendance) and overall coping problems.

Organ dysfunction

The increasing risk of acute cardiac toxicity with increasing doses of anthracyclines is well recognized, but what is still

far from clear is the true long-term risk of more moderate dose exposure. Lipshultz *et al.*¹⁴³ have shown abnormalities in patients with acute leukemia after only small doses of doxorubicin. Given that survival rates for lymphomas are high, it seems prudent to:

- limit total dose of anthracyclines wherever possible;
- avoid bolus administration of anthracyclines, although it appears that for a truly protective effect infusion times in excess of 72–96 hours are required;
- consider the use of cardioprotective agents such as dexrazoxane, which has been shown to give a significantly reduced incidence of subclinical cardiotoxicity in patients receiving anthracyclines.^{144,145}

Chest and mediastinal irradiation compounds the cardiotoxicity risk of anthracyclines. Even without chemotherapy, mediastinal irradiation has been reported to be associated with an increased early mortality risk from myocardial infarction (30 times the rate for the general population) among HD survivors¹⁴⁶ and with a high incidence of cardiovascular problems.¹⁴⁷ These risks appear to be reduced if the total irradiation dose is lowered, and combined modality therapy not involving anthracyclines is used with limited involved field irradiation.

Chest or spinal irradiation in childhood may restrict the growth of the chest wall and lungs, and subsequently progressive fibrosis may develop. For lymphomas, a much greater risk is associated with the use of bleomycin, particularly for HD. Acute toxicity is associated with high single doses, cumulative dose and exposure to high levels of oxygen.¹⁴⁸ The chronic toxicity of bleomycin is under further investigation as is the impact of other chemotherapies.¹⁴⁹

Soft tissue hypoplasia and bony damage from high-dose local irradiation has been mentioned in the context of early HD therapy, and is another reason for the reduction, wherever possible, of total dosages used.

Future prospects

Further improvements in cure rate while minimizing lapse sequences will come from a range of strategies.

- Better use of existing drugs based on pharmacogenetics and dose individualization.^{150,151}
- Better understanding of molecular phenotyping and its significance in tumor behavior.¹⁵²
- Improved risk stratification based on response using novel imaging and minimal residual disease quantitation.^{7,103,153}
- Novel molecular therapies directed toward tumor-specific targets.^{88,154}

Inherited and congenital thrombocytopenia

Owen P. Smith

Introduction

The normal range of the platelet count in fetal life is similar to that seen in adulthood, being about $150\text{--}400 \times 10^9/\text{L}$. Neonatal thrombocytopenia, defined as a platelet count of $< 150 \times 10^9/\text{L}$ is common, with a reported frequency of approximately 0.9% in unselected newborns and 40% in infants in intensive care units.¹ The differential diagnosis of thrombocytopenia in the neonatal period is similar to thrombocytopenia in older children, with a number of exceptions including the inherited thrombocytopenias and those that arise due to pathophysiologic events unique to the antenatal and perinatal periods. It is important to remember to confirm that the low platelet count is genuine by careful inspection of the blood sample and smear before initiating further investigations. Once established, the approach to the diagnosis of the thrombocytopenia should be tailored to the individual infant and mother. For example, assessment of the child's general well-being is very important as healthy neonates usually have an immune or an inherited etiology, whereas the presence of lymphadenopathy, hepatosplenomegaly, mass lesions, hemangiomas, bruits and congenital anomalies point toward a totally different spectrum of causes. It should also be emphasized that obtaining a detailed maternal history, including bleeding problems, preeclampsia and drug ingestion in the present and any previous pregnancies, and history of viral infections (cytomegalovirus, rubella, herpes simplex and HIV) or connective tissue disease (systemic lupus erythematosus), will save time and unnecessary investigation.

In this chapter the causes of thrombocytopenia are divided into two broad categories: (i) those arising on a background of an established genetic defect (inherited thrombocytopenia) and (ii) those associated with birth (congenital thrombocytopenia).

Historic perspective

Although Donne,² Geber,³ Addison,⁴ and Simon⁵ are said to have each independently described the platelet first in 1842, the first true description is generally credited to Max Schultze of Freiburg, who in 1865 described them as "gray, colorless spherical bodies in the blood from which, when clumped, rays of finely granular protoplasm often spread, in conjunction with fibrin coagulation."⁶ In 1882, Julius Bizzozero, who coined the term *Blut Plattchen*, wrote his classic paper describing "viscous metamorphosis" of platelets in which he stated: "Platelets become granular within the lumen of an injured vessel: and this change produces a substance which activates the coagulation system to form fibrin."⁷ By 1906, Wright⁸ confirmed Bizzozero's theory of the origin of the platelet from bone marrow megakaryocytes by observing that the cytoplasmic pseudopodia from megakaryocytes have the same staining characteristics as platelets and concluded that the pseudopodia produced new platelets. These findings were subsequently confirmed in the late 1940s and early 1950s with the arrival of electron microscopy. Over the following three decades, steady, albeit limited, progress was made in characterizing platelet pathophysiologic states.

The 1970s witnessed the birth of the modern era of platelet and megakaryocyte research as newer methods of analysis (molecular biologic tools and *in vitro* systems) became available to study megakaryocytopoiesis and platelet structure and function. The fruits of this endeavor have been the recognition of different stages of normal megakaryocytopoiesis and a greater understanding of the molecular events responsible for dysmegakaryocytopoiesis. During this period, the cloning of cytokines that act on the megakaryocytic lineage and their clinical application was realized. The *c-mpl* proto-oncogene as the receptor of a major regulator of thrombocytopoiesis was identified and this greatly facilitated the

subsequent isolation and cloning of *c-mpl* ligand or thrombopoietin (TPO) by several groups.⁹ More recently, mutations in the nonmuscle myosin heavy chain II-A have been shown to be responsible for the MYH9-related disease, which is characterized by macrothrombocytopenia, granulocyte inclusions, deafness, cataracts and renal failure.¹⁰ These three discoveries represent significant recent advances in platelet/megakaryocyte research.

Inherited thrombocytopenia

The inherited thrombocytopenias comprise a group of platelet formation abnormalities in which platelet numbers are reduced. In the vast majority of patients the platelet count is only mild to moderately reduced ($50\text{--}100 \times 10^9/\text{L}$) and therefore significant spontaneous hemorrhage tends not be problematic. There are, however, a number of notable exceptions where spontaneous bleeding is a prominent clinical feature of the syndrome:

- Wiskott–Aldrich syndrome, amegakaryocytic thrombocytopenia and thrombocytopenia with absent radii where the platelet count is usually very low;
- Bernard–Soulier and Chédiak–Higashi syndromes where there is marked platelet dysfunction.

Immune-mediated thrombocytopenia is a major differential diagnosis in children with low platelet counts and therefore making the correct diagnosis of these conditions is important, as it usually prevents the useless and potentially dangerous prescribing of immunosuppressants such as corticosteroids. Although the inherited nature of these conditions has been known for the past 30 years, the molecular basis for the thrombocytopenia has only been fully elucidated in a very

small number of these conditions, in particular those arising from defects in von Willebrand factor (vWF) and its platelet receptor, glycoprotein (Gp)Ib–V–IX complex.

Hereditary thrombocytopenias are an etiologically heterogeneous group of disorders that have traditionally been classified into three groups depending on platelet volume (see Chapter 30). In this chapter they are classified into two broad categories based on the presence or absence of a concomitant platelet function abnormality (Tables 22.1 and 22.2).

Disorders with dysfunctional platelets

GpIb–V–IX complex

The GpIb–V–IX complex is one of the major adhesion receptors on the platelet surface and plays a pivotal role in primary hemostasis by mediating vWF attachment following collagen exposure on the damaged vessel wall. Its structure is well known, with each gene product possessing one or more characteristic leucine-rich domains.^{11,12} Binding of vWF occurs to one or more sites within or close to a double disulfide-bonded and sulfated loop region close to the amino-terminal of the receptor during high shear conditions involving the platelet cytoskeleton. The three inherited bleeding disorders associated with gene defects within this complex are Bernard–Soulier syndrome (BSS), pseudo-von Willebrand disease (vWD) and type 2B vWD.

Bernard–Soulier syndrome (see Chapter 25)

This is the best-characterized inherited thrombocytopenia with associated abnormal platelet function.¹³ Typically there is (i) moderate-to-severe thrombocytopenia (automated platelet counting usually underestimates the true platelet count as

Table 22.1 Inherited thrombocytopenia with dysfunctional platelets.

Disorder	Inheritance	Platelet feature	Platelet size	Other findings
Bernard–Soulier syndrome	AR	↓ Aggregation to ristocetin	Large	Qualitative and/or quantitative defects in platelet GpIb–V–IX
Pseudo-von Willebrand disease	AD	↑ Aggregation to ristocetin	Normal	Spontaneous ↑ platelet binding of vWF due to GpIb defect
Type 2b von Willebrand disease	AD	↑ Aggregation to ristocetin	Large	Spontaneous ↑ vWF binding to platelets due to vWF defect
Montreal syndrome	AD	Spontaneous aggregation	Large	Calpain defect, pale-staining platelets, agranular megakaryocytes
Gray platelet syndrome	AR	α-Granule defect	Normal	Pale platelets due to α-granule deficiency, bone marrow fibrosis
Paris–Trousseau syndrome	AD	Giant α-granules	Normal	Chromosome 11 (del(11)(q23.3;qter))
Wiskott–Aldrich syndrome	X-linked	↓ Dense granules in some	Small	WASP mutations at Xp11.22–11.23, infections, eczema
X-linked thrombocytopenia	X-linked	↓ Dense granules in some	Small	WASP mutations at Xp11.22–11.23
XLTT	X-linked	↓ α-granules	Large	GATA-1/FOG-1 mutations
XLTDEA	X-linked	↓ α-granules	Large	GATA-1/FOG-1 mutations
Chédiak–Higashi syndrome	AD	↓ Aggregation to Ep and Co	Normal	Oculocutaneous albinism, recurrent infections, large white cell inclusions
Quebec syndrome	AD	↓ Aggregation to Ep	Normal	↓ Platelet P-selectin, fibrinogen, vWF, factor V, thrombospondin, osteonectin; normal platelet factor 4 and β-thromboglobulin

AR, autosomal recessive; AD, autosomal dominant; Ep, epinephrine (adrenaline); Co, collagen; vWF, von Willebrand factor protein; XLTT, X-linked thrombocytopenia/thalassemia; XLTDEA, X-linked thrombocytopenia/dyserythropoietic anemia; FOG-1, friend of GATA-1.

Table 22.2 Inherited thrombocytopenia without dysfunctional platelets.

Disorder	Inheritance	Platelet feature	Platelet size	Other findings
May–Hegglin anomaly	AD	Function studies vary	Large	Neutrophil inclusions ± hearing loss, cataracts and/or renal diseases. Gene locus: <i>MYH9</i> (22q12–13)
Epstein syndrome	AD	↓ Aggregation to Ep and Co	Large	Neutrophil inclusions ± hearing loss ± cataracts ± renal diseases. Gene locus: <i>MYH9</i> (22q12–13)
Eckstein syndrome	AD	Normal platelet function	Large	Neutrophil inclusions with features of Alport syndrome. Gene locus: <i>MYH9</i> (22q12–13)
Fechtner syndrome	AD	Function studies vary	Large	Neutrophil inclusions ± hearing loss ± cataracts ± renal diseases. Gene locus: <i>MYH9</i> (22q12–13)
Sebastian syndrome	AD	Normal platelet function	Large	Neutrophil inclusions ± hearing loss ± cataracts ± renal diseases. Gene locus: <i>MYH9</i> (22q12–13)
Thrombocytopenia with absent radii	AR	↓ Aggregation to Ep and Co	Normal	↓ Marrow megakaryocytes
Pure genetic thrombocytopenia	AD	Not known	Large	Normal morphology and platelet survival
Mediterranean thrombocytopenia	AD	Not known	Large	Dysmegakaryocytopoiesis

AR, autosomal recessive; AD, autosomal dominant; Ep, epinephrine (adrenaline); Co, collagen.

some platelets are so large), (ii) prolonged bleeding time and (iii) platelet morphology usually reveals “giant” forms as mentioned above. The platelets in this condition are incapable of interacting with vWF and hence the bleeding seen is typical of a primary hemostatic defect. While BSS platelets show normal shape change, secretion, signal transduction and aggregation in the presence of ADP, epinephrine (adrenaline), collagen and arachidonic acid, they do not aggregate with ristocetin in the presence of vWF.

BSS is inherited in an autosomal recessive manner with the underlying molecular defects due to quantitative or qualitative defects in the GpIb–V–IX complex. In homozygotes the platelets are comparable in size to those seen in MYH9-related diseases (see below). Numerous variants of BSS have been described at the molecular level, ranging from “classic” BSS, where the entire glycoprotein complex is missing from the membrane, to full platelet expression of the GpIb–V–IX complex but with a point mutation in codon 156, the crucial leucine-repeat region (Ala¹⁵⁶ → Val¹⁵⁶) of the subunit GpIb α , which in turn prevents vWF binding, the so-called “Bolzano” variant.^{13–15}

Pseudo-von Willebrand disease (see Chapter 27)

This is an autosomal dominant disorder characterized by mild intermittent thrombocytopenia, mild bleeding, absence of high-molecular-weight vWF multimers, and increased ristocetin-induced platelet aggregation.¹³ It is caused by a mutation(s) in the major double-loop structure of GpIb α that causes a conformational change in the receptor, which in turn leads to enhanced vWF binding and hence spontaneous platelet aggregation and thrombocytopenia.^{14–16} It can be differentiated from type 2B vWD, where the mutation resides in the vWF protein, by spontaneous aggregation of the patient’s platelets with normal plasma (see below).

Bolin–Jamieson syndrome is a mild bleeding disorder characterized by one allele of the GpIb α gene producing a molecule about 10 kDa larger than the normal range.¹⁷ How this defect leads to an increased bleeding susceptibility is not known.

Type 2B von Willebrand’s disease

This subtype of vWD is clinically and biochemically very similar to pseudo-vWD. It is an autosomal dominant disorder, usually diagnosed by the increased platelet agglutination induced by low concentrations of ristocetin. However, it should be remembered that in some cases defects can be delineated in the absence of ristocetin. Like type 2A vWD, the mutations causing type 2B are clustered within exon 28 of the vWF gene.¹⁸ These mutations result in gain of function, i.e., there is spontaneous binding of the mutant vWF to GpIb, with consequent loss of high-molecular-weight multimers from the plasma and a tendency to thrombocytopenia. Desmopressin (DDAVP) may result in more marked thrombocytopenia by increasing the levels of vWF multimers that have increased avidity for platelet glycoproteins and result in further exacerbations of platelet agglutination. Assessment of vWF multimer size and platelet agglutination profile distinguishes this disorder from pseudo-vWD.

Montreal platelet syndrome

This syndrome is characterized by thrombocytopenia, large platelets, spontaneous platelet aggregation, and a reduced response to thrombin-induced aggregation.¹⁹ It can be distinguished from BSS by its autosomal dominant inheritance and normal platelet agglutinability response to ristocetin. The platelets have a quantitative and qualitative reduction of the calcium-dependent proteinase calpain that prevents them from returning to normal volume after agonist stimulation.^{20,21}

Gray platelet syndrome (see Chapter 25)

This is an extremely rare syndrome that in the majority of cases is inherited in an autosomal recessive fashion. It is characterized by markedly reduced platelet α -granule content but normal dense bodies and lysosomes.²² The name “gray platelet” comes from the bland gray agranular appearance of platelets on Wright–Giemsa-stained blood smears, which reflects the reduced number of platelet α -granules. Other features include a prolonged skin bleeding time, morphologically large platelets and highly variable platelet aggregation profiles. The platelet α -granules that are present, albeit in reduced numbers, are deficient in the storage proteins coagulation factor V, vWF, platelet factor 4, β -thromboglobulin, fibrinogen, platelet-derived growth factor (PDGF) and thrombospondin.²³ Concomitant elevation in plasma levels of platelet factor 4 and β -thromboglobulin are seen, implying that there is an abnormality in α -granule protein packaging within the megakaryocyte; this would appear to be lineage restricted to megakaryocytes as vWF biosynthesis within endothelial cells is normal.²⁴ Myelofibrosis is not an uncommon finding in these patients and the continuous premature release of α -granule proteins such as PDGF into the bone marrow microenvironment may be key to its development.²⁵ The accompanying thrombocytopenia and bleeding symptoms are usually mild. The mechanism responsible for the bleeding propensity is not fully understood but is likely to be multifactorial, involving mild impairment of platelet aggregation and adhesion together with impaired thrombin and fibrin generation as there is probably a paucity of coagulation factor V within the α -granules.²⁶

Appropriate on-demand or prophylactic treatment needs to be individualized. For example, those patients with moderate thrombocytopenia and evidence of abnormal platelet aggregation are most likely to benefit from a combination of platelet transfusion and desmopressin, whereas for those with very mild thrombocytopenia and a prolonged bleeding time desmopressin alone is all that is needed.

Jacobsen or Paris–Trousseau syndrome

This is a recently described autosomal dominant syndrome that comprises mild thrombocytopenia, normal platelet lifespan, moderate hemorrhagic tendency, giant α -granules in a subpopulation of platelets, bone marrow micromegakaryocytes with enhanced megakaryocyte apoptosis, and deletion of the distal part of chromosome 11 at position 11q23, i.e., del(11)(q23.3;qter).²⁷ The giant α -granules fail to release their content following thrombin exposure and this may explain the moderate bleeding events seen in this disorder. The cytogenetic abnormality seen in this syndrome is probably responsible for the abnormal megakaryocytopoiesis as the two protooncogenes *ETS1* and *FL1* map to 11q23–24 and are involved in normal expression of megakaryocyte-specific genes.

Wiskott–Aldrich syndrome

Wiskott–Aldrich syndrome (WAS) is inherited as an X-linked recessive trait and is characterized by eczema, microthrombocytopenia and combined immunodeficiency.^{28,29} It is often fatal by the early teens due to infection, lymphoreticular malignancy or bleeding. Hemorrhagic events are common during the first 2 years of life and the reason for this is multifactorial. For example, platelet survival is modestly reduced to half normal,³⁰ ineffective megakaryocytopoiesis is prominent as reflected by platelet turnover 25% that of normal with normal megakaryocyte mass,³⁰ and there is evidence of platelet functional abnormalities related to abnormal storage of adenosine nucleotides and impaired platelet energy metabolism.^{31,32}

Allogeneic bone marrow transplantation (BMT) is the treatment of choice when there is a fully matched donor available as this corrects the abnormal stem cell compartment.³³ When there is no suitable donor, splenectomy is the therapeutic first choice as this usually raises the platelet count into the normal range, improves platelet survival and normalizes platelet size.³⁴ It should be remembered that splenectomy in patients with WAS may produce an increased risk of overwhelming sepsis compared with other diseases where splenectomy is indicated. Splenectomy is not advocated for the other hereditary thrombocytopenic disorders as it usually gives little benefit.

Wiskott–Aldrich syndrome variants (X-linked thrombocytopenia)

This is a heterogeneous group of thrombocytopenic disorders with X-linked inheritance. Some families have microthrombocytopenia and no associated abnormalities, while others have mild eczema and impaired immune responses.³⁵ The thrombocytopenia is usually less severe in WAS variants and requires no treatment but in the rare case with severe thrombocytopenia splenectomy has been shown to be effective.³⁶

Both WAS and WAS variants appear to be caused by different mutations of the same gene on the short arm of the X chromosome (Xp11.2), with the latter involving primarily exon 2 of the *WASP* gene.³⁷

X-linked thrombocytopenia and erythropoiesis

The transcription factor GATA-1 and its cofactor FOG-1 regulate erythropoiesis and megakaryocytopoiesis.³⁸ Therefore it is not surprising that when mutations occur within these key regulatory proteins, platelets and red cells may be affected as seen in X-linked thrombocytopenia associated with dyserythropoietic anemia and/or thalassemia (see Table 22.1). Defects in megakaryocyte maturation with associated macrothrombocytopenia α -granule deficiency have also been observed in some of these patients.³⁸

Oculocutaneous albinism (Hermansky–Pudlak and Chédiak–Higashi syndromes)

Oculocutaneous albinism denotes a group of inherited disorders characterized by reduced or absent pigmentation of skin, hair and eyes. While the majority of these patients have an isolated platelet storage pool defect, in some an accompanying low platelet count can occur.

Hermansky–Pudlak syndrome

Hermansky–Pudlak syndrome is an autosomal recessive disorder with the classic triad of oculocutaneous albinism (tyrosinase positive), platelet dense-body or combined dense-body and α -granule storage pool deficiency, and deposits of ceroid-like material in the monocyte–macrophage system (see Chapter 24). The bleeding tendency is usually mild (related to the storage pool defect and not thrombocytopenia, as the latter is not a feature of the syndrome); however, excessive bleeding following tooth extractions and tonsillectomy is the rule. The ceroid-like deposits in the lungs, gastrointestinal tract and renal tubule cells may lead to restrictive lung disease, colitis or renal failure respectively.

Chédiak–Higashi syndrome

The features of Chédiak–Higashi syndrome include partial oculocutaneous albinism, the presence of giant granules in all granule-containing cells, neutropenia, peripheral neuropathy, and platelet storage pool deficiency that usually involves the dense bodies. Thrombocytopenia usually occurs during the accelerated phase of the disease, which involves the development of pancytopenia, hepatosplenomegaly, lymphadenopathy and extensive tissue infiltration with lymphoid cells. The accelerated phase, which is clinically similar to virus-associated hemophagocytic lymphohistiocytosis, unfortunately occurs in most patients and the majority die. The precise molecular basis of Chédiak–Higashi syndrome has not been fully elucidated and the only curable therapeutic modality is allogeneic BMT, which in one report was successful in six of seven patients grafted.³⁹

Quebec syndrome

This condition is characterized by an autosomal dominant inheritance pattern, mild thrombocytopenia, an epinephrine platelet aggregation defect, and a severe posttraumatic bleeding tendency.⁴⁰ Deficiency in multimerin, a large complex multimeric protein expressed in platelet α -granules and endothelial cell Weibel–Palade bodies, is responsible for the reduced levels of α -granule proteins such as factor V, P-selectin, fibrinogen, vWF, thrombospondin and osteonectin.⁴⁰ Platelets in this disorder have unusually large amounts of urokinase-type plasminogen activator that is released on platelet activation, and whose presence in excess of the natural inhibitors of this protease accounts for the

in situ protein degradation in the α -granules.⁴¹ The platelet aggregation defect is most striking with epinephrine, the mechanism of which remains to be elucidated.

RUNX1–thrombocytopenia–leukemia syndrome

RUNX1 (also known as AML1 and CBFA2), a hematopoietic transcription factor, is mutated in affected members of families with autosomal dominant thrombocytopenia in association with platelet dense-body storage pool deficiency.⁴² These individuals are predisposed to the development of acute myeloid leukemia and, to a lesser extent, solid organ tumors. Although the thrombocytopenia is usually mild ($80\text{--}100 \times 10^9/\text{L}$), bleeding is the norm as the platelets are functionally impaired. The mechanism of the thrombocytopenia is most likely related to low TPO receptor levels on megakaryocytes.⁴²

Disorders without dysfunctional platelets

MYH9-related disease

These are rare autosomal dominant macrothrombocytopenic disorders with characteristic Döhle body-like cytoplasmic inclusions in the granulocytic series.⁴³ They are distinguished from each other by different clinical and laboratory features, such as sensorineural hearing loss, cataract, nephritis and white cell inclusions. Mutations in the *MYH9* gene encoding the nonmuscle myosin heavy chain IIA have been identified in all these syndromes.⁴³ These conditions are now felt to be most likely a single disorder with a continuous clinical spectrum, varying from mild macrothrombocytopenia with granulocyte inclusions to a severe form complicated by hearing loss, cataract and renal failure. *MYH9* expression patterns most likely differ in each MYH9-related disease, accounting for the diverse phenotype observed (see Table 22.2). Outlined below are the classical descriptions of what we now call the MYH9-related disease.

May–Hegglin anomaly

This is an autosomal dominant disorder characterized by giant platelets, variable thrombocytopenia and Döhle-like inclusions within granulocytic cells, including monocytes.^{44,45} These structures are blue on Wright–Giemsa staining (denoting RNA), spindle-shaped, occur singly in each cell, and have a distinctive ultrastructure of 7–10 nm filaments of remnant rough endoplasmic reticulum oriented in parallel in the long axis.⁴⁶ A small percentage of patients have persistent leukopenia, which has been associated with occasional infections, and in one case neutrophil chemotaxis and chemokinetic responses were impaired.⁴⁶ Platelet function has been reported to be normal in some and impaired in others.^{23,47–50} Troublesome primary hemostatic bleeding,⁴⁷ which is seen in approximately 40% of these patients, is felt to be most likely

secondary to the degree of thrombocytopenia at the time of hemorrhage.

Alport syndrome

This is associated with sensorineural deafness (usually high tone), hematuria, cataracts and progressive renal failure.⁵¹ The disorder is a heterogeneous group, with the majority having autosomal dominant inheritance. Many variants of Alport syndrome have been described, the commonest being associated with hyperprolinemia. The genetic basis of this syndrome is believed to involve deletions or rearrangements in the $\alpha 5(\text{IV})$ collagen gene (*COL4A5* locus) located on Xq22.3.⁵² Three variants have been described with associated thrombocytopenia. It is not known whether the gene defect seen in "classic" Alport syndrome is linked to the thrombocytopenia seen in the variants described below.

Epstein and Eckstein syndromes

Epstein syndrome was first described in 1972 in a family with features of Alport syndrome, macrothrombocytopenia, and defective platelet aggregation and secretion in response to ADP and collagen.⁵³ Three years later, Eckstein syndrome was reported and described to have all the features that characterized Epstein syndrome but in contrast had normal platelet function.⁵⁴

Fechtner syndrome

This is characterized by the same morphologic features as those seen in Sebastian platelet syndrome (see below) but in addition is associated with deafness, cataracts and renal failure.⁵⁵ The white cell inclusion bodies (Fechtner inclusions) are characteristic of the syndrome and resemble toxic Döhle bodies (seen with infection and malignancies) and May-Hegglin granulocyte inclusions. They can be differentiated by light and electron microscopy as Fechtner inclusion bodies are smaller and lighter-staining than those seen in May-Hegglin granulocytes and are composed of dispersed filament, ribosome and endoplasmic reticulum. Fechtner inclusion bodies lack the parallel bundles of fine filaments seen in May-Hegglin inclusions.⁵⁶

While these syndromes are associated with a mild-to-moderate bleeding tendency, significant hemorrhagic morbidity is usually encountered following trauma, dental extraction and other forms of surgery and platelet concentrates are the main therapeutic intervention. It should be remembered that the progressive renal failure seen in these patients usually adds to the hemorrhagic tendency and is also the main etiologic factor contributing to overall morbidity and indeed mortality.

Sebastian platelet syndrome

Sebastian platelet syndrome resembles May-Hegglin anomaly but the Döhle body-like inclusions seen in granulocytes are different in that they are smaller and ultrastructural analysis

shows them to consist of ribosomes and dispersed filaments without an enclosing membrane. They are detected by light microscopy only if the blood smear is stained within 4 hours after venepuncture,⁵⁷ which implies that this syndrome is probably an underreported cause of hereditary thrombocytopenia.⁵⁸ This syndrome is felt to be a variant of Fechtner syndrome without the associated Alport syndrome features.⁵⁷ It is inherited in an autosomal dominant manner and while the bleeding tendency is considered to be mild to moderate, hemorrhagic deaths have been reported.⁵⁹

Inherited bone marrow failure syndromes

Thrombocytopenia with absent radii (see Chapter 3)

This is a rare autosomal recessive disorder that is usually diagnosed at birth as the vast majority of these patients are thrombocytopenic and have the pathognomonic physical signs of bilateral absent radii or indeed other orthopedic anomalies involving the ulna, humerus and tibia.⁶⁰ Other skeletal abnormalities involving the ulnae, fingers and lower limbs are also seen but are much rarer.⁶¹ Thrombocytopenia with absent radii (TAR) differs from Fanconi anemia in several ways: the absent radii are accompanied by the presence of thumbs, the thrombocytopenia is the only cytopenia, there is absence of spontaneous or clastogenic stress-induced chromosomal breakage, and evolution of aplastic anemia and leukemia has not been reported.⁶¹ It is not uncommon for these children to be anemic and have transient white cell counts at presentation (the former is felt to be secondary to bleeding as it is always accompanied by a reticulocytosis and the latter usually subsides by 6 months of age). The striking morphologic feature within the bone marrow is the absence or greatly reduced numbers of megakaryocytes with normal granulopoietic and erythroid compartments.^{62,63} Although the precise pathophysiologic defect responsible for TAR is not known, signaling through the TPO receptor *c-mpl* is abnormal.⁶⁰ The restoration of platelet count seen following sibling allogeneic BMT supports the idea that the thrombopoietic defect lies within the hematopoietic stem cell compartment rather than being a deficiency of TPO or another platelet humoral factor.⁶⁴

The majority of children with TAR have recurrent significant bleeding episodes in the first 6 months of life. Intracerebral and gastrointestinal hemorrhage are the usual cause of mortality with previously 1 in 4 of these children dying by 4 years of age.⁶¹ However, the majority of these deaths occurred in the first year of life. The severity of the bleeding problem is related to the degree of thrombocytopenia, which in the majority of children is usually $< 20 \times 10^9/\text{L}$, and in some there is evidence of qualitative platelet defects (storage pool and abnormal aggregation profiles).^{61,65} The mainstay of treatment is the judicious use of single donor platelet concentrates, aiming to keep the platelet count above $20 \times 10^9/\text{L}$, especially in the first year of life as this is the time

of maximum morbidity and mortality. This more aggressive platelet transfusion approach should dramatically reduce the unacceptable hemorrhagic mortality and morbidity rate. If the patient survives the first year of life, survival appears to be normal.⁶¹ All elective reconstructive orthopedic surgery should be postponed during the first few years of life.

Prenatal diagnosis of TAR is possible, with absent radii easily visualized with radiography and/or ultrasound and thrombocytopenia diagnosed following fetal blood sampling obtained by fetoscopy or cordocentesis.^{66,67} This relatively recent advance in obstetric care allows for the possibility of prophylactic antenatal management.

Amegakaryocytic thrombocytopenia (see Chapter 3)

This is an extremely rare disorder of infancy and early childhood. In the majority of cases it results from a mutation in the TPO receptor *c-mpl* and as a consequence megakaryocytes do not proliferate following TPO ligation.⁶⁰ The thrombocytopenia is nonimmune and usually severe and early bone marrow examination shows a normal karyotype, absence or greatly reduced numbers of megakaryocytes, with normal granulopoietic and erythroid elements.⁶⁸ Some patients have macrocytic red cells with increased expression of i antigen and elevated hemoglobin F levels,⁶⁹ implying that the pathophysiologic trigger occurs at the stem cell level. The inheritance pattern in the majority of cases is X-linked, the remainder being autosomal recessive. Patients with amegakaryocytic thrombocytopenia can be broadly divided into two groups, those with physical anomalies and those without. The pattern of somatic anomalies is not unlike that seen with Fanconi anemia; however, in those children tested, there was no evidence of DNA repair abnormality. The presence of anomalies influences outcome; projected median survivals are 6 years for those with no anomalies and 2 years when anomalies are present.⁶⁹ Those with isolated thrombocytopenia usually die from hemorrhagic complications whereas those with aplasia, which usually occurs after a relatively long period of thrombocytopenia, succumb to infection and bleeding.⁶¹ Amegakaryocytic thrombocytopenia is considered to be a leukemia predisposition syndrome.^{61,70}

Platelet transfusions are the main therapeutic intervention following diagnosis. Treatment with corticosteroids alone or in combination with androgens, the cytokines, granulocyte-macrophage colony stimulating factor and IL-11 have been disappointing, and splenectomy has no role. Encouraging platelet responses following the administration of IL-3 have been reported⁶⁸ and clinical trial results with TPO are eagerly awaited. Allogeneic BMT offers the only probable chance of cure, although gene therapy in which insertion of an artificial TPO receptor intended to convey a growth advantage in stem cells has now begun.

Fanconi anemia (see Chapter 3)

This is a premalignant disorder, inherited as an autosomal

recessive trait, with genetic heterogeneity and a gene frequency of about 1 in 600.⁷¹ Thrombocytopenia is usually the first cytopenia to appear, followed by granulocytopenia and ultimately severe aplasia, which occurs in the majority of patients.⁷² The average age of onset of the hematologic abnormalities varies, with boys developing pancytopenia earlier than girls at 6.6 years and 8.8 years, respectively, with ranges from 18 months to 22 years.⁷³ The diagnosis of Fanconi anemia should always be considered in a child with an isolated cytopenia even when somatic anomalies are absent as a significant number of these cases are physically normal.

Trisomy syndromes

Moderately severe thrombocytopenia is seen in some cases of trisomy 18,⁷⁴ trisomy 13,⁷⁵ and to a lesser extent trisomy 21.⁷⁵ Both trisomy 13 and 18 are usually diagnosed at birth as the associated abnormalities are usually quite striking. The majority of these cases die in the neonatal period from non-hemorrhagic sequelae.⁷⁶

Pure genetic thrombocytopenia

This is an autosomal dominant macrothrombocytopenic disorder characterized by a chronic low platelet count, normal platelet half-life, normal platelet function (aggregation and adhesion), normal skin bleeding time, absent platelet-associated immunoglobulins, and a morphologically normal bone marrow megakaryocyte compartment.⁷⁷ Although the molecular lesion causing the thrombocytopenia has not been elucidated, platelet isotope studies using homologous and autologous platelets are highly suggestive that there is a pure production defect within the bone marrow.^{77,78} The majority of cases are detected following routine blood tests carried out for nonhematologic indications. The diagnosis is usually considered when there is a negative surrogate marker profile for inherited thrombocytopenia and is confirmed with isotope studies using the tracer ¹¹¹In-oxine and autologous platelets, which show a normal platelet lifespan.⁷⁸ The dose of radioactive ¹¹¹In necessary to perform the study is approximately 50 kBq (1.5 μ Ci)/kg, which is negligible and perfectly acceptable in children, although not all pediatricians are comfortable with this view. Failure to differentiate this pure genetic thrombocytopenia from the commoner immune thrombocytopenias may expose the child to potentially toxic and unnecessary expensive therapeutics such as corticosteroids, chemotherapy and immunoglobulin. As the majority of these patients have platelet counts in the region of $50\text{--}100 \times 10^9/\text{L}$ with normal skin bleeding times, the hemorrhagic potential for spontaneous bleeding is low and only rises at menses or following trauma or surgery.⁷⁸

Mediterranean macrothrombocytopenia

This type of macrothrombocytopenia was initially reported from Australia in blood donors with Greek and Italian ancestry and has subsequently been shown to be present

in the North African immigrant population in France.^{79,80} The thrombocytopenia is mild with platelet counts ranging between 100 and 150 × 10⁹/L and platelet morphology showing only a mild increase in platelet size. Inheritance is autosomal dominant and the low platelet count is very rarely if ever associated with troublesome bleeding.⁸¹ The defect is felt to be in the demarcatory membrane system by which megakaryocytes divide up their cytoplasm into platelets, although the precise mechanism by which this is achieved remains to be elucidated.

Congenital thrombocytopenia

Congenital thrombocytopenia is defined as a low platelet count at birth that does not result from the association of a specific gene defect; it accounts for the majority of cases of neonatal thrombocytopenia. However, thrombocytopenia is a common finding in sick neonates, and since the introduction of automated cell counters it is now considered a relatively common (~ 1%) finding in apparently normal infants. In the vast majority of cases the thrombocytopenia results from increased platelet destruction, which can arise by several mechanisms, the majority of which are not known. It is helpful to consider etiologic factors contributing to neonatal thrombocytopenia in terms of whether the insult is maternal (Table 22.3), infant (Table 22.4) or placentally based.

Maternal factors

Immune thrombocytopenia

Immune-mediated thrombocytopenia is usually seen in term babies who are clinically well and may be responsible for one-third of cases of thrombocytopenia seen in the general neonatal population.¹ There are two broad categories of conditions: those mediated by an alloimmune mechanism and those with associated autoimmune phenomena.

Table 22.3 Congenital thrombocytopenias: maternal factors.

<i>Immune thrombocytopenia</i>
Neonatal alloimmune thrombocytopenia
Maternal autoimmune thrombocytopenia
<i>Intrauterine infections (TORCH syndromes)</i>
Toxoplasmosis
Rubella
Cytomegalovirus
Herpes simplex
Other (including HIV and parvovirus B19)
<i>Preeclampsia/hypertension</i>
<i>Drugs</i>

Table 22.4 Congenital thrombocytopenias: infant and placental factors.

<i>Infant factors</i>
Disseminated intravascular coagulation
Primary microangiopathic hemolytic anemias
Hemolytic–uremic syndrome
Thrombotic thrombocytopenic purpura
Giant hemangioma syndrome (Kasabach–Merritt syndrome)
Hypercoagulable states
Birth asphyxia
Cyanotic congenital heart disease
Respiratory distress syndrome
Necrotizing enterocolitis
Bacterial infection
Rhesus hemolytic disease
Anticoagulant deficiency (homozygous antithrombin, protein C and S deficiency)
Heparin-induced thrombocytopenia
Rare bone marrow diseases
Transient abnormal myelopoiesis
Hemophagocytic lymphohistiocytosis
Osteopetrosis
Congenital leukemia
Metastatic neuroblastoma
<i>Placental factors</i>
Infarction
Angiomas (chorioangiomas)
Lupus anticoagulant/anticardiolipin antibodies

Neonatal alloimmune thrombocytopenia (see Chapter 30)

This arises following maternal sensitization to paternal antigens present on fetal platelets.⁸² It occurs in approximately 1 in 1500–2000 births, with the mother having a normal platelet count and a negative history of bleeding.^{83,84} The maternal alloantibody produced does not react with the mother’s platelets but crosses the placenta and destroys fetal platelets. The paternal-derived fetal platelet antigen target against which the maternal alloantibody is directed is usually HPA-1a (also called P1A¹ or Zw^a), which is present on the platelets of 98% of the population and is responsible for neonatal immune thrombocytopenia (NAIT) in approximately 80% of cases.⁸³ The second commonest platelet antigen involved in NAIT is HPA-5b (also called Br^a, Zav^a or Hc^a).⁸⁵ While NAIT is in other ways analogous to hemolytic disease of the newborn due to Rhesus or ABO incompatibility (see Chapter 8), in NAIT the first child is usually affected with thrombocytopenia.⁸² Given that 2% of the population is HPA-1a negative, it is somewhat surprising that the frequency of NAIT is lower than would be predicted from the prevalence of the alloantigen.^{84,86} The most likely reason for this discrepancy is that certain HLA types are more likely to be associated with alloantibody formation, e.g., women who have the HLA-DR3 alloantigen account for the majority of affected cases of HPA-1a-induced NAIT.^{84,87–89} A similar finding is seen with the Br^a alloantigen and HLA-DRw6.⁹⁰

NAIT typically presents as an isolated severe thrombocytopenia in an otherwise healthy child at birth. Severe thrombocytopenia may be present early in gestation and at least 20% of cases suffer intracranial hemorrhage (ICH),⁹¹ some sustaining it *in utero*, which usually results in long-term severe neurologic sequelae such as porencephalic cysts and optic hypoplasia.^{92,93} Widespread petechial hemorrhage is present in more than 90% of cases, while cephalohematomas, hematuria and gastrointestinal bleeding occur in a significantly smaller number of children. Typically, the platelet count spontaneously returns into the normal range within 3 weeks after birth.

Neonates with alloimmune thrombocytopenia usually have platelet counts $< 20 \times 10^9/L$. Making the distinction from autoimmune causes is usually facilitated by the maternal platelet count, in that the mother has no thrombocytopenia nor is there any history of immune thrombocytopenic purpura (ITP). The diagnosis of NAIT is usually confirmed by platelet antigen typing of the parents, showing the antigen to be absent on the mother's platelets and present on the father's platelets, or by demonstrating antibody activity to the antigen in the mother's serum using indirect immunofluorescence assay^{93,94} or enzyme-linked immunoassay.⁹⁶ It should be remembered that failure to detect a platelet-specific alloantibody in the maternal serum does not exclude the diagnosis,^{96,97} and testing for NAIT does not require testing of the baby.

The mainstay of treatment for affected infant is washed, irradiated, maternal platelet concentrates.^{98–100} The reason for washing the platelets is to remove antibody-laden plasma,^{96,97} while irradiation destroys maternal lymphocytes that are capable of stimulating transfusion-associated graft-versus-host disease.¹⁰¹ Both unrelated matched and maternal platelets can be administered; however, the latter are preferred because of their certain compatibility, availability and, perhaps most importantly, safety. With *de novo* cases of NAIT, platelets can be rapidly procured from the mother and following washing and gamma-irradiation given to the infant in a matter of a few hours. Random donor platelets should be given to infants who are actively bleeding while awaiting maternal platelets. In less severe cases, high-dose (1 g/kg) immunoglobulin therapy on two consecutive days will usually increase the platelet count within 2 days of administration.^{101–104} In those cases of known NAIT where elective cesarean section is the preferred route of delivery, platelets are usually collected from the mother a few days before surgery; if this is deemed logistically problematic, then platelets can be collected early in the pregnancy or indeed when the mother is not pregnant and frozen for use at a later stage.¹⁰⁵ Alternatively, nonmaternal HPA-1a-negative platelets can be ordered in advance from a blood bank.

All children born to a father homozygous for the implicated antigen will harbor the antigen, whereas half of the offspring will have it if there is paternal heterozygosity. This has

important implications for future pregnancies as imaging with ultrasound early in the pregnancy will indicate if intervention is required. Sampling fetal blood at 20 weeks' gestation allows accurate assessment of the platelet count and fetal alloantigen genotyping can also be carried out on the sample.^{106,107} Knowing the fetal platelet count and whether intracranial bleeding is present usually dictates the most appropriate therapeutic intervention. For example, a fetus with severe thrombocytopenia and high risk of ICH will probably benefit from antigen-negative platelets transfused weekly.⁹⁶ At the other end of the clinical spectrum, a fetus who is at risk of NAIT, who has mild thrombocytopenia and a normal cranial ultrasound may equally benefit from maternal high-dose immunoglobulin therapy alone.^{108,109} It should be noted, however, that there is no published randomized trial comparing the more aggressive approach of intrauterine platelet transfusion with the least aggressive therapeutic modality of maternal immunoglobulin infusion. Elective cesarean section is recommended for all affected mature fetuses as this optimizes postnatal management.¹¹⁰

Maternal autoimmune thrombocytopenia (see Chapter 30)

Autoimmune thrombocytopenia (AIT) is due to the passive transfer of autoantibodies from mothers with isolated ITP or it may be seen in association with conditions that have immune dysregulatory features, such as maternal systemic lupus erythematosus, hypothyroidism and lymphoproliferative states.^{111,112} Unlike NAIT, the specificity of the platelet antibody seen in AIT is to antigen(s) common to maternal and fetal platelets.¹¹³ Approximately 1 in 10 000 pregnancies are complicated by maternal ITP.¹¹⁴ The risk of significant infant morbidity and mortality is minimal as the infant platelet count is rarely $< 50 \times 10^9/L$ and ICH rarely if ever occurs; when it does, it is not related to birth trauma.^{114,115} It is also clear that there is no correlation between the platelet count and level of autoantibody seen in the mother to the severity of thrombocytopenia observed in the infant; in fact, it has been well documented that women with normal platelet counts following splenectomy for ITP still deliver babies who are thrombocytopenic.¹¹⁶ AIT needs to be distinguished from incidental or "gestational" thrombocytopenia, where the thrombocytopenia is usually mild ($70\text{--}100 \times 10^9/L$) with no history of bleeding or thrombocytopenia outside pregnancy and the platelet count swiftly returns to normal following delivery.^{117,118} Infants born to mothers with "gestational" thrombocytopenia never or extremely rarely have a low platelet count.

The bleeding manifestations, including the risk of ICH, in children of mothers with AIT is significantly less than in children with NAIT.^{114,115,119} These infants are usually very well and born at term. The neonatal platelet count often falls after birth to a nadir on days 1–3 and it is during this time that bleeding occurs.¹²⁰ Spontaneous recovery of the infant platelet count is usually observed within 3 weeks after birth.

However, if the platelet count is $< 20 \times 10^9/L$ or if there is significant bleeding, then intravenous immunoglobulin (1 g/kg) should be given on two consecutive days; if this fails to raise the platelet count, then a short course of prednisolone (2–4 mg/kg daily by mouth) for 7–14 days should be added.¹²¹ The mother's immune thrombocytopenia should be treated in accordance with the severity of the platelet count and not for a theoretical risk estimate of bleeding in the baby. As there are no reliable maternal predictors of severe thrombocytopenia in the infant, prenatal treatment of the mother with immunoglobulin and/or steroids does not make therapeutic sense.¹²² Birth is usually by spontaneous vaginal delivery and cesarean section should only be contemplated in those pregnancies where problems are anticipated or if there is a history of a previous complicated delivery.

Intrauterine infections (TORCH syndromes) (see Chapters 30 and 35)

Intrauterine viral infections rarely produce thrombocytopenia ($< 20 \times 10^9/L$) and therefore therapeutic intervention in the form of platelet concentrate and/or antiviral therapy is only indicated when there is active bleeding or surgical intervention is being considered. The mechanism(s) responsible for thrombocytopenia secondary to intrauterine infection is not fully understood but is probably multifactorial, including megakaryocyte injury with decreased platelet production, splenic removal, liver dysfunction and platelet–endothelial cell injury. In the vast majority of cases, the platelet count returns into the normal range within 2–4 weeks after birth but may persist to 4 months of age.¹²³ The well-established intrauterine infections that cause congenital thrombocytopenia are outlined below.

Toxoplasmosis

Contracted during pregnancy, toxoplasmosis can result in serious damage to the fetus, including hydrocephaly, intracranial calcification, chorioretinitis and neurologic manifestations. Fortunately, as maternal screening for toxoplasmosis in pregnancy and good antenatal treatment is now available, the severe form is less frequently seen. Subclinical forms are now more frequently encountered, with chorioretinitis occurring in approximately one-third of cases. Thrombocytopenia is seen in one-quarter of cases of congenital toxoplasmosis and in approximately 20% of these cases the platelet count is $< 50 \times 10^9/L$.¹²³ Blood eosinophilia is also a common hematologic manifestation of this disease.

Congenital rubella

This is always due to a primary infection occurring in the first 3 months of pregnancy. The risk of serious malformation is highest if the infection is contracted in the first trimester. Mild-to-moderate thrombocytopenia is seen in approximately 20% of affected cases.¹²⁴ Hemolytic anemia and dermal

extramedullary hematopoiesis, which resembles the skin manifestation seen in congenital leukemia (so-called “blueberry muffin”), and other hematologic abnormalities are seen.

Cytomegalovirus

Like the other herpes viruses, especially herpes simplex (types I and II), cytomegalovirus (CMV) can cause thrombocytopenia in the fetus and newborn. Approximately 1 in 5000 births have evidence of CMV inclusion disease, characterized by hypotrophy, jaundice, hepatosplenomegaly, thrombocytopenia, anemia, microcephaly, intracerebral calcification and/or chorioretinitis. While most newborns congenitally infected with CMV are asymptomatic, symptoms and sequelae are much more likely to occur in infants congenitally infected as a result of the mother's primary infection during pregnancy than in those infected from reactivation of latent virus.¹²⁵ In two studies, thrombocytopenia was observed in 36% and 77% of infants infected with CMV, respectively;¹²⁵ in the former study, the platelet count was $< 50 \times 10^9/L$ in more than one-third of infants.¹²⁵

Herpes simplex

Herpes simplex infection only causes problems to the fetus when the mother has a primary infection prior to 20 weeks' gestation. The risk of congenital malformation is very low; however, the frequency of fetal loss may be as high as 25% if the mother is infected during this time period. Thrombocytopenia is a well-established hematologic abnormality associated with congenital herpes simplex infection.¹²⁶

Other causes

Other causes of intrauterine viral-induced neonatal thrombocytopenia include human immunodeficiency virus (HIV)^{127,128} and parvovirus B19.¹²⁹ Estimates of the rates of HIV transmission from mother to newborn range from 20 to 60% depending on the study.¹³⁰ The risk is reduced significantly when the mother is asymptomatic but increases with the length of time that she is seropositive.¹³⁰ Thrombocytopenia is rarely if ever the first clinical manifestation of congenital HIV and, like parvovirus B19 infection, thrombocytopenia seems to be less frequently seen than with the other well-established causes of intrauterine viral-induced thrombocytopenia.^{127–129}

Maternal preeclampsia

The association of neonatal thrombocytopenia and maternal preeclampsia and maternal hypertension is a controversial one. As there are more premature infants born to mothers with hypertensive disorders of pregnancy, it is most likely that the increased rate of thrombocytopenia seen in these infants is more a reflection of how sick and premature the child is at birth, rather than a direct result of the maternal hypertension. Very few of these infants have severe thrombocytopenia and ICH is exceedingly rare.¹¹⁴

Maternal use of drugs

Drug-induced thrombocytopenia in the mother may also affect the neonate and when it occurs is usually mediated by immune destruction of platelets.¹¹⁴ It should be stressed that maternal use of drugs is an extremely rare cause of low platelets in the newborn and the drugs that have been implicated include anticonvulsants (valproic acid, phenytoin, carbamazepine), quinidine and possibly thiazides and hydralazine.¹¹⁴

Infant factors

Disseminated intravascular coagulation

(see Chapters 29 and 30)

Disseminated intravascular coagulation (DIC) is an acquired hemostatic syndrome usually seen in association with well-defined clinical disorders. It is characterized by consumption of procoagulant and natural anticoagulant proteins, which contributes to a state of mixed hemorrhage and thrombosis. The classic laboratory markers are thrombocytopenia, prolonged thrombin, prothrombin (PT) and activated partial thromboplastin (APTT) times, elevated D-dimers, and reductions in plasma levels of fibrinogen, factors II, V and VIII, protein C and antithrombin. The causes of DIC in infants and children are legion (see Chapters 29 and 30).

As a general axiom in medicine, when a pathologic syndrome is secondary to another primary disease state, the appropriate therapy should be directed when at all possible toward the underlying disease in order to correct the associated problem. For example, the appropriate treatment of the thrombotic DIC seen shortly after birth in children with homozygous protein C deficiency is replacement with protein C concentrate. As the plasma protein C level comes into the normal range following protein C concentrate infusion, the laboratory markers of DIC are corrected and resolution of skin purpura then becomes apparent.¹³¹ The same clinical and laboratory response is seen following administration of protein C in children with severe acquired protein C deficiency secondary to meningococemia.¹³² Supportive treatment in the form of clotting factor replacement (fresh frozen plasma [FFP] 15 mL/kg to maintain PT below 17 s), cryoprecipitate (1 bag/5 kg to maintain fibrinogen above 1 g/L) and platelets (5 bags/m² to keep the count above 50×10^9 /L) is usually administered as initial therapy, especially when there is evidence of active surface bleeding.¹³³ Use of heparin and natural anticoagulant concentrates (antithrombin and protein C) should also be considered.

Primary microangiopathic hemolytic anemias

(see Chapter 29)

Microangiopathic hemolytic anemia (MAHA) is a term that

describes intravascular destruction of red cells in the presence of an abnormal microcirculation. In a significant number of clinical syndromes associated with MAHA there is also thrombocytopenia. The thrombocytopenia results from platelet activation and thus platelet thrombi formation, while the red cell fragmentation is a consequence of the shearing force produced by the abnormal flow within the abnormal microvasculature in concert with the microthrombi. The hallmark of MAHA is red cell fragmentation, polychromasia and thrombocytopenia on the blood smear, with absent haptoglobulins, hemoglobinuria and elevated serum lactate dehydrogenase and bilirubin levels. The PT and APTT are usually within the normal range as are the plasma levels of clotting factors V and VIII.

Hemolytic-uremic syndrome (see Chapter 29)

Hemolytic-uremic syndrome (HUS), with its classic triad of MAHA, low platelets and renal failure, is usually seen in infants and children following seasonal epidemics of gastroenteritis caused by *Escherichia coli* (0157:H7 strain) producing verotoxin. It is one of the commonest causes of renal failure in childhood and while the precise pathogenic mechanism responsible for it is not fully understood, renovascular endothelial damage is probably a key event in promoting platelet activation and fibrin deposition that ultimately leads to microthrombi formation.¹³⁴ The other important contributing factor may be elevated levels of abnormal vWF multimer released from the damaged endothelium, which enhance platelet aggregation and adhesion.^{135,136} Treatment is essentially supportive with early renal dialysis allowing for better control of fluid and electrolyte balance. Unlike the situation in thrombotic thrombocytopenic purpura (see below), the role of plasma infusions and plasma exchange remains to be proven and therefore they are not used in the treatment of classic HUS.¹³⁷

Thrombotic thrombocytopenic purpura

While Moschcowitz initially described thrombotic thrombocytopenic purpura (TTP) in a 16-year-old girl,¹³⁸ it is more commonly seen in young adults, with < 20% of all patients reported to be under 21 years of age.¹³⁷ It is characterized by MAHA, low platelets, fluctuating neurologic symptoms, fever and renal failure. However, severe thrombocytopenia, intravascular hemolysis with many red cell fragments on the blood smear, and neurologic symptoms and signs constitute the characteristic TTP clinical triad. Unlike HUS, the pathophysiologic mechanisms involved in TTP (acquired or inherited forms) are now beginning to be understood and are most likely caused by severe deficiency of the vWF cleavage protease ADAMTS-13.¹³⁹ Deficiency of this protease results in the presence of unusually large vWF multimers in the circulation, causing platelet activation with resultant platelet thrombi formation.^{139,140} TTP should not be considered as a single disorder but as a heterogeneous group or a

spectrum of disease with at least four clinically distinguishable subtypes:¹⁴⁰

- single-episode TTP (occurs *de novo* and seldom if ever recurs);
- intermittent TTP (characterized by occasional relapses at infrequent intervals);
- secondary TTP (usually seen in association with recognized clinical entities such as BMT, chemotherapy, pregnancy and infection, e.g., HIV);
- chronic relapsing TTP (frequent episodes occurring at regular intervals).

The commonest form seen in infancy and childhood is the chronic relapsing variety, which may be different from its adult counterpart as there is usually no end-organ damage and only very small quantities of FFP (without plasma exchange) are needed to reverse the anemia and thrombocytopenia.¹⁴¹ However, the vWF multimer profile, characterized by the presence of unusually large vWF multimers, seen in both chronic relapsing types is similar, making it most likely that they are indeed the same disease state.^{142,143}

The mainstay of treatment is plasma exchange with FFP or plasma devoid of the large vWF multimers (cryosupernatant or solvent detergent treated). Plasma infusions have also been shown to be efficacious, but plasma exchange is now considered the therapeutic modality of choice as controlled clinical trials have shown it to have superior efficacy.¹⁴⁴ Plasma exchange is continued until the platelet count and lactate dehydrogenase level return into the normal range. For those patients who do not respond to first-line treatment, a variety of other therapeutic approaches can be considered. These include corticosteroids, immunosuppression (vincristine, azathioprine, immunoglobulins), antiplatelet-aggregating agents (aspirin, dipyridamole) and splenectomy. It should be stated that all of these approaches have been reported to be successful anecdotally and not in a controlled clinical setting.

Giant hemangioma syndrome (Kasabach–Merritt syndrome)

Kasabach–Merritt syndrome (KMS) is the association of giant cavernous hemangiomas and DIC.¹⁴⁵ The consumptive coagulopathy seen in approximately 25% of cases of KMS is usually low grade and compensated. However, acceleration into the fulminant form, characterized by hypofibrinogenemia, raised D-dimers, red cell microangiopathy and severe thrombocytopenia, is not uncommon. This transformation can arise without an identifiable precipitating cause but it is usually accompanied by an expansion of the vascular tumor. The tumors are usually present at birth, grow in size over the first few months of life and then gradually recede. Therefore, the thrombocytopenia and indeed hemostatic failure that can be seen with these tumors may not be manifest until well into infancy. Most of the hemangiomas are cutaneous; however

“hidden” visceral tumors, especially splenic, should always be included in the differential diagnosis of a child with unexplained thrombocytopenia with or without evidence of compensated intravascular coagulopathy as these forms of KMS have a high mortality rate if appropriate therapeutic measures are not undertaken.^{146,147} Computed tomography or magnetic resonance imaging is useful, but platelets labeled with ¹¹¹In-oxine is probably a more sensitive modality in delineating the size and number of hemangiomas present.

Fortunately, spontaneous regression of these tumors occurs in the majority of patients.¹⁴⁶ A number of therapeutic approaches can be instituted in those who fail to undergo spontaneous regression and depend on the severity of the hemostatic failure and anatomic location and size of the hemangiomas. Treatment modalities that have been used with varying success include corticosteroids,^{147,148} surgical resection,^{147,148} α -interferon,¹⁴⁹ embolization,^{150,151} and radiotherapy.¹⁵² Replacement therapy with platelets, fibrinogen concentrate, FFP, cryoprecipitate and antifibrinolytic drugs and antiplatelet agents have a role in the fulminant phase of severe forms. In situations where there is no obvious systemic hemorrhage but at the same time there is ongoing significant consumptive coagulopathy, it may be worth considering withholding platelet concentrate infusions. Blocking platelet function may also be a possibility, as there is now some evidence to suggest that degranulation with release of angiopoietins from endogenous and exogenous platelets as they become activated within the vascular tumor adds “fuel to the fire” and promotes further vascular tumor growth.

Hypercoagulable states (see Chapter 31)

Consumptive thrombocytopenia, mainly secondary to DIC following thrombin generation, can be the first manifestation of an acquired or inherited hypercoagulable state. The clinical hallmark in a significant number of these disorders is an inappropriate thrombotic event(s). It should be remembered, however, that venous and arterial thrombotic events in young children and neonates are rare, but when they do occur can be associated with morbidity and significant mortality such as limb loss and organ impairment. Most events occur in the neonatal period and while the majority are usually associated with indwelling vascular catheters,¹⁵³ other etiologic factors, both inherited and acquired, characteristic of the neonatal period may predispose to hypercoagulability and these are discussed below.

Birth asphyxia

Birth asphyxia as reflected by low Apgar scores is strongly associated with neonatal thrombocytopenia.^{154,155} The mechanism responsible for the low platelet count has not been fully elucidated but consumption secondary to thrombin generation/DIC is probably the key event as hypoxia is known to

upregulate tissue factor expression, reduce thrombomodulin activity and enhance plasminogen activator inhibitor-1 production by endothelial cells.¹⁵⁶

Cyanotic congenital heart disease

The same mechanism probably plays a role in the thrombocytopenia seen in association with polycythemia in some cases of cyanotic congenital heart disease; however, other factors such as increased platelet destruction on abnormal anatomic vascular beds¹⁵⁷ and an artifactual low platelet count secondary to a high hematocrit may also be operating.

Respiratory distress syndrome

A significant number of infants with respiratory distress syndrome also develop thrombocytopenia,¹⁵⁸ which is usually accompanied by evidence of DIC. Postmortem findings in some infants who die from respiratory distress syndrome show pulmonary microvascular thrombosis¹¹⁴ and again, like most of the other perinatal conditions seen in association with thrombocytopenia, the precise mechanism(s) responsible for the low platelet count in respiratory distress syndrome is not known. The degree of thrombocytopenia may be exacerbated with treatment as it is known that mechanical ventilation can induce mild thrombocytopenia in newborn infants.¹⁵⁹

Necrotizing enterocolitis

The majority of infants with necrotizing enterocolitis have evidence of thrombocytopenia. In one study, 90% of infants studied had a platelet count $< 150 \times 10^9/L$ and over half a platelet count $< 50 \times 10^9/L$. Over 50% of the severe thrombocytopenic group had bleeding complications, with one-third having serious sequelae that were felt to be a contributing factor to infant mortality. A significant number of the severe cases had evidence of DIC.¹⁶⁰ Increased platelet destruction is thought to be the principal mechanism contributing to necrotizing enterocolitis-associated thrombocytopenia.

Bacterial infections

Thrombocytopenia is frequently seen in septic infants and probably results from consumptive coagulopathy, especially in those with bacterial infections.^{75,161,162} Immune-mediated platelet destruction as well as impaired platelet production secondary to bone marrow infection have also been shown to contribute to the thrombocytopenia.¹⁶³ A low platelet count is usually seen after the onset of infectious symptoms and resolution of the platelet count occurs promptly when infection control is achieved.^{164–167}

Rhesus hemolytic disease

Severe Rhesus hemolytic disease of the newborn may be associated with thrombocytopenia, especially in the setting of liver dysfunction and DIC.^{168–170} The mechanism of the thrombocytopenia has not been fully elucidated but

is probably multifactorial, involving hyperbilirubinemia, phototherapy, consumptive coagulopathy and the immune process. The thrombocytopenia usually improves during the first week of life and following exchange transfusion.¹⁷¹ It should be remembered that exchange transfusion itself may cause thrombocytopenia, a process felt to be due to a dilutional effect, which can be prevented in some infants by using whole blood.^{170,171}

Protein C and S deficiency

Hereditary protein C (PC) and protein S (PS) deficiency (homozygosity or compound heterozygosity) are associated with a high venous thromboembolic risk at birth or in the first few months of life.^{131,172} The first clinical manifestation is usually necrotic purpura mainly affecting the extremities, and in some cases massive large-vessel thrombosis (renal and iliac veins, vena cava) can also be a presenting feature. Laboratory markers of DIC are usually present within the first week of life. Low levels of PC and PS are also usually seen in DIC associated with other etiologies, especially infection, and therefore it is important to make the correct diagnosis of hereditary PC or PS deficiency because optimum therapy involves factor replacement (protein C concentrate in PC deficiency or FFP in PS deficiency) and heparin in the acute phase and oral anticoagulation in the long term. Within hours of factor replacement, restoration of plasma coagulation proteins and platelets levels is apparent.^{172,173} Homozygotes for antithrombin deficiency producing functional defects are also associated with a high risk of venous thromboembolic disease; however, only one case of thrombosis presenting in childhood has been reported.¹⁷⁴ Like PC deficiency, emergency or elective therapy involves antithrombin concentrate and heparin infusions.¹⁷⁵ Heterozygotes for PC, PS and antithrombin deficiency generally do not experience thrombosis until adolescence or early adulthood.

Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia constitutes the severest adverse effect of heparin therapy. It is of highly variable incidence, depending on the type of heparin used and whether the patient was infected/inflamed at the time of administration, but generally varies between $> 1\%$ and $< 15\%$ of patients receiving unfractionated heparin.¹⁷⁶ There are two types of heparin-induced thrombocytopenia:

- type I occurs within 1–2 days, is nonimmune and is usually totally benign;
- type II usually occurs after a latent period of 7–14 days, is immune mediated and is associated with paradoxical thrombosis/thromboembolism.¹⁷⁷

Fortunately, the latter is an extremely rare event in neonates; nevertheless, when an infant is receiving heparin, no matter how small the dose, whether to keep a catheter patent or in total parenteral nutrition, a watchful eye should always be kept on the daily platelet count.

Rare bone marrow diseases

Transient abnormal myelopoiesis (see Chapters 16 and 18)
Transient abnormal myelopoiesis associated with Down syndrome (trisomy 21) or trisomy 21 mosaicism is a clonal disorder usually affecting children under 3 months of age. It is classically manifest as a myeloproliferative syndrome, with hepatosplenomegaly, elevated white cell count, normal hemoglobin and commonly thrombocytopenia. Blood smear examination usually reveals increased numbers of eosinophils and basophils but also blast cells that in the majority resemble megakaryoblasts.¹⁷⁸ Essentially, transient abnormal myelopoiesis looks like congenital leukemia; however, spontaneous remission is usually seen. Approximately 1 in 4 of these children develop megakaryoblastic leukemia by their third birthday.¹⁷⁹

Hemophagocytic lymphohistiocytosis (see Chapter 15)

Hemophagocytic lymphohistiocytosis is a rare, probably autosomal recessive disorder of the monocyte–macrophage lineage. It usually occurs within the first 6 months of life and is characterized by fever, maculopapular rash, jaundice, hepatosplenomegaly, lymphadenopathy, pancytopenia, hypofibrinogenemia, hypertriglyceridemia and abnormal liver chemistry. Bone marrow examination shows numerous macrophages actively engulfing bone marrow elements including platelets. This disorder is usually rapidly fatal and allogeneic BMT offers the only real chance of cure.¹⁸⁰ Infection-associated hemophagocytic syndrome, especially in the immunocompromised host, can also present with thrombocytopenia as can the systemic variety of Langerhans cell histiocytosis; however, older children are those usually affected.¹⁸⁰

Osteopetrosis

Variable cytopenias and a leukoerythroblastic blood smear are not uncommon features of autosomal recessive osteopetrosis (severe form). This usually presents during the first few months of life as failure to thrive, hypocalcemia, thrombocytopenia and anemia with or without infection. Generalized hyperostosis leads to bone marrow cavity obliteration and thus induces extramedullary hematopoiesis, which results in hepatosplenomegaly. Allogeneic BMT is the optimal therapeutic option for the severe disease as a significant number of these children die early in childhood.

Congenital leukemia

Congenital leukemia is a rare disease, usually of the myelomonoblastic, monoblastic or megakaryoblastic phenotype.¹⁸¹ Nodular skin infiltration, the so-called “blueberry muffin” appearance, and hepatosplenomegaly are not uncommon associations. Thrombocytopenia alone or in association with other cytopenias is usually present at diagnosis.

Metastatic neuroblastoma

Metastatic neuroblastoma may also cause cytopenias secondary to marrow infiltration. Neuroblastoma cells are usually easily identifiable on marrow smears as they usually appear in tight groups and/or rosettes. While thrombocytopenia occurs in metastatic neuroblastoma, thrombocytosis is more common as a presenting hematologic abnormality.¹⁸²

Placental factors

Placental infarction, which is not uncommon in women with circulating lupus anticoagulants and anticardiolipin antibodies, together with circulating lupus (chorioangiomas) can lead to thrombocytopenia which is usually present early in neonatal life. The mechanism(s) responsible for the thrombocytopenia has not been fully elucidated but is probably the end result of localized DIC within the abnormal vascular bed.

Conclusions

The inherited and congenital thrombocytopenias represent a very diverse group of disorders ranging from those with little or no hemorrhagic problems to those where significant mortality occurs within the neonatal period if appropriate therapy is not initiated. The inherited thrombocytopenias are very rare disorders compared with the congenital or acquired thrombocytopenias and making the correct diagnosis at the outset is very important as it usually avoids the prescribing of unnecessary and potentially toxic therapies. The differential diagnosis of neonatal thrombocytopenia differs enormously depending on the general well-being of the infant and therefore a detailed maternal history and neonatal examination are essential in making a speedy diagnosis. Platelet concentrate transfusions are the mainstay of therapy in the inherited group, whereas treating the underlying cause in the congenital group usually raises the platelet count into the normal range.

The past 25 years have witnessed remarkable progress in the understanding, at the molecular level, of the mechanism(s) by which platelet production and survival is controlled. More recently, the molecular basis of MYH9-related disease has been elucidated. Despite these impressive breakthroughs, much remains to be learned about the molecular defects responsible for the majority of inherited thrombocytopenias. No doubt, the next 25 years will see not only the isolation of the rogue genes responsible for these conditions but also gene therapies for these disorders will become a reality.

Idiopathic thrombocytopenic purpura

Paul Imbach

Idiopathic thrombocytopenic purpura (ITP) is a bleeding disorder that occurs as either an acute self-limiting condition or a recurrent or chronic autoimmune disorder. Synonyms for this condition are immune or autoimmune thrombocytopenic purpura (AITP; often used for chronic ITP in adults), Morbus Werlhof and purpura hemorrhagica. Pathophysiologically, it is characterized by early platelet destruction due to antibody binding and subsequent removal of platelets by the mononuclear phagocytic system. ITP also presents in association with other disorders such as infections or connective tissue diseases, or as thrombocytopenia after bone marrow transplantation. Moreover, ITP may also occur with alloimmune platelet destruction as observed in neonatal purpura and posttransfusion purpura. Finally, drug-induced ITP is seen more frequently in adults than in children.

History

In 1735, Werlhof described a bleeding disorder which he called morbus maculosus hemorrhagicus.¹ In 1883, Krauss observed decreased platelets and in 1890 Hayem performed the first platelet count and found a low number of platelets in the disease. The first splenectomy in ITP was successfully performed in Prague in 1916.² Subsequently, splenectomy became the main treatment for chronic ITP despite a lack of knowledge concerning the pathophysiologic role of the spleen in this disorder.

Since 1950 there has been increasing clinical evidence for an immunopathogenetic mechanism of ITP. In 1951, Harrington *et al.*^{3,4} observed that newborns of mothers with chronic ITP often had a transient decrease in their platelet count, suggesting the transfer of a humoral antiplatelet factor from the mother to her baby. Harrington developed classical transient ITP after self-administration of plasma from a patient with ITP, as did other volunteers (Fig. 23.1A). Later, Shulman *et al.*⁵ showed that the thrombocytopenic factor was associated with the 7S IgG fraction of ITP plasma and,

importantly, that this factor binds to autologous as well as homologous platelets. Since 1975, laboratory techniques have demonstrated elevated platelet-associated IgG in the majority of patients with thrombocytopenia.⁶ In 1980, Imbach *et al.*⁷ observed that the intravenous administration of intact 7S IgG, fractionated and pooled from single blood donors, raises the platelet count in patients with acute and chronic ITP (Fig. 23.1B). Two years later Salama *et al.*⁸ described the use of anti-D-immunoglobulin in ITP.

In 1982, Van Leeuwen *et al.*¹⁰ provided the first evidence for autoantibodies in chronic ITP. They reported that 32 of 42 eluates from ITP platelets would bind to normal but not to thrombasthenic platelets. Since these latter platelets are deficient in glycoproteins (Gp) IIb and IIIa, they postulated that ITP patients have autoantibodies to one of these glycoproteins. In 1987, two assays were developed that can detect both platelet-associated and free plasmic autoantibodies: the immunobead assay¹¹ and the monoclonal antibody-specific immobilization of platelet antigens (MAIPA) assay.¹²

In 1991, Semple and Freedman¹³ documented that chronic ITP was associated with a CD4⁺ T-helper cell defect in which peripheral blood T cells secrete interleukin (IL)-2 on stimulation with autologous platelets. In 2000/2001, the role of phagocytosis and the Fcγ receptor in ITP was elucidated by the group of Ravetch.^{14,15}

Incidence

ITP is diagnosed more frequently than any other form of destructive thrombocytopenia. In its acute form, it affects mostly children, while the chronic form is frequently seen in young adults. By arbitrary definition chronic ITP starts after the disease has been present for > 6 months. ITP is more common in white than black children and its severity and duration may display geographic variations.

Of children with ITP, 80–90% have an acute transient bleeding episode that resolves within a few days or weeks

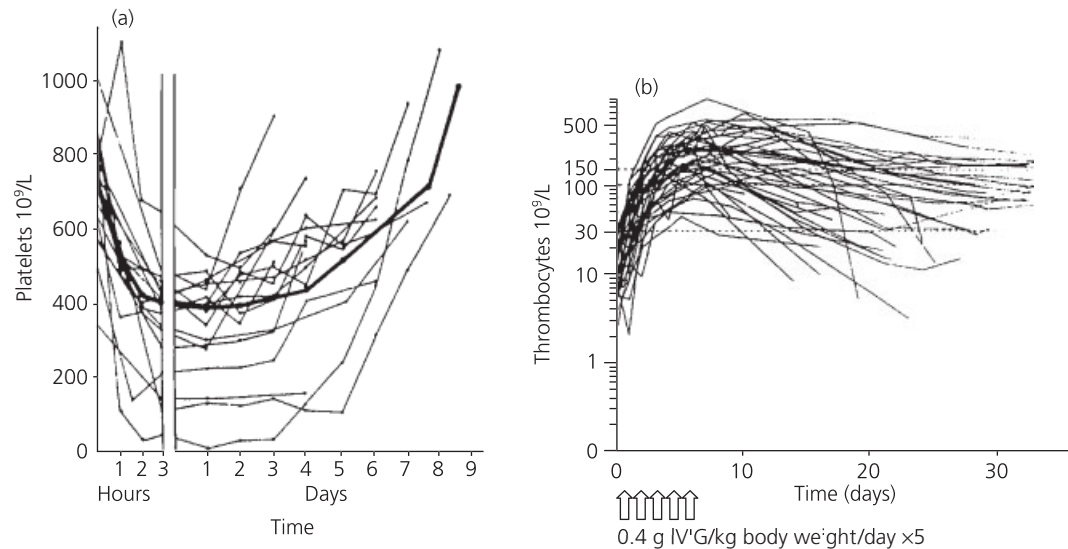

Fig. 23.1 (a) Platelet counts of volunteers after infusion of plasma from patients with immune thrombocytopenic purpura (ITP). (b) Platelet counts of 42 children with ITP during and after intravenous immunoglobulin (IVIG) treatment. Reproduced with permission from Ref. 9.

and, by definition, ends within 6 months. A prospective registry has documented a higher rate of acute ITP in boys than girls (54.8% vs. 45.2%) on all continents worldwide.¹⁶ The male/female ratio was highest in infants and decreased with age.¹⁷ Peak occurrence is between 2 and 5 years of age. There is frequently a history of viral or bacterial infection or vaccination 1–6 weeks prior to the onset of acute ITP. The onset of bleeding is often abrupt and is associated with a platelet count $< 20 \times 10^9/L$.

Chronic ITP in children manifests with similar clinical features to those seen in adults, i.e., the onset is usually insidious and there is a predominance among females.^{16,18,19} Chronic ITP occurs significantly less frequently in infants (23.1%) than in children over 10 years of age (47.3%).¹⁷

The recurrent form of ITP is defined as episodes of thrombocytopenia at intervals of > 3 months and occurs in 1–4% of children with ITP.^{20,21}

Familial ITP is a rare disorder^{22–27} and the precise nature of inheritance remains unclear.

Pathogenesis

The clinical signs and symptoms of ITP are caused by an increased rate of premature platelet destruction, which occurs preferentially in the spleen, liver, bone marrow and lung. The severity of thrombocytopenia thus reflects the balance between platelet production by megakaryocytes and the accelerated clearance of sensitized platelets. Thrombocytopenic bleeding occurs when the platelet counts fall below $10\text{--}50 \times 10^9/L$.

The pathogenesis of acute ITP is regarded as a consequence of inappropriate immune recovery after an infection.

Circulating antigens or antibodies may alter the platelet membrane. Alternatively, immune complexes derived from primary or underlying disease processes may nonspecifically adsorb to platelet surfaces, resulting in opsonization and destruction of young platelets (Fig. 23.2).^{27–31} Chronic ITP is attributed to autoantibodies directed against platelet constituents such as glycoproteins. Corroborating these findings, labeling studies^{32,33} of autologous or homologous platelets using ^{51}Cr or ^{111}In -oxine have shown that platelet survival is decreased in patients with ITP.^{34–39}

Platelet antigen and autoantibody

The main epitope for ITP-associated antibody binding lies on either the platelet GpIIb–IIIa or the GpIb–IX complex.^{11,12,41,42} There is also evidence that some antibodies implicated in ITP bind to glycolipids.⁴³ The sensitivity of platelet-associated antibody assays is 49–66% and the specificity 78–95%.^{44–46} In a controlled laboratory study,⁴⁷ platelet and plasma samples from 67 children and 23 adults with chronic ITP were evaluated for glycoprotein autoantibodies. As shown in Table 23.1, platelet-associated autoantibodies were detected in 26 of 36 (72.2%) children with thrombocytopenia of the chronic form and in 15 of 31 (48.4%) with a history of ITP but normal platelet counts at the time of sampling. Of 23 adults with chronic ITP, 12 of 18 (66.7%) with thrombocytopenia displayed platelet-associated antibodies. A significant correlation was noted between the platelet-associated autoantibody level and the patient's age at the time of diagnosis. Children with high platelet-associated autoantibody levels were older, with a mean age of 12.4 years (range 8–17 years) compared with an average age of 7.1 years (range 1–16) for children with moderate or negative autoantibody levels.

Fig. 23.2 Pathogenic aspects of platelet opsonization and phagocytosis. Reproduced with permission from Ref. 40.

Table 23.1 Antiglycoprotein antiplatelet autoantibody in chronic immune thrombocytopenic purpura (ITP).

	Ongoing ITP*	Prior ITP†
<i>Children (n = 67)</i>		
Autoantibody level‡ elevated	26/36	15/31
Autoantibody level‡ negative	10/36	16/31
<i>Adults (n = 23)</i>		
Autoantibody level‡ elevated	12/18	4/5
Autoantibody level‡ negative	6/18	1/5

* Ongoing ITP: platelet count at time of sampling < 150 × 10⁹/L.
† Prior ITP: history of platelet count < 50 × 10⁹/L for at least 6 months but with normal counts, without therapy, at the end of sampling.
‡ Autoantibody level: ratio of patient autoantibody value to that of the mean control value plus 3 standard deviations.
Reproduced with permission from Ref. 47.

These data suggest that there may be different forms of childhood ITP. Younger children with moderate autoantibody levels appear to have an increased likelihood of spontaneous remission or compensated disease with a platelet count > 20–150 × 10⁹/L. The course of adolescents with high autoantibody levels seems similar to that of adults, in whom spontaneous remission or compensation of ITP is unusual. In the above study,⁴⁷ children with a history of chronic ITP but normal platelet counts at the time of blood sampling had elevated autoantibody levels. This suggests a compensated form of ITP. However, recurrence of disease is likely to occur if this balance is altered by factors that decrease platelet production (i.e., viral infection) or that increase autoantibody production and/or platelet consumption.

Furthermore, the offspring of a mother with the compensated stage of ITP and platelet autoantibodies may be at risk of neonatal thrombocytopenia.

Platelet destruction

The mechanisms of platelet destruction are outlined in Fig. 23.2. The rapid destruction of platelets is due to either autoantibodies that bind via the antigenic site or immune complexes that bind via Fc receptors on platelets. These opsonized cells are rapidly removed by cells of the mono-nuclear phagocytic system. The quantity of antibodies correlates with the degree of thrombocytopenia.⁴⁸ Phagocytosis of platelets has been demonstrated by *in vivo* studies using reticuloendothelial blockade with monoclonal anti-Fc receptor antibodies.⁴⁹ The role of complement is documented by increased platelet-associated C4 and C3. *In vitro* studies show binding of C4 and C3 followed by platelet lysis after incubation of platelets with patients' plasma and fresh serum.⁵⁰

For effective platelet destruction, there must be sufficient antigens and autoantibodies on platelets. The specific anatomic configuration of the spleen is optimal for engulfment and subsequent phagocytosis.⁵¹ In some patients with ITP, the reticuloendothelial system of the liver may also be efficient in removing platelets. In the bone marrow, thrombopoiesis and intramedullary platelet destruction could be concomitantly inhibited as there is antibody production⁵² and antibody binding to platelets and megakaryocytes.⁵³ In addition, platelet kinetic studies showing decreased platelet delivery into the bloodstream suggest that intramedullary events may also be critical for clinical disease in many patients with ITP.^{39,54,55}

In addition, at the level of apoptosis, Fas (CD95) antibodies

result in prolonged persistence of lymphocytes and autoantibody production in patients with ITP as well as in those with autoimmune lymphoproliferative syndrome.^{56–58}

Immune regulation

Normally, the immune response to an antigenic challenge is well regulated. Initiated by antigen-presenting cells, the pathways of humoral and cell-mediated immunity are activated via cell–cell interactions and lymphokine production resulting, among other events, in the generation of cytotoxic T-effector cells and the secretion of specific antibodies. Regulatory mechanisms, possibly involving suppressor T cells and antiidiotypic antibodies, downmodulate the degree and duration of the immune response to a specific stimulus.

In ITP, the maintenance of self-tolerance and the effective immune response may be altered in the presence of an inflammatory process directed at another target cell than platelets. As shown in Table 23.2 and Fig. 23.3, multiple defects related to cellular immunity have been described in patients with ITP.^{13,59–74} Enhanced serum levels of HLA-DR molecules have been detected.^{75–77} In acute ITP, the transient increase in surface expression of HLA-DR molecules may be induced by proinflammatory cytokines such as interferon (IFN)- γ . As a consequence of immune activation, increased serum levels of IL-2 have been observed in various autoimmune disorders, including ITP.^{71,78–83} In parallel, high levels of IL-10 have also been detected. IL-10 is a potent stimulator of human B cells⁸⁴ and downmodulates the production of inflammatory cytokines by T cells (Th1) and monocytes/macrophages.⁸⁵ Increased serum concentrations of IL-2, IFN and/or IL-10 reflecting *in vivo* T-cell activation have been observed in patients with chronic ITP, but not in those with

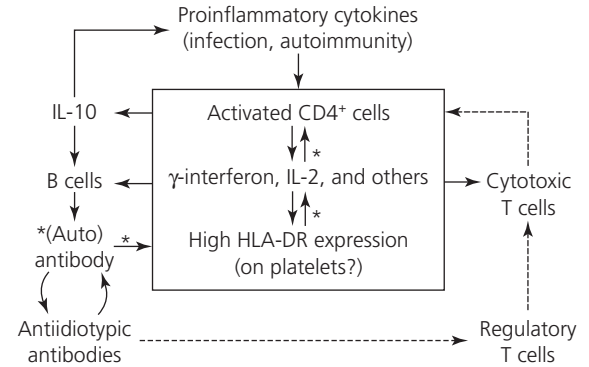

Fig. 23.3 Model of the immunopathogenesis of acute and chronic immune thrombocytopenic purpura (ITP). Dotted line represents hypothetical feedback. * Only in chronic ITP. Reproduced with permission from Ref. 88.

the acute form.^{71,86} Moreover, an increased serum concentration of IL-2 in chronic ITP correlates significantly with *in vitro* IL-2 secretion by platelet-stimulated T-helper cells.⁷¹

The difference in serum detection of IFN- γ , IL-2 and IL-10 expression suggests that different mechanisms operate in the pathogenesis of chronic versus acute ITP. It has been proposed that acute ITP may be due to a cross-reactive immune response directed against an infectious agent.⁸⁷ In contrast, chronic ITP may be perpetuated by a constant HLA-DR-stimulated immune response with enhanced cytokine production, increased activation of T cells, increased production of specific autoantibodies (Fig. 23.3) and disturbed apoptosis by prolonged persistence of lymphocytes.^{56,57} Therefore, both forms of ITP appear to result from an altered feedback mechanism critical for the termination of an immune response.

Clinical features and diagnosis

In the majority of children with acute ITP, thrombocytopenia occurs within 1–3 weeks after an infectious disease. Commonly, the infection is a bacterial or nonspecific viral (upper respiratory or gastrointestinal) infection. ITP may also occur after rubella, rubeola, chickenpox or live virus vaccination. The hemorrhagic manifestations depend on the degree of thrombocytopenia (Table 23.3) and are individually different. Common first signs of bleeding are easy bruising and skin petechiae. These signs occur with platelet counts below $20 \times 10^9/L$. Severe mucosal bleeding, hematuria and genital bleeding usually occur with platelet counts below $10 \times 10^9/L$. Adolescent girls may have prolonged menorrhagia. Intracranial hemorrhage (ICH) occurs in 0.5–1% of hospitalized children with ITP and is fatal in one-third.⁸⁹ The risk is greater during the initial days of thrombocytopenia but can occur at any time in ongoing ITP⁹⁰ and is also observed under various therapies. Salicylate-containing medications or antihistamines may increase the risk of bleeding.⁸⁹

Table 23.3 Staging due to platelet count and clinical manifestation and intervention guidelines in children with immune thrombocytopenic purpura.

Stage	Symptoms	Platelet count ($\times 10^9/L$)	Management
1	Normal daily life	$> 20\text{--}150$	Consent for observation
2	Troublesome bleeding	$> 10\text{--}20$	Punctual intervention to reach stage 1
3	Bleeding, \downarrow hemoglobin	< 20	Intervention

The characteristic features of history, physical examination and laboratory analysis are summarized in Table 23.4. Apart from bleeding and thrombocytopenia, there should be no other abnormal physical findings. Bone marrow examination is not necessary in patients displaying the typical signs and symptoms of ITP. In one study, 127 children with ITP diagnosed clinically were subjected to bone marrow examination but only five (4%) had abnormal cytologic findings not compatible with the diagnosis of ITP, and on closer examination all five had additional atypical features on presentation.⁹¹ Importantly, bone marrow examination is indicated for establishing the diagnosis in patients who fail to respond to treatment after 3–6 months.

Differential diagnosis

Initially, ITP has to be differentiated from other forms of thrombocytopenic bleeding disorders (Table 23.5). The bleeding manifestations in ITP are similar in presentation to the findings in patients with thrombocytopenia associated, for example, with bone marrow hypoproliferation. A decreased mean platelet volume suggests marrow hypoproduction of platelets or indicates findings characteristic of Wiskott–Aldrich syndrome. If there is anemia and leukocyte abnormalities, a bone marrow examination is required to rule out marrow diseases such as acute leukemia, aplastic anemia, myelodysplasia, lymphoma or metastatic disease. Autoimmune hemolysis, if suspected, can be confirmed by a Coombs test. If risk factors are present for human immunodeficiency virus (HIV) infection, serologic testing must be performed. Thrombotic thrombocytopenic purpura and hemolytic–uremic syndrome can be distinguished by the presence of hemolysis, a negative Coombs test, and microangiopathic red cell changes. Disseminated intravascular coagulation is associated with characteristic coagulation abnormalities. Splenomegaly may indicate hypersplenism.

Clinical course

Independent of treatment, complete remission of ITP occurs in 80–90% of children within 6 months and in over 90% within 3–37 years (Fig. 23.4).^{18,19,93–95} The 3–5% of children

Table 23.4 Elements of the history, physical examination and peripheral blood analysis in a child with suspected immune thrombocytopenic purpura.

History
Bleeding symptoms
Type of bleeding
Severity of bleeding
Duration of bleeding
History of prior bleedings
Systemic symptoms
Especially of recent (within 6 weeks) infectious illness
Exposure or vaccination or recurrent infections suggesting immunodeficiency
Symptoms of an autoimmune disorder
Medications
Heparin, sulfonamides and quinidine/quinine, which may cause thrombocytopenia
Aspirin, which may exacerbate bleeding
Risk of HIV infection, including maternal HIV status
Family history of thrombocytopenia or hematologic disorder
In an infant < 6 months old, include perinatal and maternal history
Comorbid conditions, which may increase the risk of bleeding
Lifestyle, including vigorous and potentially traumatic activities
Physical examination
Bleeding signs
Type of bleeding (including retinal hemorrhages)
Severity of bleeding
Liver, spleen and lymph nodes
Evidence of infection
Presence of dysmorphic features suggestive of congenital disorder, including skeletal anomalies, auditory acuity
Exclude specific congenital syndromes
Fanconi syndrome
Thrombocytopenia with absent radii
Wiskott–Aldrich syndrome
Alport syndrome (and its variants)
Bernard–Soulier syndrome
May–Hegglin anomaly
Gray platelet syndrome
Peripheral blood analysis
Thrombocytopenia: platelets are normal in size or may appear larger than normal, but consistently giant platelets (approaching the size of red blood cells) should be absent
Normal red blood cell morphology
Normal white blood morphology, normal reticulocyte count

Reproduced with permission from Ref. 92.

who do not display remission have chronic ITP (Table 23.6). Children who have chronic ITP are mostly over 7 years of age and are rarely those with postinfectious ITP. Recurrent ITP, defined as periodic episodes of thrombocytopenia at intervals of > 3 months, occurs in 4% of children with acute ITP.^{20,21} In children with persistent ITP of 3–6 months’ duration, additional laboratory testing is indicated (Table 23.7).

ICH occurs in 0.5–1% of hospitalized children with ITP and is fatal in one-third despite treatment with corticosteroids⁸⁹

or intravenous immunoglobulin (IVIg).¹⁰⁷ Postsplenectomy sepsis constitutes the other major cause of death in children with ITP (Table 23.6). Only limited observational data are available regarding the complications of ICH. In a review of

14 children with ICH, Woerner *et al.*⁸⁹ reported that four children died and two others may have had neurologic long-term effects. Of 30 children with ICH described in a retrospective study by the American Society of Hematology,⁹² this complication occurred in 12 patients (40%) within 12 days after diagnosis, including in two with a history of head trauma. ICH in the other 18 patients occurred after 1 month to 5 years of diagnosis, and was typically associated with the administration of glucocorticoids and/or splenectomy subsequent to a lack of remission. At least 24 of these 30 patients were reported prior to 1981 when the benefits of IVIG therapy in ITP were initially described.⁷ This finding argues against immunosuppression and/or splenectomy in the long-term treatment of ITP.

Unlike ITP in adults, persistent thrombocytopenia is uncommon in children. In the 12 series summarized in Table 23.6, ITP resolved in 1207 (76%) of the 1597 children. Clinical features of the presenting illness and parameters associated with an increased risk of chronic persistent thrombocytopenia included a history of purpura for more than 2–4 weeks before diagnosis,^{93,94,96–98,107} female sex,^{93,95,99,100} age over 10 years,^{95,99,100} and a platelet count at presentation in excess of $20 \times 10^9/L$.⁹⁵ The fate of children with chronic ITP is uncertain, although about one-third appear to have spontaneous remission several months to many years after diagnosis (Fig. 23.4).^{93,108–111}

Management

General aspects

Parents and the child/adolescent with ITP are often worried about bleeding. They are concerned by low platelet counts and perturbed by lifestyle restrictions.¹¹² On the other hand, the physician knows the low risk of severe bleeding but cannot indicate prognostic risk factors and the real origin of the disorder. The Intercontinental Childhood ITP Study (ICIS) Registry II entitled “Frequency, location and timing of hemorrhage in children with newly diagnosed ITP”¹¹³ collected 1015 children prospectively. From this cohort, 629 children initially had platelet counts $\leq 20 \times 10^9/L$: 20/629 (3.2%) had severe bleeding, 150 (23.6%) moderate and 459 (73%) mild or no bleeding, which is in accordance with the British assessment¹¹⁴ and the single-center analysis in the USA.¹¹⁵ Some experienced hematologists^{116,117} and the British guidelines¹¹⁴ would only give medical treatment to a patient with severe or troublesome bleeding.

With this in mind, treatment is indicated in children either at risk, or with overt signs, of bleeding. Table 23.3 summarizes the recommendations for the treatment of ITP in children according to a staging system. Hospitalization is required for severe bleeding regardless of the platelet count. Treatment is indicated for a child with troublesome bleeding

and a platelet count below $20 \times 10^9/L$ (stage 2). The goal is to reach stage 1, where no active intervention/treatment but observation is recommended. In stage 1, the physician should obtain consent from the individual patient/parents for observation in the presence of normal daily life. Therapeutic measures in the acute management of ITP should be maintained until bleeding has ceased and the platelet count has reached hemostatic levels (i.e., $> 20 \times 10^9/L$). However, continued treatment beyond this defined point is not indicated. Moreover, it also seems unnecessary to treat patients without signs of bleeding and with platelet counts in excess of $10\text{--}20 \times 10^9/L$.

Recent insight into the immunopathogenesis of ITP (see above) has formed the clinical base for novel therapeutic strategies. The therapy of ITP focuses on measures modulating the immune response and includes IVIG,^{7,118} anti-Rh(D) immunoglobulin,¹¹⁹ monoclonal anti-CD20 antibody (rituximab),¹²⁰ and eventually IFN- α .¹²¹ Immunosuppressive treatment with corticosteroids^{122–124} is used as an alternative therapeutic strategy and cytostatic agents,^{125–132} splenectomy,^{93–100,107–109,133–136} and other treatment possibilities are only indicated in special situations. The mechanisms of action of the therapies employed in ITP have been recently reviewed by Cines and Blanchette.¹³⁷

The following recommendations focus on children with bleeding symptoms (stage 2 or 3; see Table 23.3) and are generally in accordance with the practical guidelines of the American Society of Hematology for diagnosis and treatment of ITP.⁹²

There is a considerable amount of convincing evidence-based data available on incidence, demographics, natural history and management of ITP. Retrospective case series,⁹² surveys,^{138,139} guidelines,^{140,141} assessments,¹¹⁴ reports from expert meetings,¹⁴² and consensus conferences^{143,144} are the sources of information for patient management. As a result of the heterogeneity of ITP and various controversies, current practice does not always follow the recommendations. Prospective evidence-based studies are needed. Since 1997 the ICIS group has been establishing an international network of physicians and scientists collaborating in prospective databases and studies (see www.unibas.ch/itpbasel) that will define less heterogeneous patient subgroups for controlled treatment efficacy trials. Indeed, the first results are promising.^{16,17,145,146} The ongoing Pediatric and Adult Registry of Chronic ITP database for children and adults with ITP has the objective of defining subgroups within ITP on the basis of natural history, genetics, quality of life and other criteria. One of the side studies will focus on genetic differences. In these studies, polymorphisms and variations of genes^{147,148} in patients with ITP, which might be involved in loss of tolerance and unbalanced immune responses, have shown variants in IL-1 haplotypes and association with autoimmune disease.

Table 23.8 Immediate response rate (platelet count $> 20 \times 10^9/L$) to different treatment regimens.^{150,151}

Randomized group	Rapid responders (≥ 72 hours) (%)
No treatment	9/16 (56)
Intravenous anti-Rh(D) 25 $\mu g/kg$ for 2 days	31/38 (82)
Corticosteroids 4 mg/kg daily for 7 days	45/57 (79)
Intravenous immunoglobulin 1 g/kg daily for 2 days	50/53 (94)
Intravenous immunoglobulin 0.8 g/kg once	34/35 (97)

Acute bleeding

Acute bleeding in children with ITP (stage 2 or 3; see Table 23.3) may warrant a rapid increase in platelets. As a follow-up of earlier studies,¹⁴⁹ two Canadian multicenter studies prospectively analyzed children diagnosed with acute ITP and platelet counts below $20 \times 10^9/L$.^{150,151} The first study compared treatment using IVIG or corticosteroids with no intervention.¹⁵⁰ The second trial randomized treatment with IVIG, oral corticosteroids or intravenous anti-Rh(D).¹⁵¹ The results are summarized in Table 23.8, which details specifically the effect of each therapeutic regimen within 72 hours after initiation. Both studies demonstrated that IVIG produced the fastest recovery to safe, hemostatic platelet counts. Treatment with corticosteroids 4 mg/kg body weight given daily for 7 days was recommended as the second choice. However, long-term corticosteroid treatment in children should be avoided due to unacceptable side-effects. In addition, the second study found that a single dose of IVIG 0.8 g/kg was sufficient and comparable to the more traditional larger dose of 2 g/kg given over 48 hours. Treatment with the lower IVIG dose decreases the duration and cost of hospitalization. Based on these findings, the American Society of Hematology panel recommends the use of IVIG in preference to corticosteroids for the treatment of children with ITP.⁹²

Table 23.9 summarizes studies of the effectiveness of corticosteroids, IVIG and anti-Rh(D), and Table 23.10 shows standard treatment regimens and dosages.

Emergency treatment

Severe life-threatening bleeding justifies intervention, including IVIG (0.8–1 g/kg per dose), high-dose intravenous methylprednisolone 30 mg/kg or dexamethasone 1–2 mg/kg, and platelet transfusions. The latter should be given as a third line of treatment because transfused platelets may survive longer *in vivo* after IVIG and/or corticosteroid administration. Emergency splenectomy in urgent life-threatening bleeding is not recommended.⁹²

Mild bleeding and long-term bleeding problems

Children with a history of mild bleeding or recurrent bleeding should receive treatment aimed at maintaining their platelet count at a level that renders them free of symptoms (stage 1; see Tables 23.3 and 23.10). This level is individual and patients at increased risk of hemorrhage (i.e., those playing contact sports, undergoing surgery, etc.) may benefit from additional therapy. Recommended treatment modalities are IVIG (0.4–0.8 g/kg at 2–8 week intervals) or corticosteroids (2–4 mg/kg for 4 days). Children and adolescents who fail to respond to IVIG or corticosteroids, i.e., do not maintain safe platelet counts, may benefit from one of the following treatment regimens (see below): anti-Rh(D), IFN- α or, in special circumstances, plasma exchange, protein A immunoabsorption of antibodies or administration of cytostatic agents. The role of ascorbic acid in the treatment of ITP remains uncertain.

Prolonged response to long-term cyclic treatment versus natural course of ITP

The long-term effects of treatment in ITP must be interpreted with caution, since the natural history of ITP in children and in some young adults is one of gradual spontaneous resolution.^{106,110,111,158} Several studies have reported that patients with chronic ITP display long-lasting recovery (sustained platelet counts $> 20 \times 10^9/L$) when treated with repeated courses of IVIG (Table 23.10)^{160–162} with a high-dose cyclic dexamethasone regimen or with methylprednisolone.^{124,157,159,163} Andersen¹²⁴ treated 10 adults with persistent symptomatic ITP with six cycles of oral dexamethasone (40 mg/day for 4 days every 4 weeks). All patients demonstrated a therapeutic response with platelet counts $> 100 \times 10^9/L$ for at least 6 months after completion of treatment. Adult patients tolerated this treatment well. In contrast, children with chronic ITP given a comparable dexamethasone regimen demonstrated not only a less impressive response to treatment but also suffered significant side-effects (fatigue, weight gain, difficulty in sleeping, significant behavioral changes, hyperadrenocorticism, transient increase of blood glucose levels).¹⁶⁴ Based on these observations, there is a need for adequately controlled studies to determine whether long-term or cyclic treatments can alter the natural course of chronic ITP in children.

Refractory ITP

A minority of children have the refractory chronic form of ITP with bleeding problems (stage 2 or 3; see Table 23.3). The aim of management is to reach stage 1 ITP with minimal intervention and to prevent bleeding. If bleeding is not under control, other medical treatment options (see below and Table 23.12) or splenectomy has to be considered.

Table 23.9 Effectiveness of corticosteroids, intravenous immunoglobulin (IVIg) and anti-Rh(D).

Reference	Study population			Outcome			Adverse effects
	Number	Age	Follow-up	Randomized treatment arms	Outcome measure	Outcome result	
152	27	6 years (mean)	NR	Prednisone (2 mg/kg daily for 21 days) No treatment	Median time to platelet count of $150 \times 10^9/L$	21 days 60 days ($P \leq 0.3$)	NR NR
153	93	6 months to 16 years	> 6 months	Prednisone (60 mg/m ² daily for 21 days, then tapered) Placebo	Proportion with platelet count > 30 and > $100 \times 10^9/L$, and negative Rumpel–Leede test	Prednisone > placebo ($P < 0.01$)	NR
154	27	< 11 years	28 days	Prednisone (2 mg/kg daily for 14 days, then tapered to day 21) Placebo	Platelet count, bleeding time, clinical bleeding score at day 0–28	Prednisone > placebo ($P < 0.05$) only at day 7	Increased appetite, weight gain
149	94	< 16 years	1 year	Prednisone (60 mg/m ² daily for 21 days, follow-up protocol for poor response/remissions) IVIg (0.4 g/kg daily for 5 days, follow-up protocol for poor response/remissions)	Proportion with platelet count > $100 \times 10^9/L$	77%	77% with weight gain or acne
155	61	2–12 years	> 6 months	Prednisone (0.5 mg/kg daily for 1 month or until platelet normalization) Prednisone (1.5 mg/kg daily for 1 month or until platelet normalization)	Proportion with platelet count > $150 \times 10^9/L$	62% 81% ($P < 0.05$)	22% with headache, fever, vomiting, vertigo NR NR
156	160	< 15 years	> 12 months	Prednisone (0.25 mg/kg daily for 3 weeks) Prednisone (1 mg/kg daily for 3 weeks)	Proportion with platelet count > $100 \times 10^9/L$ for > 3 months	71% 77% (no difference)	NR NR

157	30	2 months to 15 years	> 6 months	Methylprednisolone (10 mg/kg i.v. daily for 5 days) Prednisone (2 mg/kg daily for 4 weeks) IVIg (0.4 g/kg daily for 5 days)	Mean platelet count on days 1–14	Methylprednisolone = IVIg > prednisone ($P < 0.001$)	NR NR NR
158	20	2 months to 11 years	> 6 months	Methylprednisolone (30 mg/kg p.o. daily for 3 days, then 20 mg/kg daily for 4 days) IVIg (0.4 g/kg daily for 5 days)	Proportion with platelet count > $150 \times 10^9/L$ at 3 days and 6 months	60%, 90% (no difference)	NR
150	53	7 months to 14 years	180 days	Prednisone (4 mg/kg daily for 7 days, then tapered to day 21) IVIg (1 g/kg daily for 2 days) No therapy	Median time to platelet count > $20, > 50 \times 10^9/L$	2 days, 4 days 1 day, 2 days ($P < 0.01$ vs. prednisone) 4 days, 16 days ($P < 0.1$ vs. either treatment)	NR Weight gain, behavioral change, 75% with nausea, vomiting, headache, fever
151	146	6 months to 18 years	6–32 months	Prednisone (4 mg/kg daily for 7 days, then tapered to day 21) IVIg (1 g/kg daily for 2 days) IVIg (0.8 g/kg once only) Anti-Rh(D) (25 µg/kg daily for 2 days)	Median time to platelet count > $20, > 50 \times 10^9/L$	2 days, 3 days 2 days, 2 days 1 day, 2 days ($P < 0.05$ vs. prednisone) 2 days, 2.5 days ($P < 0.05$ vs. both IVIg regimens)	None 16–18% with fever, nausea, vomiting, headache 24% with hemoglobin < 10 g/dL
159	57	2 months to 17 years	6 months	Methylprednisolone (30 mg/kg p.o. daily for 7 days) Methylprednisolone (50 mg/kg p.o. daily for 7 days) IVIg (0.5 g/kg daily for 5 days)	Mean platelet count on days 0–30	Mean > $100 \times 10^9/L$ by day 4. No difference among groups	Increased appetite and Cushingoid appearance Increased appetite and Cushingoid appearance 1 patient with aseptic meningitis, 2 with headache, vomiting

NR, not reported.

Table 23.10 Standard treatment modalities for children with immune thrombocytopenic purpura.

<i>Intravenous immunoglobulin (IVIG)</i>
Initial treatment: 0.8 g/kg once. Repeat the same dose if platelet count is < 30 × 10 ⁹ /L on day 3 (72 hours after first infusion)
In emergency bleeding: 1–2 times 0.8 g/kg, eventually together with corticosteroids and platelet transfusion Treatment in chronic ITP: 0.4 g/kg once every 2–8 weeks
<i>Corticosteroids</i>
Prednisone 4 mg/kg daily orally or intravenously for 7 days, then tapering over a 7-day period
In emergency bleeding: methylprednisolone 8–12 mg/kg i.v. or dexamethasone 0.5–1.0 mg/kg i.v. or orally, together with IVIG or platelet transfusion
<i>Anti-Rh (D) antibody</i>
50 µg/kg i.v.

Specific treatment modalities

Standard treatment (see Table 23.10)

Immunoglobulin

IVIG treatment of children with ITP (platelet count < 20 × 10⁹/L) resulted in a quicker and more extensive increase in platelet counts compared with patients receiving corticosteroid therapy.^{7,149–151,161,162} Importantly, a single daily dose of IVIG 0.8 g/kg appears to have the identical initial effect as five IVIG doses of 0.4 g/kg or two IVIG doses of 1.0 g/kg given each day.¹⁵¹ Adverse effects noted with IVIG include flu-like symptoms such as headache, backache, nausea and fever.^{150,151,165,166} Aseptic transient meningitis is a rare complication.¹⁶⁰ It is important to use quality-controlled, commercially available (not experimental) intact 7S IgG preparations from which there is no risk of hepatitis infection.^{167–170}

Mechanism of action

Following the observation that IVIG is clinically effective, it was hypothesized that the inhibition of platelet destruction by phagocytosis may have resulted from blockade of Fc receptors (FcRs).^{171,172} FcRs are expressed on a range of cells and are functionally important for scavenging immunoglobulin-sensitized cells such as platelets. The plausibility of this explanation is underscored by the finding that anti-Rh(D)-coated erythrocytes also show prolonged survival with IVIG treatment.¹⁷² A decrease in leukocyte counts or the size of the various lymphocyte subpopulations is inversely proportional to the platelet counts during IVIG treatment.^{173,174} These observations suggest that not only FcRs on mononuclear phagocytes but also those on other cells are affected

by IVIG infusion. In a murine model of passive ITP, Samuelsson *et al.*¹⁷⁵ demonstrated that IVIG requires the presence of the inhibitory low-affinity IgG receptor Fcγ RIIB and that monocytes from IVIG-treated mice begin to express Fcγ RIIB at increased levels within 4 hours of IVIG exposure. Since the humoral immune response *in vivo* works in concert with the cellular immune response and vice versa, IVIG could modulate the synthesis and release of cytokines from FcR-bearing lymphocytes and monocytes.^{59,176,177} *In vitro*, IgG administration induces downregulation of IL-6, IL-2, IL-10, IFN-γ and tumor necrosis factor (TNF)-β in lipopolysaccharide-stimulated monocytes, and reduces IL-2 receptor expression in activated lymphocytes.^{178,179} In ITP, overproduction of IL-4 has been reported in one study,¹⁸⁰ while high levels of IL-2, IL-10, IFN-γ and TNF-α have been described in other studies.^{76,181} Availability of FcRs may be altered by IgG dimers or larger complexes in the IVIG preparations, or by erythrocyte alloantibodies.¹⁸² Inhibition of complement activation by IVIG is another possible mechanism of action.¹⁸³ In addition, at the level of apoptosis,^{56,57} antiidiotypic Fas (CD95) antibodies in IVIG stop the prolonged persistence of lymphocytes and autoantibody production in patients with ITP as well as in those with autoimmune lymphoproliferative syndrome.¹⁸⁴

Long-term effects following IVIG administration (Table 23.11) may be induced by antiidiotypic antibodies. As mentioned above, antibodies against GpIIb–IIIa and GpIb–IX can be identified in 70–80% of children and adults with chronic ITP.^{11,47} It has been demonstrated that IVIG contains antiidiotypic antibodies against anti-GpIIb–IIIa autoantibodies and these inhibit the binding of autoantibodies to platelet GpIIb–IIIa.¹⁸⁵ Thus, restoration of the balance within the anti-idiotypic network or, alternatively, suppression of secretion of antiidiotypic antibodies may lead to long-term improvement of ITP.^{186–188} In this context, it is of note that the size of the donor pool from which IVIG is prepared may be relevant, as the chance that a given antibody idio type is recognized and bound by a complementary antiidiotypic antibody is obviously dependent on the donor-pool size.¹⁸⁹

Table 23.11 Studies showing long-term improvement for therapy with intravenous immunoglobulin.

Study	Total in study	Long-term improvement
<i>Children</i>		
Imholz <i>et al.</i> ¹⁶¹	42	22 (52%)
Bussel <i>et al.</i> ¹⁹⁰	12	5 (42%)
<i>Adults</i>		
Bussel <i>et al.</i> ¹⁹¹	40	16 (40%)
Godeau <i>et al.</i> ¹⁹²	18	7 (39%)

Corticosteroids

The mechanism of action of corticosteroids in ITP remains uncertain. Corticosteroids may inhibit the phagocytosis of antibody-bearing platelets¹⁹³ and may suppress antibody production by B lymphocytes.^{194,195} Other indirect mechanisms may account for the beneficial therapeutic effect of corticosteroids: maintenance of capillary integrity^{196–203} or inhibition of vascular prostacyclin synthesis leading to normalization of the possible prolonged bleeding time in ITP.^{204,205}

In randomized clinical trials,^{150,151} the median time to achieve a platelet count $> 50 \times 10^9/L$ was 4 days if patients received prednisone 4 mg/kg daily for 7 days. In contrast, children receiving no treatment displayed comparable platelet counts only 16 days after onset of disease. The higher dosage of steroids (4 mg/kg daily) is preferable to the classical dose of 2 mg/kg daily of oral prednisone for 21 days^{122,154–156} because the side-effects are fewer and less extensive. Methylprednisolone in very high doses for several days (10–30 mg/kg oral or intravenous methylprednisolone daily) has been administered in uncontrolled studies and resulted in a dramatic increase in platelet counts with long-term improvement in some but not all patients.^{123,159,163,206–209} Adverse effects include signs and symptoms of hypercortisolism, such as facial swelling, weight gain, hyperglycemia, hypertension and behavioral abnormalities. Long-term application of high corticosteroid dosages has the risk of growth retardation and cataracts,²¹⁰ and should thus be avoided. Sustained corticosteroid doses of 0.5–0.7 mg/kg daily may suppress platelet formation as well.^{211,212}

Anti-Rh(D) immunoglobulin

The rationale for using anti-Rh(D) as a therapeutic measure in ITP is based on the hypothesis that an increase in platelet count following IVIG therapy may be due to competitive inhibition of the monocyte/phagocyte system as effected by the preferential sequestration of autologous erythrocytes sensitized by alloantibodies present in the IgG preparations. Indeed, a clinical trial by Salama *et al.*²¹³ demonstrated a clinical effect. Administration of anti-Rh(D) globulin to Rh-positive patients with ITP resulted in a significant increase in platelet counts ($> 20 \times 10^9/L$) in 6 of 10 patients. Other uncontrolled studies have demonstrated that anti-Rh(D) treatment may increase the platelet count in approximately 80% of Rh-positive children.^{214–217} However, a controlled clinical study showed that anti-Rh(D) therapy was less effective in comparison with IVIG or corticosteroids, demonstrating a prolonged delay in achieving platelet counts of $20 \times 10^9/L$ as well as $50 \times 10^9/L$.¹⁵¹ The therapeutic effect of antiRh(D) usually lasts for 1–5 weeks and appears to depend on the presence of an intact spleen.

The recommended dose is 50 µg/kg intravenously. Adverse effects include alloimmune hemolysis. With this

Table 23.12 Treatment options in refractory immune thrombocytopenic purpura (see text for dosage and other details).

Current treatment options

Vinca alkaloids
Azathioprine
Cyclophosphamide
Cyclic high-dose corticosteroids
Danazol
Plasmapheresis or protein A immunoadsorption
Ascorbic acid (vitamin C)
Splenectomy

Recent treatment options

Treatment influencing antigenemia
Treatment influencing the T-cell immune response: ciclosporin, CTLA-4-Ig
Treatment influencing the B-cell immune response: anti-CD20 monoclonal antibody (rituximab), anti-CD52 monoclonal antibody (alemtuzumab), interferon- α
Other options: thrombopoietin, autologous hematologic stem cell transplantation

treatment, children develop a positive direct Coombs test, which is accompanied by a transient decrease in hemoglobin concentration for 1–2 weeks.^{151,216} The higher single dose of 75 µg/kg seems to increase platelet count as rapidly as IVIG. However, a higher rate of the adverse effect of hemolysis has to be taken into consideration.

Treatment of refractory ITP

If standard treatment is ineffective, the following options for refractory ITP should be considered (Table 23.12) (for overview of mechanisms of action see Cines and Blanchette¹³⁷).

Conventional treatment options

Vinca alkaloids

The use of vinca alkaloids in ITP is based on the observation that the administration of vincristine and vinblastine can cause lymphocytopenia and suppression of antibody production. The increase in platelets after treatment with vincristine or vinblastine lasts 1–3 weeks in two-thirds of patients.^{125,126,218–226}

The recommended dose of vincristine is 1–1.5 mg/m² intravenously (maximal single dose 2 mg) every 1–2 weeks. Combination with oral corticosteroid 1–2 mg/kg daily for 3 days may enhance the effect. For vinblastine the recommended dosage is 6 mg/m² intravenously every 1–2 weeks. Adverse effects include neuropathy, constipation, leukopenia and fever. The infusion of vinblastine-loaded platelets has not shown convincing results.²²⁰

Azathioprine

Azathioprine, an immunosuppressive drug, was the first

compound reported to be effective in chronic ITP refractory to glucocorticoid treatment and splenectomy; 50–70% of patients may achieve an improvement. Continuous treatment for 4 months appears to be necessary before a patient is considered unresponsive. The recommended dose is 50–300 mg/m² by mouth daily. Adverse effects are mainly leukopenia and the risk of developing malformations during pregnancy.

Cyclophosphamide

Of patients treated with cyclophosphamide, 60–80% will respond with an increase in platelet count.^{127–132} Although of similar therapeutic potency as azathioprine, cyclophosphamide has more severe side-effects. The recommended dose is 3–8 mg/kg by mouth daily. Adverse effects are leukopenia, alopecia, infertility, teratogenicity and urinary bladder hemorrhage.

Cyclic high-dose methylprednisolone

Cyclic high-dose methylprednisolone (20–30 mg/kg i.v.) or dexamethasone (1 mg/kg orally) can be given on three to four consecutive days every 4 weeks for 4 months.^{124,157,159,163} However, both the adverse effects and response rates of these high-dose corticosteroid regimens are disappointing in children.¹⁶⁴

Danazol

The use of danazol, an androgenic steroid with minimal virilizing effects, was suggested for the treatment of ITP because one of the documented side-effects is thrombocytosis. There is a broad range of response to danazol in patients with ITP (10–80%).^{232–249} The recommended dose is 100–150 mg/m² orally three times daily. Adverse effects include weight gain, headache, hair loss, liver dysfunction, myalgia, amenorrhea, some virilization and even thrombocytopenia.

Plasma exchange and protein A immunoadsorption

Plasma exchange^{250–252} and protein A immunoadsorption^{253–256} are *ex vivo* physical measures to remove antiplatelet antibodies. In 20–30% of patients with chronic ITP, plasma exchange may transiently result in a response. In one report using protein A immunoadsorption to remove antiplatelet antibodies, 16 of 72 patients demonstrated a sustained platelet increase.²⁵³ This extracorporeal treatment is required daily for 3–5 days.

Ascorbic acid (vitamin C)

Although a response rate of 15% has been reported, the role of ascorbic acid in the treatment of ITP remains to be determined.^{257–264} The recommended dose is 1–1.5 g/m² by mouth daily.

Splenectomy

Splenectomy as a therapeutic intervention in children with

ITP should be restricted to those with uncontrollable bleeding. Recent studies document the decline in rates of splenectomy.^{109,190,208} Splenectomy is indicated in children in whom thrombocytopenia has persisted for over 1 year in association with substantial bleeding episodes. In 16 reports (277 children in total), 72% of patients with ITP achieved a remission following surgical splenectomy.^{93–100,107–109,133–136}

Elective splenectomy in children with chronic ITP is only recommended if platelet counts remain below $10 \times 10^9/L$ in the absence of treatment (IVIG, corticosteroids, anti-RhD) for more than 14 days or in instances of severe and repetitive hemorrhage. It is paramount that children are immunized against *Haemophilus influenzae*, pneumococci and meningococci prior to splenectomy.²⁶⁵

Adverse effects

The important late effect of splenectomy is the increased risk of fatal bacterial infections, particularly in children below 5 years of age; a fatality rate of 1 in 300–1000 patient-years has been calculated.^{265–267} The difficulty is therefore to decide whether the adverse effects of splenectomy outweigh its potential benefits since spontaneous recovery from ITP has been observed many years after diagnosis.^{108,268}

Recent treatment options

New therapeutic developments have the main goal of influencing the altered immune response associated with ITP.

Treatment influencing antigenemia

Platelet counts were improved after antibacterial eradication of *Helicobacter pylori* and a positive urea breath test for *H. pylori* associated with gastritis or peptic ulcer disease in patients with chronic ITP.^{269,270} Downmodulation of antigenemia may also be the reason for the improvement seen during antiviral treatment in patients with HIV-related thrombocytopenia.²⁷¹

Treatment influencing the T-cell immune response

Ciclosporin

In child or adult patients with normal renal function, ciclosporin causes a dose-dependent increase in platelet count.^{272–274} The dose of ciclosporin should be adjusted according to the serum level and with the aim of achieving a safe thrombocyte count. In this way, low-dose ciclosporin treatment with less adverse effects may be possible.^{272–274} In one study, the long-term response rate in refractory idiopathic ITP was 11 of 20 patients (five complete responses, six partial responses) after discontinuation of treatment.²⁷⁴ No large study exists.

CTLA-4-Ig

CTLA-4-Ig, a fusion protein between CTLA-4 and the immunoglobulin Fc portion, aims to block T-cell costimulation.²⁷⁵ This treatment was successfully used in patients with

psoriasis. Such a drug may also be effective in other autoimmune disorders driven by dysregulated T cells, including ITP, but no data are yet available.

Treatment influencing the B-cell immune response

Anti-CD20 monoclonal antibody (rituximab)

(for overview see ref. 120)

The human/mouse anti-B-cell monoclonal antibody rituximab is a κ immunoglobulin with murine light- and heavy-chain variable sequences and human constant sequences.²⁷⁶ The chimeric molecule binds to the CD20 antigen on B cells and mediates its lysis by immune effector cells. Among other autoantibody-producing disorders, refractory ITP and Evans syndrome benefit from rituximab.²⁷⁷ With three to four courses of rituximab (375 mg/m² i.v. per week for 4 weeks), approximately two-thirds of patients had an increase in platelet count and some had long-lasting responses (>6 months). Adverse events during treatment were transient and mild, and comprised fever, chill, headache, dizziness, asthenia, nausea, vomiting and hypotension. No infections were noted.

Anti-CD52 monoclonal antibody (alemtuzumab)

CD52 antigen is present on lymphocytes and monocytes.^{278,279} Monoclonal antibody directed against CD52 (alemtuzumab) is effective in clearing B lymphocytes. Of 21 children and adults with hemolytic anemia, pure red cell aplasia, ITP or Evans syndrome, 15 showed a response to treatment with alemtuzumab; some patients had a sustained response.²⁸⁰ Adverse effects during treatment included fever and chill. Serious adverse effects can potentially occur with alemtuzumab, such as profound lymphocytopenia (with potential for opportunistic infection), intravenous hemolysis, systemic venous thrombosis, or thrombotic thrombocytopenic purpura.

Interferon- α

Uncontrolled studies with IFN- α showed a response rate of 25% in children and adults with chronic ITP.^{121,281} However, it may not be feasible to conduct the essential controlled trials needed to establish the efficacy of IFN in ITP because the drug is associated with significant adverse effects, a difficult mode of application (300 000 units i.m. three times weekly for 4 weeks) and is expensive.

Other options

Thrombopoietin may be effective in those patients with ITP and megakaryocyte involvement (depletion by specific antibodies). Initial data have shown favorable responses.²⁸²

Autologous hematologic stem cell transplantation has been performed in 12 adult patients with severe refractory ITP.²⁸³ Four patients achieved complete remission and two patients partial remission. This approach must be considered experimental.

Thrombocytosis

Christof Dame

Introduction

Thrombocytosis occurs in up to 15% of hospitalized infants and children. In almost all cases, platelet counts are elevated secondary to infection, anemia, surgery, chronic inflammatory disorders, malignancies, or pharmaceutical agents (reactive thrombocytosis).¹⁻⁴ In contrast, essential thrombocytosis is very rare in children and is subdivided into nonfamilial and familial forms. Since essential thrombocytosis is a myeloproliferative disorder, such as chronic myelogenous leukemia, polycythemia vera and idiopathic myelofibrosis (agnogenic myeloid metaplasia), in any child with newly recognized thrombocytosis the question should be addressed whether thrombocytosis is reactive or a sign of a primary hematopoietic disorder. It is also necessary to analyze the immediate risk of the child developing thrombosis or hemorrhage, and to decide how this risk should be managed. To answer these questions, fundamental knowledge of the pathogenesis, clinical manifestation, diagnosis, prognosis, and treatment of essential and reactive thrombocytosis is required.

Definition and classification of thrombocytosis

Thrombocytosis in children is defined by an elevated platelet count, as in adults. A normal platelet count of $150-450 \times 10^9/L$ is generally accepted for healthy preterm and term neonates, infants, children, and adolescents. However, the definition of thrombocytosis varies, from a platelet count $> 400 \times 10^9/L$ to one $> 1000 \times 10^9/L$.⁵ In order to consider the characteristics and clinical implications of thrombocytosis and to compare published data, the following arbitrary classification of thrombocytosis has been chosen in most recent publications.

- Mild thrombocytosis: platelet count > 450 and $< 700 \times 10^9/L$.
- Moderate thrombocytosis: platelet count > 700 and $< 900 \times 10^9/L$.

- Severe thrombocytosis: platelet count $> 900 \times 10^9/L$.
- Extreme thrombocytosis: platelet count $> 1000 \times 10^9/L$.^{5,6}

Thrombocytosis is classified into an essential (primary) and a reactive (secondary) form. Essential thrombocytosis is a myeloproliferative disorder, caused by monoclonal or polyclonal abnormalities of hematopoietic cells or by abnormalities in the biology of thrombopoietin (Tpo), the primary regulator of megakaryopoiesis. Reactive thrombocytosis is caused by stimulated megakaryopoiesis in the absence of a chronic myeloproliferative/dysplastic disorder of hematopoiesis. Reactive thrombocytosis is associated with various hematologic or nonhematologic diseases, and platelet counts normalize after resolution of the underlying medical condition.

Symptoms of thrombocytosis in childhood

Regardless of its pathogenic origin, thrombocytosis can cause thrombosis (particularly in the vena cava, subclavian vein, renal vein, or intracerebral vessels), hemorrhage (particularly epistaxis) and vasomotor complications (especially headache, visual symptoms, light-headedness, seizures). These complications are much less likely to occur in reactive than in essential thrombocytosis. However, many children remain asymptomatic, even in extreme thrombocytosis with platelet counts in excess of $1000 \times 10^9/L$.^{1,7,8}

Diagnostic features of thrombocytosis

Counting of platelets

A gold standard for the method of blood sampling (venous or capillary blood sample) or platelet counting (automated cell counter, counting under the microscope) is still not defined. If an abnormal platelet count has been found by automated cell counting, analysis of a blood smear is necessary to exclude morphologic abnormalities of platelets or other blood cells,

such as abnormal platelet granules, cytoplasmic fragments, red cell fragments, or extremely microcytic red blood cells.⁶

Other diagnostic features of thrombocytosis

In most children with thrombocytosis, clinically apparent symptoms of an active underlying systemic disease or medical condition causing stimulated megakaryopoiesis may be evident. However, in single cases, it can be very difficult to differentiate between essential and reactive forms of thrombocytosis. The initial laboratory analysis of complete blood count, including examination of the peripheral blood smear, and of serum ferritin concentration is helpful to differentiate the origin of thrombocytosis. These tests allow exclusion of iron deficiency, hyposplenism or asplenia (Howell–Jolly bodies), and inflammatory or infectious conditions (neutrophilic leukocytosis, increased numbers of neutrophilic band forms and/or metamyelocytes, neutrophilic vacuolization, toxic granules) as indices for reactive thrombocytosis. If these tests are unrevealing, additional measurements of C-reactive protein, interleukin (IL)-6, plasma fibrinogen, and analysis of erythrocyte sedimentation rate may help further decision-making, although their specificity for differentiating various forms of thrombocytosis is low.⁹ The measurement of the plasma concentration of Tpo is generally not helpful for distinguishing reactive from essential forms of thrombocytosis, although differences in the regulation and clearance of Tpo do exist.^{10–14}

Before ascribing thrombocytosis to an essential disorder of megakaryopoiesis, which is largely a diagnosis of exclusion, repeated complete blood counts and extended diagnostics are necessary, including the analysis of platelet counts from family members.^{15,16} As in adults, the gold standard diagnostic criteria for essential thrombocytosis remain those proposed by the Polycythemia Vera Group, summarized in Table 24.1.^{6,17,90} Besides the morphologic (reticulin staining) and genetic/cytogenetic analysis of a bone marrow specimen (exclusion of Philadelphia chromosome, Bcr/Abl fusion protein, chromosomal translocation), many other diagnostic features have been studied. These include measurement of reticulated platelets, culture of megakaryocyte colonies (megakaryocytic colony-forming units), clonal analysis using X-chromosome inactivation patterns, analysis of Tpo receptor expression on platelets and/or megakaryocyte progenitor cells, and measurement of various megakaryopoietic growth factors or cytokines, particularly Tpo and transforming growth factor (TGF)- β . The analysis of such diagnostic features has significantly contributed to a better understanding of the pathogenesis of essential thrombocytosis, but a hallmark feature for essential thrombocytosis has still not been identified.¹⁸ Of note, preliminary data suggest that in adults the combined presence of decreased Tpo expression on megakaryocytes, marked bone marrow megakaryocyte proliferation, and increased bone marrow angiogenesis is highly

Table 24.1 Diagnostic criteria for essential thrombocytosis: ‘A’ criteria are diagnostic; ‘B’ criteria are confirmative.

A1	Platelet count $> 600 \times 10^9/L$ and no known cause of reactive thrombocytosis
A2	Increase in and clustering of mature giant megakaryocytes with hyperploid nuclei
A3	No preceding or allied other subtype of myeloproliferative disorder or myelodysplastic syndrome
B1	Normal or elevated leukocyte alkaline phosphatase score, normal erythrocyte sedimentation rate, no fever
B2	Normal or slightly increased cellularity and no or minimal reticulin fibrosis
B3	Splenomegaly on palpation or spleen length > 11 cm* on diagnostic imaging procedure
B4	Spontaneous erythroid colony and/or spontaneous megakaryocyte colony formation in bone marrow progenitor assays

* A spleen length above two standard deviations of normal may fulfil this criterion in children.

Reproduced with permission from Ref. 6.

sensitive and specific in distinguishing essential from reactive thrombocytosis.¹⁹ Currently, there is no evidence to suggest that these features have the same or even a higher diagnostic value in children than in adults, because some of them can be normal in children with essential thrombocytosis.^{6,8}

Physiology of stimulated platelet production

Tpo is the key regulator of megakaryopoiesis and plays a pivotal role in normal platelet production.²⁰ Developmental changes or abnormalities in the biology of Tpo and its receptor (Tpo-R) have significant implications for the pathogenesis of thrombocytosis in children. The human *Tpo* gene is located on chromosome 3q26–27.²¹ The full-length Tpo protein is composed of 332 amino acids and characterized by two distinct domains plus an additional 21-amino acid secretory leader sequence. The N-terminal receptor-binding domain shares 20% sequence identity plus 25% sequence homology with erythropoietin (Epo) (“Epo-like” domain).^{22,23} This domain is essential for the signaling and the proliferative activity of the molecule.²⁴ The C-terminal domain specifically characterizes the Tpo molecule (Tpo glycan domain). The human full-length Tpo protein is highly glycosylated and has an apparent molecular mass of approximately 70 kDa (68–85 kDa as analyzed in SDS page electrophoresis).²⁵ The *Tpo* gene is primarily expressed in the liver and to a lower extent in the kidneys, bone marrow, and other organs.^{24,26–29} Tpo acts by binding to its specific receptor and through the JAK-STAT (members of the Janus tyrosine kinase family and members of the Stat family of transcription factors) signal transduction pathway.³⁰

The human *Tpo-R* gene is located on chromosome 1p34.³¹ Since Tpo-R was characterized some years before Tpo was identified as its ligand, the *Tpo-R* gene is still named with the acronym *c-Mpl* (for cellular homolog of a retrovirus complex inducing *myeloproliferative leukemia*).³² Tpo-R belongs to the cytokine receptor family and is composed of a 466-amino acid extracellular ligand-binding domain, which includes two cytokine receptor motifs, a 22-residue transmembrane domain, and a 122-amino acid cytoplasmic domain.³¹ The distal cytokine receptor motif of the extracellular domain is responsible for ligand binding. In the absence of Tpo, it inhibits the constitutive signaling activity of the membrane proximal cytokine receptor motif.³³ The juxta-membrane WSXWS motif (tryptophan-serine-X-tryptophan-serine, where X represents any amino acid), which is a common motif in each member of the cytokine receptor family, is thought to be responsible for maintaining the proper structural conformation of the extracellular domain as well as for internalization and signal transduction. The intracellular domain, which contains the highly conserved box 1 and box 2 motifs, is crucial for full biological activity of Tpo-R.³⁴ Although precise data are not available, it is assumed that megakaryocyte progenitor cells display a significantly higher number of Tpo-Rs on their surface than platelets, which display approximately 220 receptors per cell.³⁵ Among hematopoietic cells, the Tpo-R is expressed on CD34⁺ cells, pluripotent early hematopoietic progenitor cells, megakaryocytes, and platelets.³⁶ Tpo acts on the commitment of early hematopoietic stem and progenitor cells into lineage-specific differentiation, and it stimulates the proliferation of committed megakaryocyte progenitor cells and the differentiation of megakaryoblasts to megakaryocytes.^{37,38} However, Tpo seems not to be required

for megakaryocyte proplatelet formation, the final step in thrombopoiesis.³⁹

Hepatic Tpo production is primarily constitutive.^{35,40} Circulating Tpo is regulated by binding to Tpo-R-bearing cells. Functional Tpo-Rs remove Tpo by absorption and internalization of the cell surface complex. Thereby, under normal conditions circulating Tpo concentrations are inversely proportional to the mass of megakaryocytes and platelets. The concept of end-cell-mediated regulation of Tpo is illustrated in Fig. 24.1. Accordingly, circulating Tpo concentrations are elevated if thrombocytopenia results from reduced megakaryopoiesis.⁴¹ In contrast, Tpo concentrations are normal or slightly elevated if thrombocytopenia results from platelet destruction.^{42,43} However, there is evidence that hepatic Tpo production can be upregulated in response to hepatic growth factor and IL-6.^{44–47} These regulatory mechanisms are specific, since other factors such as IL-1 β , IL-11, tumor necrosis factor (TNF)- α , interferon (IFN)- α , IFN- β or IFN- γ do not modulate Tpo production in human hepatoma cells.^{44,48}

Besides Tpo, other cytokines or hematopoietic growth factors such as granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3, IL-6, IL-11, and leukemia inhibitory factor contribute directly to megakaryopoiesis, each of them with a specific activity at certain steps in this process.⁴⁹ Most recently, the role of IL-1 in megakaryopoiesis has been further elucidated. IL-1 β stimulates directly the formation of megakaryocytic colony-forming units (CFU-Meg).⁵⁰ Moreover, in megakaryocytic progenitor cells IL-1 β stimulates the expression of both Tpo and transcription factors, such as the zinc finger protein GATA-1 and the basic leucine zipper NF-E2, which are involved in the proliferation and differentiation of megakaryocyte progenitor cells.⁵¹

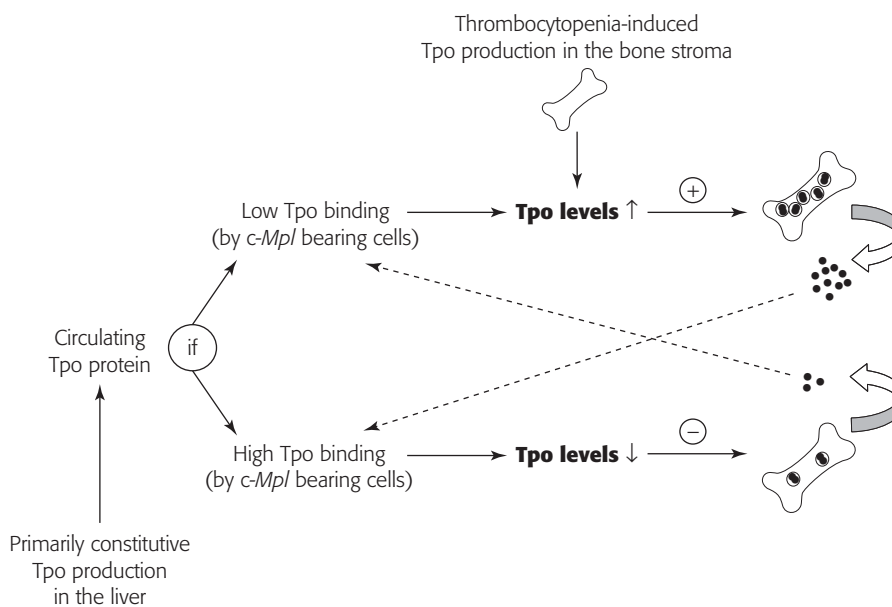

Fig. 24.1 Model of the regulation of circulating thrombopoietin (Tpo) concentrations. The model is based on the concept of end-cell-mediated regulation by the mass of *c-Mpl* (Tpo receptor)-bearing cells and a mainly constitutive Tpo production in the liver and kidneys. In the bone marrow, stromal cells contribute to Tpo production if thrombocytopenia occurs. This model implicates an autoregulatory loop mechanism as illustrated by the dashed lines. Modified with permission from Ref. 125.

Essential thrombocytosis

Pathogenesis

Essential thrombocytosis is classified as a chronic myeloproliferative disorder of hematopoiesis, resulting in uncontrolled platelet production as the major hematologic abnormality.⁵² Essential thrombocytosis can be a monoclonal or polyclonal disorder. In adults, the risk of thromboembolic complications seems to be higher in cases of monoclonality.⁵³ Since essential thrombocytosis is extremely rare in childhood, data on pathogenesis have been obtained nearly exclusively in adults.

During recent years, research on the pathogenesis of essential thrombocytosis has focused on the role of Tpo in this disorder. In adolescents and adults with essential thrombocytosis, normal or even slightly elevated circulating Tpo concentrations have been measured, although decreased Tpo concentrations would be expected as a consequence of the elevated mass of Tpo-R-bearing megakaryocytes and platelets.^{11,12,14,54–56} The findings of “inadequately high” circulating Tpo concentrations raises the question of abnormal Tpo production or a defect in Tpo clearance from the plasma. In contrast to familial forms of thrombocytosis, structural defects in the *Tpo* or *c-Mpl* gene locus have not yet been found in children or adults with nonfamilial essential thrombocytosis.^{8,57–59} However, the expression of c-Mpl on megakaryopoietic progenitors and platelets can be decreased in essential thrombocytosis.^{55,60–62} Thereby, defective clearance of circulating Tpo and subsequent Tpo excess result in the stimulation of megakaryopoiesis.^{55,62} However, neither “inadequately high” (or even elevated) Tpo concentrations nor reduced Tpo clearance are specific for essential thrombocytosis, and both have also been described in polycythemia vera.^{60,63} In polycythemia vera, reduced Tpo clearance may be caused by the posttranslational hypoglycosylation of c-Mpl protein with derailment of membrane localization.⁶⁴

Spontaneous formation of CFU-Meg colonies is another well-known phenomenon in serum-free hematopoietic progenitor cell assays from both adults and children with nonfamilial essential thrombocytosis.^{65–67} Megakaryopoiesis can be additionally stimulated, and increased sensitivity of these CFU-Meg colonies to Tpo has been observed.^{68,69} One pathogenic factor leading to the increased sensitivity of CFU-Meg to cytokines may be a decreased response to TGF- β , which normally suppresses megakaryocyte growth.⁷⁰ Reduced Smad4 (Sma- and Mad-related protein-4) expression in CFU-Meg may cause the lack of megakaryopoietic suppression by TGF- β .⁷¹ While the proliferation of megakaryopoietic progenitor cells cannot be inhibited by antibodies directed against IL-3, IL-6, GM-CSF or Tpo, blocking of c-Mpl reduces the proliferation rate of megakaryopoietic progenitor cells *in vivo*.^{72,73} This phenomenon has been described

as “a paradox, Tpo-independent, but c-Mpl-dependent modulation” of megakaryopoietic progenitors in essential thrombocytosis.⁵² As in adults, children with nonfamilial essential thrombocytosis show spontaneous formation of CFU-Meg, which can be (at least in some children) combined with spontaneous formation of erythroid progenitors (erythroid burst-forming units), indicating that two different cell lines or a bi-potent erythromegakaryocytic progenitor are affected in this disorder.^{66,67}

The role of the bone marrow microenvironment in the pathogenesis of essential thrombocytosis is not completely elucidated. In bone marrow stromal cells, expression of *Tpo* is regulated by proteins released from platelet α -granules. Specifically, platelet-derived growth factor and fibroblast growth factor-2 stimulate *Tpo* mRNA expression, whereas platelet factor-4, thrombospondin and TGF- β suppress *Tpo* mRNA expression.^{74–76} However, in adults, *Tpo* mRNA expression in bone marrow and mononuclear cells isolated from peripheral blood does not significantly differ from that of patients with myelofibrosis or controls.⁷⁵ Neither (serum) Tpo concentrations nor platelet counts correlate with measured transcripts.⁷⁷

It is unclear whether stimulated angiogenesis in the bone marrow stroma has a primary pathogenic implication or whether it is a secondary phenomenon of essential thrombocytosis.¹⁹ Recently published data indicate that the expression of hematopoietically relevant genes, such as the polycythemia rubra vera-1 (*PRV-1*) gene or the gene of the transcription factor *NF-E2*, can be changed in essential thrombocytosis.^{61,78–80} Adult *PRV-1*-positive patients with essential thrombocytosis seem to have a significantly increased risk for vascular complications compared with *PRV-1*-negative patients.⁸¹

Most recently, data obtained in mice with mutations of the *c-Myb* gene indicate a fundamental role of this transcription factor in the development of thrombocytosis.⁸² *C-Myb* is a helix-loop-helix basic-leucine zipper protein that controls the proliferation of immature progenitors and interacts with ubiquitous transcriptional coactivators, such as CBP and p100. *C-Myb* mutant mice, bearing single amino acid substitutions in the *c-Myb* DNA-binding domain or within the leucine zipper domain, referred to as *Plt3* and *Plt4* alleles of *c-Myb*,⁸³ exhibit excessive megakaryopoiesis in both the presence and absence of Tpo (*c-mpl* $-/-$ or *Tpo* $-/-$ background).⁸² The half-life of platelets in these mice is normal, and *in vivo* labeling studies have confirmed the enhanced rate of platelet production. Although the development of CFU-Meg is independent of Tpo, GM-CSF stimulates megakaryocyte progenitors carrying the *Plt3* or *Plt4* mutant *c-Myb* genes. These cells are also hyperresponsive to other cytokines, such as stem cell factor, IL-3 and Epo.⁸² Future studies might show whether mutations of *c-Myb* are relevant for thrombocytosis in humans.

Clinical and laboratory features of essential thrombocytosis in childhood

In children, the annual incidence of newly diagnosed essential thrombocytosis is about 1 per 10 million, 60 times lower than the rate in adults.^{84,85} Based on the criteria of the Polycythemia Vera Study Group, about 75 children with essential thrombocytosis have been reported between 1966 and 2005.^{8,66,85–89} Clinical and laboratory features of essential thrombocytosis in childhood are summarized in Table 24.2 and compared with those characteristic of reactive thrombocytosis. Familial forms occur in 40–55% of children with essential thrombocytosis. Approximately two-thirds of children with essential thrombocytosis have platelet counts in excess of $1000 \times 10^9/L$. In childhood, the median age at diagnosis of essential thrombocytosis is 11 years. Similar to adults, about 30% of patients experience thromboembolic or hemorrhagic complications at the time of diagnosis or later; 20% of initially asymptomatic children suffer these complications later.^{85,86} Splenomegaly has been found in 50% and hepatomegaly in 25% of children with essential thrombocytosis. As far as longitudinal analysis is available, 10% of patients

died due to the underlying hematopoietic disorder and another 5% developed other myeloproliferative disorders.⁸⁶

The risk of hemorrhage may increase with extreme thrombocytosis ($>1500 \times 10^9/L$).⁹⁰ Hemostasis is altered in about 20% of patients with essential thrombocytosis, as indicated by a prolonged bleeding time, prothrombin time, and partial thromboplastin time. Platelet function is also often diminished due to increased proteolysis of large von Willebrand factor multimers.⁸⁶ In adults, clot lysis is reduced and a higher amount of plasminogen activator inhibitor 1 is released from platelets.⁹¹ Adult patients with essential thrombocytosis also show an increased prevalence of anti-phospholipid antibodies, which may be associated with thrombosis.⁹²

Morphologic abnormalities of platelets include giant platelets, platelet conglomerates, bizarre forms, megakaryocytic fragments, and hypogranularity. Ultrastructural abnormalities include reduced numbers of pseudopodia and α -granules. Bone marrow examination reveals hypercellularity, mostly with an elevated number of megakaryocytes. These cells also display hyperploidy, dysplasia, or giant forms. Histologic criteria, such as stimulated angiogenesis, reduced c-Mpl expression on megakaryocytes, and increased proliferation

Table 24.2 Characteristics of essential (primary) and reactive (secondary) thrombocytosis in childhood.

Criteria	Essential thrombocytosis	Reactive thrombocytosis
Age-dependent occurrence	Mostly 11 years*	Mostly < 2 years*
Incidence per year	1 per million children	> 600 per million children
Duration of thrombocytosis	Months, years, or permanently	Days, weeks or months; temporary
Splenomegaly	Often	Rare
Fever	No	Often
Bleeding disorders and thrombosis	Often in monoclonal essential thrombocytosis, rare in familial thrombocythemia	Extremely rare
Frequent laboratory findings	Prolonged bleeding time, increased PT and PTT in 20%; increased prevalence of anti-phospholipid antibodies	Increased vWF, fibrinogen, proinflammatory cytokines, and C-reactive protein if reactive thrombocytosis is caused by infection
Platelet count	Mostly $> 1000 \times 10^9/L$	Mostly $< 800 \times 10^9/L$
Platelet morphology	Large or small, dysmorphic	Large, but normal morphology
Platelet function	Abnormal	Normal
Bone marrow	Increased megakaryocyte number with abnormal morphology	Increased megakaryocyte number, normal morphology
Pathogenic mechanisms	Clonal defect in hematopoietic or megakaryopoietic progenitors, decreased c-Mpl expression and/or hyperreactivity to Tpo. In some familial forms, mutations in the Tpo or c-Mpl gene locus	Increased Tpo production or release of megakaryopoietic growth factors, particularly IL-6

* Relevant only for primary thrombocytosis in childhood.⁸⁶

IL, interleukin; PT, prothrombin time; PTT, partial thromboplastin time; Tpo, thrombopoietin; vWF, von Willebrand factor.

Reproduced with permission from Ref. 6.

of megakaryocytes, are helpful in distinguishing essential from reactive thrombocytosis.

Familial forms of essential thrombocytosis

Familial, mostly recessive, but also autosomal dominant or (rarely) X-linked forms of essential thrombocytosis should be classified as a separate entity.^{93,94} In familial thrombocytosis, mutations in the *Tpo* gene locus have been identified. These mutations occur typically in the 5' untranslated region. They result in functional loss of untranslated open reading frames, causing increased translational efficiency for the mutant *Tpo* mRNA and overproduction of Tpo. Of note, hematocrit values and leukocyte counts are normal in these individuals.^{95–98} Familial thrombocytosis can also be caused by mutations in the *c-Mpl* gene. Recently, a mutation in the transmembrane domain of c-Mpl resulting in the activation of intracellular signaling has been identified as causing familial thrombocytosis in a Japanese family.⁹⁹ Another mutation in the Tpo-binding domain of c-Mpl causes decreased c-Mpl function and reduced Tpo absorption by platelets, resulting in overstimulation of megakaryopoiesis.¹⁰⁰ Currently known germline mutations in the *Tpo* and *c-Mpl* gene loci are summarized in Table 24.3. However, in other individuals with familial thrombocytosis, *Tpo* or *c-Mpl* mutations have been excluded, suggesting that one or more additional genes are involved in the origin of familial thrombocytosis.^{101,102}

In children with familial thrombocytosis, platelet counts are lower than in nonfamilial essential thrombocytosis. Splenomegaly is less frequent, and almost no thrombotic or hemorrhagic complications occur.⁸⁶ Therefore, strategies to reduce platelet numbers in familial thrombocytosis are much more conservative. The clinical and pathogenic differences

may restore the terms “familial thrombocythemia” or “familial thrombocytosis” to describe this subgroup of essential thrombocytosis.

Treatment options in nonfamilial essential thrombocytosis

Cytoreductive treatment for mild (nonfamilial) essential thrombocytosis, defined as the absence of bleeding or thrombosis in the patient's history and a platelet count $< 1500 \times 10^9/L$, is not recommended, since the incidence of thrombosis or hemorrhage is not significantly different from that of an age- and sex-matched control population.¹⁰³ Low-dose acetylsalicylic acid has been used to reduce platelet aggregation in adolescents and some children with recurrent thromboses and seems to be safe, if the platelet count is $< 1500 \times 10^9/L$.^{7,87,104,105} To prevent major arterial or venous thrombotic complications, children with dehydration should be efficiently rehydrated to reduce blood viscosity.

Children and adolescents with a platelet count in excess of $1500 \times 10^9/L$ may have an indeterminate risk of thrombotic or bleeding complications, but considered. In this group, cytoreductive treatment is also not generally recommended. If the platelet count is $> 1500 \times 10^9/L$, the use of low-dose acetylsalicylic acid is controversial, since in adults no significant benefit of this treatment in preventing thrombosis has been shown and reduced platelet aggregation is loosely associated with an increased risk of gastrointestinal bleeding.⁵² In patients at high risk for thrombotic or hemorrhagic complications, defined as extreme thrombocytosis plus previous hemorrhage, previous thrombosis or medical conditions with increased risk for these complications, cytoreductive therapy may be indicated.

Table 24.3 Summary of currently identified mutations in the *Tpo* and *c-Mpl* gene locus causing familial forms of essential thrombocytosis.

Variant	Functional implication	Tpo concentration	Platelet count ($\times 10^9/L$)	Reference
<i>Tpo</i> gene locus (NCBI accession no. D32046)				
ΔG 3252 (exon 3, 5'UTR)	Increased translation efficacy of Tpo	6.04–26.03 fmol/mL	847–1600	95, 96
G→T 3271 (exon 3, 5'UTR)	Increased translation efficacy of Tpo	5.6–8 fmol/mL	1095–1380	150
G→C 3315 (intron 3, 5'UTR)	Increased translation efficacy of Tpo	74–1180 pg/mL	530–1280	97
A→G 3320 (intron 3, 5'UTR)	Increased translation efficacy of Tpo	430–980 pg/mL	700–1000	98
<i>c-Mpl</i> gene locus (NCBI accession no. M90102)				
G→T 117 Lys → Asn 39 (ligand-binding domain)	Decreased c-Mpl function	Not done	“Significantly higher”	100
G→A 1514 Ser→Asn 505 (transmembrane domain)	Activation of intracellular signaling	Not done	> 600–1300	99

Note that the Tpo protein translation start site is the eighth initiation codon (exon/intron 3). Mutations in this region disturb normal arrangements and result in the functional loss of open reading frames, causing increased translation efficacy of Tpo gene expression.
UTR, untranslated region.

Hydroxycarbamide, an antimetabolite that impairs DNA repair by inhibiting ribonucleotide reductase in all cell lines, may be one effective agent. Hydroxycarbamide has been demonstrated in a clinical trial to produce a significant reduction (from 24 to 4%) in the incidence of thrombotic complications in patients of all ages with essential thrombocytosis.¹⁰⁶ The initial dose of hydroxycarbamide is 15 mg/kg daily, subdivided in two doses. Doses should then be decreased or increased in order to achieve a balance between a platelet count of $150\text{--}400 \times 10^9/\text{L}$ and undesired effects such as neutropenia and anemia. Hydroxycarbamide should not be used in women of childbearing age, during pregnancy and during breast-feeding. However, the risk of leukemic transformation after long-term treatment with hydroxycarbamide in children and young adults is still a major concern, and its use is controversial.^{7,16,107} Two recent studies reported no increased incidence of leukemic or neoplastic transformation after long-term treatment (5–14 years) with hydroxycarbamide in 25 young adults (18–49 years) with essential thrombocytosis and in nine children (5.7–13.7 years) with severe sickle cell disease treated for a median of 14 months (range 12–46 months).^{108,109}

Anagrelide, an oral imidazo-quinazoline derivative that reduces platelet counts by interfering with megakaryocyte maturation, may be an alternative agent for treating essential thrombocytosis in children and young adults.^{86,110–113} In young adults, anagrelide has been administered at 2–4 mg/day in four doses, with increases of 0.5 mg/day every 5–7 days up to a maximal dose of 10 mg/day. The median maintenance dose is 2.5 mg/day.¹¹¹ One 16-month-old infant was treated with an initial dose of 0.02 mg/kg daily, which was progressively increased up to 1.5 mg/day.¹¹⁴ A long-term analysis of the use of anagrelide in young adults with essential thrombocytosis showed good tolerability but complications were still high, with thrombosis in 20%, major bleeding in 20%, and anemia in 24% of patients. Complete normalization of platelet counts may be required in order to minimize the residual risk for thrombosis or hemorrhage.¹¹¹ Anagrelide has no known leukemogenic potential. Therefore, anagrelide is increasingly considered as first-line therapy for nonfamilial essential thrombocytosis in children.⁷

As previously reviewed, other platelet-lowering agents such as busulfan, IFN- α , radio-phosphorus, or dipyridamole have been used only in single children or young adults, and cannot be recommended in general.¹ Platelet apheresis has been used to reduce platelet counts in adults with severe acute thrombotic or hemorrhagic complications or platelet counts $> 1500 \times 10^9/\text{L}$, but this treatment option has not yet been proven in randomized controlled trials and there is no experience in treating children or adolescents.^{2,90}

In children and adolescents, the decision for treating essential thrombocytosis should be made primarily by weighing up the potential risks of all treatment options (particularly the leukemogenic or myelosuppressive side-effects of

cytoreductive therapy) and the expected benefit in terms of preventing thrombotic or hemorrhagic complications.¹⁶ Laboratory examinations prior to this decision should include the determination of proteins C and S, antithrombin, anti-cardiolipin antibodies, homocysteine, and mutations of factors II and V.⁵² If a platelet-lowering treatment is indicated, it is highly recommended that these patients are enrolled in controlled studies because careful long-term follow-up will help to clarify the natural course of essential thrombocytosis in children and to develop best management strategies.

Reactive thrombocytosis

Pathophysiology

Reactive thrombocytosis results from increased megakaryopoiesis associated with various hematologic (nonproliferative) or nonhematologic diseases. Megakaryopoietic activity can be stimulated up to 10-fold of normal.¹¹⁵ The proinflammatory cytokine IL-6 plays a major role in the pathogenesis of reactive thrombocytosis by direct stimulation of megakaryocyte progenitor cells and by upregulation of Tpo production. *In vitro* experiments have showed that IL-6 increases Tpo gene expression in human hepatocytes and murine liver endothelial cells, and *in vivo* studies have confirmed that reactive thrombocytosis induced by bacterial lipopolysaccharides results from increased hepatic Tpo production.^{44–46,116} The effects of IL-6 on both megakaryocyte progenitor cells and Tpo-producing cells may explain why in reactive thrombocytosis circulating Tpo concentrations do not correlate inversely with the mass of Tpo-R-bearing cells.^{12,117,118}

The analysis of circulating Tpo concentrations has helped to elucidate in detail the role of Tpo in reactive thrombocytosis associated with infectious diseases. In the first week, when platelet counts are still normal, Tpo is upregulated like acute-phase proteins; circulating Tpo concentrations peak on day 4 ± 2 , before they gradually decrease. When increasing platelet counts peak in the second or third week, Tpo concentrations normalize.¹⁰ In postoperative thrombocytosis, Tpo plasma concentrations also rise before platelet counts increase. Previously increased IL-6 concentrations again suggest its direct stimulation of Tpo production in hepatocytes.¹¹⁹ In malignancies, stimulation of megakaryopoiesis may result from Tpo production in tumor cells, particularly in hepatoblastoma, but also to a lesser extent in neuroblastoma, lymphoma, and others.^{120,121}

Clinical and laboratory features of reactive thrombocytosis

Reactive thrombocytosis has an estimated incidence of 3–15% among hospitalized children. Typical clinical and laboratory findings in reactive thrombocytosis are summarized in

Table 24.4 Clinical features of reactive thrombocytosis in children: only studies containing more than 130 children are considered.

* Without infants; country with high prevalence of hereditary hemolytic anaemia.

† The majority of children with autoimmune disease suffered from Kawasaki syndrome.

Reproduced with permission from Ref. 6.

Table 24.2.¹²² Variations in the reported incidence may result from differences in the definition of thrombocytosis, the study setting (hospitalized patients, outpatients, or both), the epidemic occurrence of certain infections, or other factors (Table 24.4).^{4,5} In 72–86% of children with reactive thrombocytosis, platelet counts range between 500 and $700 \times 10^9/L$ (mild thrombocytosis). Moderate thrombocytosis (platelet count $700\text{--}900 \times 10^9/L$) has been found in approximately 6–8% of children with reactive thrombocytosis, and only 0.5–3% have a platelet count $>1000 \times 10^9/L$.^{2,4,5,123,124}

The incidence of reactive thrombocytosis in childhood shows an age-dependent pattern. The highest incidence has been found in children up to 24 months old (Table 24.4). Platelet counts $>500 \times 10^9/L$ have been found in 13% of neonates at birth; during the first month, thrombocytosis occurred in 36% of neonates, most of them low birthweight infants (<2500 g) and/or neonates who suffered from infection. At this age, 10% of the studied neonates had platelet counts of $600\text{--}700 \times 10^9/L$, while 4% had platelet counts $>700 \times 10^9/L$. In the second month, 8% of infants had platelet counts $>700 \times 10^9/L$. The incidence of reactive thrombocytosis returned to 13% in the group of infants aged 6–11 months. Afterwards, the incidence gradually decreased to only 0.6% in children 11–15 years old.⁴

The higher susceptibility for thrombocytosis during the neonatal period may result from various physiologic phenomena. During the ontogeny of medullary hematopoiesis, *Tpo* is expressed at high levels in the bone marrow.²⁶ Circulating *Tpo* concentrations are significantly higher in fetuses and neonates than in children and adults.^{43,125} During

postnatal development, circulating *Tpo* concentrations underlie age-dependent changes. They increase after birth, with a peak on the second day, before they return to levels found in cord blood by the end of the first month. Later, *Tpo* concentrations gradually decrease until the end of the first year of life, where they are still somewhat higher than in adults.¹²⁶ Moreover, neonatal megakaryocytic progenitor cells have a higher sensitivity to *Tpo* compared with cells obtained in adults.^{127,128} In small-for-gestational age infants (birthweight below the 10th percentile), additional factors may be relevant for overwhelming platelet production and thrombocytosis, particularly after fetal distress or eclampsia with or without initial neonatal thrombocytopenia.

Clinical conditions frequently associated with reactive thrombocytosis are listed in Table 24.5. Bacterial or viral infections (acute or chronic) are the most common cause for reactive thrombocytosis (37–78%) at any age during childhood. Within this group, infections of the respiratory tract account for 60–80% of thrombocytosis, followed by infections of the gastrointestinal and urinary tracts.^{129,130} No relationship has been found between thrombocytosis and the prognosis or antibiotic treatment of the infection. Reactive thrombocytosis occurs in about 50% of children with bacterial meningitis after the first week of treatment, but has no influence on the neurologic outcome of surviving patients. Patients who died developed thrombocytopenia instead of thrombocytosis.¹³¹

In 1–21% of children, megakaryopoiesis is stimulated secondary to tissue damage (trauma, burns, major surgery).^{4,5} Platelet counts usually peak between the first and second

postoperative week. After splenectomy, reactive thrombocytosis results from reduced platelet storage and decreased removal by the reticuloendothelial system.⁵

Increased IL-6 serum concentrations in splenectomized adults with thalassemia again suggest a role for IL-6 in the pathogenesis of thrombocytosis; in addition, an increased platelet aggregability has been reported.^{132,133} In children, thromboembolic complications after splenectomy are very rare, but have been reported in association with immune hemolytic anemia and portal hypertension.⁵

Anemia accounts for 6–12% of reactive thrombocytosis in children. Hemolytic anemia and anemia due to iron deficiency are most frequently associated with reactive thrombocytosis. Their incidence varies with the ethnic origin of the study population and the age of the children studied (Table 24.4). Iron deficiency occurs in 4–6% of children with thrombocytosis, most frequently in infants. Within a study group of children with iron deficiency, reactive thrombocytosis was found in up to one-third of them.¹³⁴ The relationship between iron deficiency and thrombocytosis is likely to be complex, and there is increasing evidence that it is not caused by cross-reactivity between Epo and Tpo.¹³⁵ Thrombocytosis has also been observed in infants with bleeding due to vitamin K deficiency or other bleeding disorders, and in the recovery from severe hemodilution in open-heart surgery.⁵

Autoimmune diseases (juvenile rheumatoid arthritis, inflammatory bowel disease, polyarteritis nodosa, Kawasaki disease) account for 4–11% of reactive thrombocytosis in childhood (Table 24.4). Among them, Kawasaki syndrome is the major cause of reactive thrombocytosis in children under 7 years old, while other diseases occur mainly in children aged 11 years or older. As in adults, a direct correlation between IL-6 concentrations and both the activity of the underlying inflammatory disease and platelet counts has been described.¹³⁶ In active inflammatory bowel disease, Tpo concentrations are also elevated but do not correlate with thromboembolic complications. The lack of a direct correlation between Tpo and platelet counts, and the fact that the increase in Tpo concentrations precedes thrombocytosis, is highly suggestive that megakaryopoiesis is stimulated by both Tpo and other megakaryopoietic growth factors.¹³⁷ Children with Henoch–Schönlein purpura show typically mild thrombocytosis. The coincidence of reactive thrombocytosis and abdominal pain due to hemorrhage and thrombosis should be noticed.^{5,138}

About 1–3% of children exhibit thrombocytosis at the diagnosis of a malignancy.^{1,139} Elevated Tpo concentrations have been reported in malignant Tpo-producing liver tumors, particularly hepatoblastoma and hepatocellular carcinoma.¹²⁰ Less frequently, thrombocytosis can also be associated with acute lymphocytic leukemia (3.2% of children diagnosed).¹⁴⁰

Reactive thrombocytosis can also be related to treatment with several pharmaceutical agents. Epinephrine (adrenaline), corticosteroids, ciclosporin, vinca alkaloids, miconazole, peni-

cillamine, imipenem, and meropenem are claimed or known to cause or promote thrombocytosis in children.^{5,141–143} Epinephrine and stress increase the platelet count by shifting stored platelets from the spleen to the circulation.¹⁴⁴ Of children treated with corticosteroids and/or vinca alkaloids for a malignancy (solid tumor, acute lymphocytic leukemia), 90% develop thrombocytosis during therapy.⁵

Transient thrombocytosis has been described in neonates after intrauterine exposure to methadone, hydantoin, or psychopharmaceutical drugs.⁵ It has been speculated that reactive thrombocytosis is caused by rebound megakaryopoiesis after suppression of fetal Tpo production. Such a rebound phenomenon is also obvious in neonates receiving antiretroviral treatment with zidovudine due to maternal HIV infection. After initial thrombocytopenia or normal platelet counts, platelets can rise to $> 1000 \times 10^9/L$.¹⁴⁵

In children, reactive thrombocytosis can be also associated with various other diseases, such as allergies, metabolic diseases, myopathies, or neurofibromatosis.⁵

Complications of reactive thrombocytosis in childhood

In childhood, reactive thrombocytosis does not usually result in thromboembolic or hemorrhagic complications ($<1\text{--}2\%$). However, such complications occur after splenectomy or if the underlying disease is associated with additional thrombotic risk factors.¹⁴⁶ Thromboembolism, for example, occurs more frequently in (auto)splenectomized children with thalassemia or congenital spherocytosis who have persistent hemolysis, increased platelet reactivity, low protein C, and antithrombin concentrations,¹⁴⁷ or who suffer the sequelae of thalassemia such as cardiomyopathy, diabetes, hepatopathy, and portal hypertension.¹⁴⁸ Furthermore, neonates and infants have a higher thromboembolic risk if central venous catheters are placed or other thrombophilic conditions are present, such as maternal diabetes, maternal antiphospholipid syndrome, septicemia, intrauterine growth retardation, or cardiac malformation.¹⁴⁹

Indications for treatment of reactive thrombocytosis

Reactive thrombocytosis in children does not justify general prophylaxis with anticoagulants or platelet aggregation inhibitors, even if the platelet count is greater than $1000 \times 10^9/L$. There is no evidence for the efficacy of prophylaxis against thromboembolic complications in asymptomatic children with reactive thrombocytosis. Individually tailored thrombosis prophylaxis and additional laboratory screening for thrombophilia should be considered if additional thrombotic risk factors exist or if thromboembolic events are reported in family history. The underlying disease (e.g., iron deficiency) should be treated rather than the platelet count.

Only if thrombosis occurs repeatedly is reduction of platelet aggregation and platelet count indicated.¹⁴⁶

Acknowledgment

This chapter is dedicated to Professor Anton Heinz Sutor (1938–2004), formerly of the Department of Paediatrics, University of Freiburg, Germany. With great enthusiasm and the highest clinical and scientific skill, he contributed significantly for over 30 years to the understanding of thrombocytosis in childhood.

Platelet function disorders

Alan D. Michelson

Normal platelet function

Platelets are small cells of great importance in many pathophysiologic processes including thrombosis, hemorrhage, inflammation, antimicrobial host defense, and tumor growth and metastasis.¹ The mammalian platelet is derived from the cytoplasm of megakaryocytes. Polyploid megakaryocytes and their progeny, nonnucleated platelets, are found only in mammals.² In all other animal species, cells involved in hemostasis and blood coagulation are nucleated. The evolutionary event or events that resulted in the appearance of mammalian megakaryocytes and platelets, as well as the biologic advantage of this system, remains unknown.²

Megakaryocytes are descended from pluripotent stem cells and undergo multiple DNA replications without cell divisions by the unique process of endomitosis.³ On completion of endomitosis, polyploid megakaryocytes begin a rapid cytoplasmic expansion phase characterized by the development of an elaborate demarcation membrane system and the accumulation of cytoplasmic proteins and granules essential for platelet function. During the final stages of development, the megakaryocyte cytoplasm undergoes massive reorganization into beaded cytoplasmic extensions called proplatelets.³

Platelets circulate in a concentration of $150\text{--}400 \times 10^9/\text{L}$ and have a lifespan of 7–10 days. Human platelets are 2–4 μm in diameter and contain granules (α , dense, lysosomes), mitochondria, and endoplasmic reticulum. The contents of α -granules include P-selectin, von Willebrand factor (VWF), β -thromboglobulin (β -TG), platelet factor (PF)4, factor V, platelet-derived growth factor (PDGF), transforming growth factor β , plasminogen activator inhibitor 1, thrombospondin, fibrinogen, fibronectin, multimerin, albumin, and IgG.⁴ The contents of dense granules include ATP, ADP, Ca^{2+} , serotonin, CD63, and LAMP 2.⁴

Formation of the hemostatic plug at sites of vascular injury begins with the arrest of circulating platelets on exposed collagen and continues with the recruitment of additional

platelets into a growing platelet mass that will eventually be stabilized with cross-linked fibrin.⁵ Formation of a platelet plug can be thought of as occurring in three phases: initiation, extension, and perpetuation (Fig. 25.1).⁵ Initiation occurs when circulating platelets arrest and are activated by exposed collagen and VWF, allowing the accumulation of a platelet monolayer that supports thrombin generation and the formation of platelet aggregates. Key to this phase of platelet activation is the presence of receptors on the platelet surface that can bind to collagen (integrin $\alpha_2\beta_1$ and glycoprotein (Gp)VI) and VWF (GpIb–IX–V and integrin $\alpha_{\text{IIb}}\beta_3$) and initiate intracellular signaling.⁵ Extension occurs when additional platelets accumulate on the initial monolayer, a process for which $\alpha_{\text{IIb}}\beta_3$ activation is certainly essential but not necessarily sufficient. Key to this phase is the presence on the platelet surface of receptors that can respond rapidly to locally generated thrombin, secreted ADP, and released thromboxane (Tx) A_2 to activate phospholipase C, increase cytosolic Ca^{2+} concentration, and suppress synthesis of cyclic AMP (cAMP).⁵ Most of the receptors involved in these events are members of the superfamily of G protein-coupled receptors (Fig. 25.2). Perpetuation refers to the late events of platelet plug formation, when the intense but short-lived signals arising from G protein-coupled receptors have faded and the receptors responsible have been desensitized.⁵ These late events stabilize the platelet plug and prevent premature disaggregation (Fig. 25.1). Perpetuation is less well understood than initiation and extension, but recent studies point to a central role for outside-in signaling through cell surface integrins and to the signals generated by receptor tyrosine kinases, including members of the Eph and Axl families.⁵ Platelets localize, amplify, and sustain the coagulant response at the injury site⁶ and release procoagulant platelet-derived microparticles.⁷

Platelet function in the newborn

Healthy newborns maintain normal circulating platelet counts,

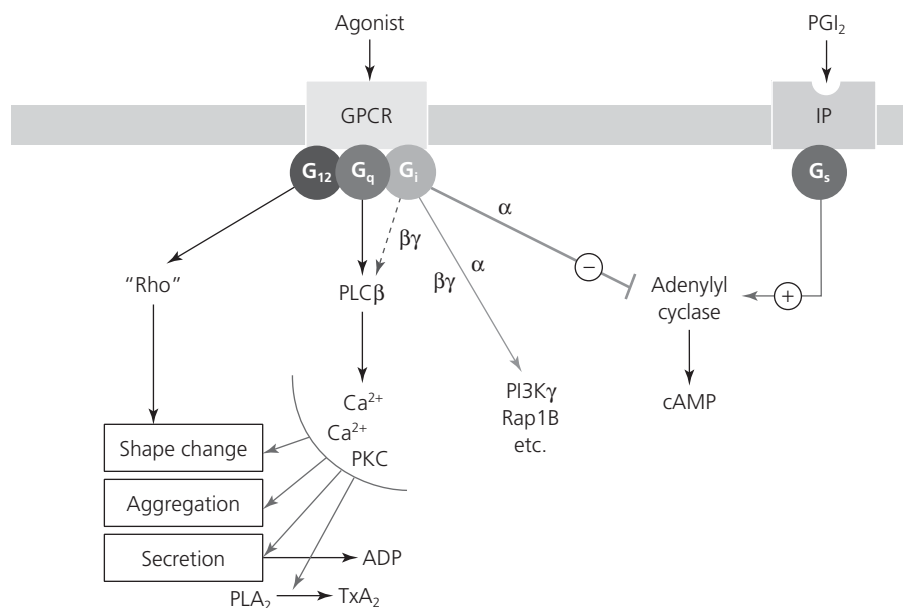

Fig. 25.1 Steps in platelet plug formation. (a) Prior to vascular injury, platelets are maintained in the resting state by a combination of inhibitory factors that place a “threshold” that must be surmounted in order for platelets to be activated. These factors include prostaglandin (PGI_2) and nitric oxide (NO) released from endothelial cells, and CD39, an ADPase on the surface of endothelial cells that hydrolyzes any small amounts of ADP that might otherwise cause inappropriate platelet activation. (b) The development of the platelet plug is initiated by the exposure of collagen and the local generation of thrombin. This causes platelets to adhere via collagen and von Willebrand factor (VWF) and spread on the connective matrix, forming a monolayer. (c) Afterwards, the platelet plug is extended as additional platelets are activated via the release or secretion of thromboxane (TxA_2), ADP, and other platelet agonists, most of which are ligands for G protein-coupled receptors on the platelet surface. (d) Finally, close contacts between platelets in the growing hemostatic plug, along with a fibrin meshwork, help to perpetuate and stabilize the platelet aggregate. Reproduced with permission from Ref. 5.

Fig. 25.2 Overview of platelet activation via G protein-coupled receptors (GPCR) and G proteins. A number of agonists activate platelets via GPCRs on the platelet surface. Although the details differ from one receptor to the next, critical responses include G_q -mediated activation of phospholipase C (PLC) β isoforms to allow an increase in cytosolic Ca^{2+} , activation of phospholipase A_2 (PLA_2) and protein kinase C (PKC), and G_{12} -mediated guanine nucleotide exchange on Rho family members to support rearrangement of the platelet cytoskeleton (shape change). Activated PGI_2 receptors (IP) stimulate adenylyl cyclase, raising platelet cAMP levels, and causing a generalized inhibition of platelet responses to agonists. G_i family members support the suppression of adenylyl cyclase by platelet agonists and may couple their receptors to other effector pathways as well, including those which activate phosphatidylinositol 3-kinase (PI3K) γ and the Ras family member Rap1B. Reproduced with permission from Ref. 5.

and have a platelet ultrastructure that does not differ from that of adults.⁸ However, *in vitro* assessments of intrinsic platelet function have demonstrated transient hyporesponsiveness that is most marked in platelets from preterm infants (Fig. 25.3).^{9,10} Decreased responses were originally considered to be the result of platelet activation and degranulation

during labor and delivery, but more recent studies of platelet activation markers have not supported this hypothesis.^{9,10} Decreased activation responses are due to relative deficiencies of phospholipid metabolism, calcium mobilization, granule secretion, and aggregation.⁸ These result in turn from differences in intrinsic signal transduction in the neonatal

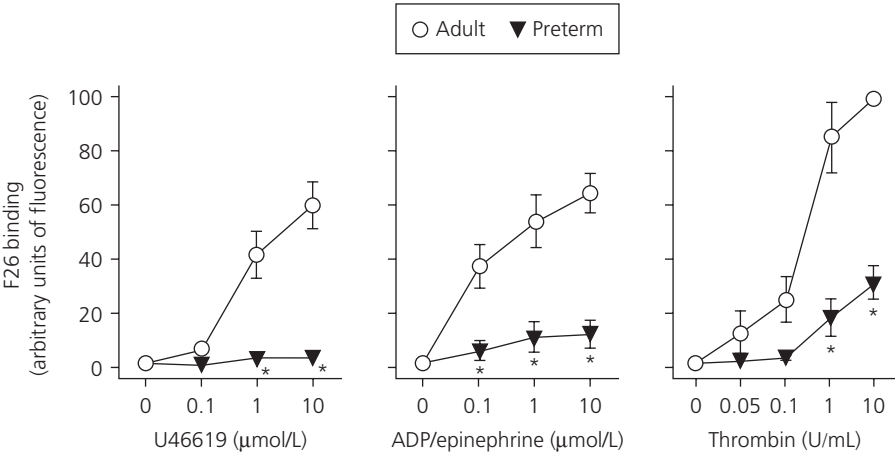

Fig. 25.3 The platelets of very low birthweight preterm neonates are less reactive than adult platelets, as determined by the activation-dependent binding of fibrinogen to the GpIIb–IIIa complex. Whole-blood flow cytometry was used to analyze the platelet surface binding of monoclonal antibody F26 (directed against a conformational change in fibrinogen bound to the GpIIb–IIIa complex) after stimulation with either U46619 (thromboxane A₂ agonist), the combination of ADP and epinephrine, or thrombin. The fluorescence intensity of adult platelets incubated with maximal thrombin (10 U/mL) was assigned a value of 100 units. Data are mean ± SEM, *n* = 5. Asterisks indicate *P* < 0.05 (by paired Student's *t* test) for platelets of preterm neonates compared with adult platelets. Reproduced with permission from Ref. 10.

platelet compared with those in the adult. In contrast, there is enhanced platelet adhesion due to the presence in neonatal plasma of larger, more functionally potent VWF multimers. These ultra-large multimers result from decreased concentrations of VWF-cleaving protease in neonatal plasma, and are associated with shorter bleeding times and platelet function analyzer (PFA)-100 closure times in neonates.⁸ In the immediate newborn period this enhanced platelet adhesion may compensate for the decreased intrinsic platelet activation in healthy neonates, but may leave sick neonates at increased risk of bleeding.

Clinical approach to platelet function disorders

The characteristic clinical features that differentiate primary hemostatic disorders (platelet function disorders, thrombocytopenia, von Willebrand disease) from coagulation disorders (e.g., hemophilia) are listed in Table 25.1. Three of these clinical features are particularly helpful.

- 1 Petechiae are a very strong pointer toward a primary hemostatic disorder and away from a coagulation disorder.
- 2 Hemarthroses are a very strong pointer toward a coagulation disorder and away from a primary hemostatic disorder.
- 3 In the setting of an injury, immediate excessive bleeding suggests a primary hemostatic disorder (because the initial platelet plug does not form correctly), whereas delayed bleeding suggests a coagulation disorder (because the lack of a well-formed fibrin clot results in gradual breakdown of the initial platelet plug).¹¹

Clinical history

Bleeding

Spontaneous bleeding, or excessive bleeding during or after an injury, is suggestive of an underlying hemostatic disorder. The clinician must obtain a history of the patient's responses to hemostatic challenges: surgery (including circumcision), dental procedures (especially tooth extractions), trauma, injections, menses, labor and delivery, and tooth brushing. Immediate bleeding suggests a primary hemostatic disorder, whereas delayed bleeding suggests a coagulation disorder (Table 25.1).

Table 25.1 Characteristic clinical features that differentiate primary hemostatic disorders from coagulation disorders.

	Primary hemostatic disorder	Coagulation disorder
Prototypic disorders	Thrombocytopenia, platelet function disorder, von Willebrand disease*	Hemophilia
Bleeding	Immediate	Delayed
Petechiae	Yes	No
Hemarthroses	No	Yes
Intramuscular hematomas	Uncommon	Common
Epistaxes	Common	Uncommon
Menorrhagia	Common	Uncommon

* In the uncommon type 3 von Willebrand disease, the factor VIII level is low enough for the clinical features to be those of a combined primary hemostatic and coagulation disorder.

Reproduced with permission from Ref. 11.

Easy bruising is common in hemostatic disorders, but does not help distinguish disorders of platelet number and function from other disorders of hemostasis. However, epistaxes, gingival bleeding, and menorrhagia are all more common in primary hemostatic disorders than in coagulation disorders. The age of onset of the excessive bleeding may help to distinguish inherited bleeding disorders from acquired bleeding disorders.

Gender and family history

Some disorders of platelet number and function are X-linked recessive (e.g., Wiskott–Aldrich syndrome) and therefore present almost exclusively in males. Other disorders of platelet number and function are autosomal recessive (e.g., Bernard–Soulier syndrome and Glanzmann thrombasthenia) or autosomal dominant (e.g., May–Hegglin anomaly). Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) are common X-linked recessive coagulation disorders that occur almost exclusively in males.

Medications

The history of the patient's intake of medications is important. A platelet function defect can be caused by many drugs, including aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), ADP receptor antagonists (clopidogrel, ticlopidine), GpIIb/IIIa antagonists (abciximab, tirofiban, eptifibatide), dipyridamole, cilostazol, antimicrobial agents (β -lactam antibiotics, nitrofurantoin, hydroxychloroquine, miconazole), cardiovascular drugs (propranolol, nitroprusside, nitroglycerin, furosemide, calcium channel blockers), ethanol, and food items and supplements (ω -3 fatty acids, vitamin E, onions, garlic, ginger, cumin, turmeric, clove, black tree fungus, *Ginkgo*).¹²

Medical history

A history of renal disease, liver disease, myeloproliferative disorder, acute leukemia, myelodysplastic syndrome, or dysproteinemia suggests a platelet function defect.

Physical examination

Hemorrhage

Petechiae very strongly suggest a primary hemostatic disorder rather than a coagulation disorder (see Table 25.1). Petechiae can also be a sign of vasculitis or, in a sick patient, bacteremia (including meningococcemia) and disseminated intravascular coagulation. In contrast, hemarthroses very strongly suggest a coagulation disorder rather than a primary hemostatic disorder (see Table 25.1). Intramuscular hematomas are more typical of a coagulation disorder than a primary hemostatic disorder.

Other physical signs

Oculocutaneous albinism is observed in Hermansky–Pudlak syndrome and Chédiak–Higashi syndrome. Deafness and cataracts suggest Fechtner syndrome. Deafness and hypertension occur in Epstein syndrome. Cardiac defects, delayed development, otorhinolaryngologic manifestations, psychiatric disturbances, and mental retardation suggest the velocardio-facial syndrome associated with Bernard–Soulier syndrome.

Clinical tests

Blood smear

Giant platelets are observed in Bernard–Soulier syndrome, May–Hegglin anomaly, Fechtner syndrome, Sebastian syndrome, Epstein syndrome, and Montreal platelet syndrome. Agranular gray platelets are observed in the gray platelet syndrome. Döhle bodies are observed in the neutrophil cytoplasm in May–Hegglin anomaly. Neutrophil inclusions are also observed in Sebastian syndrome. Giant cytoplasmic granules are observed in neutrophils, monocytes, and lymphocytes in Chédiak–Higashi syndrome, but these granules may be more easily recognized in leukocyte precursors in the bone marrow rather than in leukocytes in the peripheral blood.¹¹

Platelet aggregation

In Glanzmann thrombasthenia, the platelets do not aggregate in response to ADP, epinephrine (adrenaline), arachidonic acid, or collagen, but do agglutinate in response to ristocetin. In Bernard–Soulier syndrome, the platelets do not agglutinate in response to ristocetin but do aggregate in response to all other agonists. Patients with storage pool disease or defects in platelet secretion show decreased platelet aggregation or absence of the second wave of aggregation in response to ADP, epinephrine, arachidonic acid, or collagen. Some patients with storage pool disease cannot be reliably diagnosed by standard platelet aggregometry;¹³ the diagnosis is made by measuring the granule adenine nucleotides by biochemical assays or by labeling the platelets with the fluorescent dye mepacrine and then measuring platelet fluorescence by microscopy or flow cytometry.^{14,15}

Bleeding time

Although both thrombocytopenia and platelet function defects of sufficient degree usually result in a prolonged bleeding time, this test has a limited role in clinical medicine.¹⁶

Other tests

Other tests that may be clinically useful in patients with platelet

function disorders include the PFA-100,¹⁷ the VerifyNow rapid platelet function analyzer,¹⁸ the cone and plate(let) analyzer,¹⁹ and flow cytometry.²⁰ The PFA-100 may be useful as a screening test for primary hemostasis¹⁷ instead of the bleeding time. Other tests used in the specific diagnosis of platelet function disorders are discussed below in the context of each disorder.

Differential diagnosis

The presence of a platelet function disorder can usually be determined from the clinical history, physical examination (Table 25.1), complete blood count (including examination of the blood smear), platelet aggregation and, if necessary, tests for von Willebrand disease (ristocetin cofactor, VWF antigen, factor VIII coagulant).¹¹

The list of specific causes of platelet function defects is long (Tables 25.2 and 25.3). However, acquired defects are the commonest and the underlying medical condition is usually evident. With the exception of storage pool disease, inherited platelet function defects, at least the well-characterized ones, are all rare. These rare disorders usually require specialized

research laboratories to make a specific diagnosis, with the exception of Bernard–Soulier syndrome and Glanzmann thrombasthenia, which are easily diagnosed by platelet aggregometry and flow cytometry.

Inherited disorders of platelet function

Based on the normal function of platelets, inherited disorders of platelet function can be considered to be defects in adhesion, agonist receptors, signaling pathways, secretion, aggregation, or platelet–coagulant protein interaction (Table 25.2). Table 25.4 presents the essential characteristics of the principal inherited disorders of platelets.

Adhesion defects

Bernard–Soulier syndrome

In 1948, Bernard and Soulier described a severe hereditary bleeding disorder characterized by a prolonged bleeding time, moderate thrombocytopenia with giant and morphologically abnormal platelets, normal clot retraction but defective prothrombin consumption.²¹ Subsequent investigation of similar cases showed that the platelets aggregated normally with ADP, epinephrine, collagen, and all other platelet agonists, but were not agglutinated by VWF or ristocetin.²² In contrast to von Willebrand disease, in which the defective response to ristocetin is due to deficiency of plasma VWF, in Bernard–Soulier syndrome it is the platelet membrane that is defective, lacking receptors for VWF. Specifically, there is a defect in the GpIb–IX–V complex, of which the individual subunits (GPIb α , GPIb β , GpIX, and GpV) are members of the “leucine-rich” family of glycoproteins.²³ This complex carries a binding site for VWF on the outermost extracellular portion of the GPIb α subunit. VWF binding to GPIb α is induced *in vitro* by ristocetin, and occurs *in vivo* as a result of the conformational change in VWF that results from the prior binding of VWF to the vascular subendothelium.²³ This platelet–VWF–subendothelium interaction is an essential step in the initial adhesion of platelets to damaged blood vessels, particularly at the shear rates that occur in small

Table 25.4 Essential characteristics of the principal inherited disorders of platelets.

	Bleeding syndrome	Platelet count × 10 ⁹ /L	Platelet ultrastructure	Associations	Functional abnormality	Inheritance	Structural defects and gene affected
Bernard–Soulier syndrome	Moderate to severe	20–100	Giant platelets	DiGeorge/velocardiofacial syndrome*	Abnormal adhesivity, no agglutination with ristocetin or botrocetin, retarded response to thrombin	AR (1 report of AD)	Gplb-IX Gplb α (chr. 17) Gplb β (chr. 22) GplX (chr. 3)
May–Hegglin anomaly	Mild	30–100	Large size	Neutrophil inclusions	No consistent defects	AD	Nonmuscle myosin heavy chain MYH9
Fechtner syndrome (FS), Sebastian syndrome (SS)	Mild	30–100	Large size, large vacuoles	Hereditary nephritis and hearing loss (FS) Leukocyte inclusions (FS, SS)	No consistent defects	AD	Nonmuscle myosin heavy chain MYH9
Epstein syndrome	Mild	5–100	Large size, large vacuoles	Hereditary nephritis and hearing loss	Impaired response to collagen (not consistent)	AD	Unknown
Montreal platelet syndrome	Moderate to severe	5–40	Large size	None	Spontaneous agglutination, decreased aggregation with thrombin	AD	Unknown, reduced calpain activity
Platelet-type von Willebrand disease	Moderate	Normal or decreased	Platelet size heterogeneity	Absence of high molecular weight VWF multimers in plasma	Increased sensitivity to agglutination by ristocetin	AD	GPlb α
$\alpha_2\beta_1$ collagen receptor	Mild	Normal	Normal	Modification in receptor density with hormonal status	Decreased response to collagen	?	Probably α_2 (chr. 5)
GpVI collagen receptor	Mild	Normal	Normal	Function dependent on FcR γ chain	Decreased response to collagen	?	Probably GpVI (chr. 19)
P2Y ₁₂ ADP receptor	Mild	Normal	Normal	None known, but receptor found in brain	Small and unstable aggregates with ADP	Probably AR	P2Y ₁₂ receptor defect (chr. 3)
Thromboxane (TX)/A ₂ receptor	Mild	Normal	Normal	None known	Absence of response to TXA ₂ and analogs, diminished response to collagen	AD	TXA ₂ receptor

(continued p. 568)

Table 25.4 (continued)

	Bleeding syndrome	Platelet count × 10 ⁹ /L	Platelet ultrastructure	Associations	Functional abnormality	Inheritance	Structural defects and gene affected
Signaling [†]	Mild	Normal	Normal	None known	Diminished aggregation and secretion to multiple agonists	Not reported	Phospholipase C β_2 G_{aq} protein
Cyclooxygenase [‡]	Moderate	Decreased on occasion	Normal	None known	No aggregation with arachidonic acid, diminished response to collagen and ADP	Probably AR	Cyclooxygenase
Gray platelet syndrome	Mild	30–100	Empty α -granules	Myelofibrosis	Sometimes normal, can be decreased with thrombin, epinephrine and collagen	AR or AD	Unknown but prevents storage of α -granule proteins
Quebec syndrome	Moderate to severe	~100	Subnormal content of α -granules	None known	Absent aggregation with epinephrine	AD	Multimerin. Increased urokinase-type plasminogen activator in α -granules with degraded proteins
Wiskott–Aldrich syndrome	Mild to severe	10–100	Small size, fewer granules	Usually eczema, infections Immunodeficiency	Decreased aggregation and secretion with multiple agonists	X-linked	WASP protein (a signaling molecule)
Hermansky–Pudlak (HP), Chédiak–Higashi (CH) syndromes [§]	Mild to moderate	Normal	Reduced number of abnormal dense granules Giant granules (CH)	Oculocutaneous albinism Ceroid-lipofuscinosis (HP) Infections (CH)	Decreased aggregation and secretion with multiple agonists	AR	Proteins involved in vesicle formation and trafficking
Glanzmann thrombasthenia	Moderate to severe	Normal	Normal	Possible increased bone thickening and low fertility (β_3)	Absent aggregation with all agonists, clot retraction often defective	AR	α_{IIb} and β_3 (chr. 17q21–23)
Scott syndrome	Moderate to severe	Normal	Normal	Defects extend to other blood cells	Low expression of procoagulant activity and microparticle release	AR	Unknown

* Condition associated with loss of Gplb β gene in chromosome 22q11 deletion.

† Two examples only are given.

‡ Other enzyme deficiencies have been reported (e.g., thromboxane synthetase, lipooxygenase).

§ Other types of storage pool disease are described in the text.

arteries and capillaries, and it is the failure of this initial step in platelet plug formation which accounts for the bleeding tendency of Bernard–Soulier syndrome.

The thrombocytopenia of Bernard–Soulier syndrome is chiefly due to a shortened platelet lifespan, which may be an end result of the deficiency of the sialic acid-rich glycoprotein. Unstimulated platelets also have a high basal prothrombinase activity.²⁴ The partial defect of thrombin binding and aggregation reported by Jamieson and Okumura²⁵ suggested that the GpIb–IX–V complex carries a thrombin receptor, and this has subsequently been confirmed and shown to be distinct from the VWF receptor.²³ The abnormally deformable membrane of platelets in this syndrome²⁶ is evidently also related to the GpIb–IX–V deficiency, since this complex plays an important part in linking the plasma membrane to the cytoskeleton of the platelet.²³

Clinical features

Bernard–Soulier syndrome is an extremely rare autosomal recessive disorder. It is clinically indistinguishable from Glanzmann thrombasthenia and, like it, usually presents early in life with multiple petechiae and ecchymoses, and bleeding from mucous membranes and superficial grazes and cuts. Epistaxes and menorrhagia are among the commonest symptoms and can present difficult problems in management. Several children have died from uncontrollable bleeding, and the original patient of Bernard and Soulier, who presented with epistaxis and anal hemorrhage at the age of 15 days, had numerous bleeding episodes during his first 7 years, after which hemorrhage occurred less frequently and usually only after injury; he died at the age of 28 from a cerebral hemorrhage following a bar-room brawl.²⁷ As in Glanzmann thrombasthenia, clinical severity may vary widely between affected family members.

Laboratory diagnosis

The platelet count is usually only moderately reduced (commonly $50\text{--}100 \times 10^9/\text{L}$), but the bleeding time and PFA-100 closure time are very prolonged. The giant platelets may not be recognized as such by electronic cell counters, leading to spuriously low counts, but their presence in the blood film will suggest the diagnosis. It is difficult to prepare platelet-rich plasma for aggregation and other tests because the large dense platelets tend to sediment with the red and white cells. The failure to agglutinate in response to ristocetin (even in the presence of normal plasma or VWF), together with the normal or even increased aggregation response to ADP, epinephrine and collagen, and the demonstration of normal VWF in the patient's plasma, further establishes the diagnosis, which can be confirmed by demonstrating the deficiency of GpIb–IX–V complex in the platelet membrane. This can be achieved by biochemical methods such as polyacrylamide gel electrophoresis or by the use of specific monoclonal antibodies in flow cytometric or immunochemical tests.

Molecular genetics

Mutations in GpIb α , GpIb β , and GpIX but not GpV have been described in Bernard–Soulier syndrome.²² Most of the described mutations have been homozygous, resulting from consanguinity in the parents of the affected individual. An exception is the seemingly frequent association of the velocardiofacial syndrome with hemizygous mutation of GpIb β as a cause of Bernard–Soulier syndrome. Velocardiofacial syndrome is a congenital disorder characterized by variable manifestations of cardiac defects, delayed development, otorhinolaryngologic manifestations, psychiatric disturbances, and mental retardation. The disorder results from deletion of the region of chromosome 22 (22q11.2) that includes the gene encoding GpIb β .²³ Thus, it is important to be alert to the concomitant presence of cardiac disorders and potentially subtle IQ and facial abnormalities when evaluating patients with Bernard–Soulier syndrome.

Detection of heterozygotes and prenatal diagnosis

Most heterozygotes for Bernard–Soulier syndrome in whom platelet size has been examined possess larger than normal platelets, despite generally normal hemostatic parameters. In a recent evaluation of causes of autosomal dominant macrothrombocytopenia in Italy, Savoia *et al.*²⁸ found that a predominance of affected individuals were heterozygotes for Bernard–Soulier syndrome. Quantitation of the GpIb–IX–V complex in small volumes of whole blood by means of monoclonal antibodies and flow cytometry²⁰ provides the most suitable method for detecting heterozygotes and for prenatal diagnosis. Prenatal blood sampling may carry a high risk to the affected fetus, as in the case of Glanzmann thrombasthenia. In those few cases in which the genetic defect has been identified, early prenatal diagnosis by chorionic villous sampling may be feasible.

von Willebrand disease

Von Willebrand disease is not primarily an inherited disorder of platelet function but an inherited disorder of VWF. However, because of the key role of VWF in platelet adhesion via its binding to the GpIb–IX–V complex (see above), von Willebrand disease results in a platelet adhesion defect. Thus it can present clinically with mucocutaneous bleeding, petechiae, and a prolonged bleeding time (see Table 25.1). Von Willebrand disease is discussed in detail in Chapter 27. Of particular relevance here is the rare platelet-type or “pseudo” von Willebrand disease which, like Bernard–Soulier syndrome, results not from an abnormality in VWF but from an abnormality in the platelet GpIb–IX–V complex. However, unlike Bernard–Soulier syndrome, in this autosomal dominant disease there is an unusual gain of function phenotype with facilitated binding of plasma VWF to platelets and increased platelet agglutination in the presence of low amounts of ristocetin. The mutations giving rise to this

disorder are Gly²³³→Val and Met²³⁹→Val.²² These amino acid substitutions occur within the disulfide-bonded double-loop region of GpIb α . It has been speculated that these mutations induce conformational changes that mimic those induced by high shear. Because the mutated GpIb α binds VWF multimers spontaneously, the VWF multimers are cleared from the plasma. The result is a clinical condition that resembles type 2B von Willebrand disease. In this latter disease, mutations within the VWF monomer result in an abnormal protein that binds spontaneously to platelets. Platelet-type von Willebrand disease varies from clinically mild to severe. Most have patients have moderately prolonged bleeding times and a degree of thrombocytopenia, probably due to platelet aggregation *in vivo*, and some have an increased platelet volume (see Table 25.4). Platelet agglutination by low-dose ristocetin is increased, and indeed the patient's platelets are usually agglutinated by the addition of normal plasma or VWF in the absence of ristocetin. The distinction from type 2B von Willebrand disease depends on the demonstration of binding of normal VWF to isolated platelets: lower concentrations of ristocetin are required for binding to platelets from patients with platelet-type von Willebrand disease than to either normal platelets or those from patients with type 2B von Willebrand disease.

Agonist receptor defects

Integrin $\alpha_2\beta_1$ deficiency

Nieuwenhuis *et al.*²⁹ reported the case of a young woman who had suffered from easy bruising and menorrhagia since her teens, with a constantly prolonged bleeding time, whose platelets failed to respond by aggregation, secretion or thromboxane synthesis to collagen (although they responded normally to other agonists) or to adhere to purified type I or type III collagen or subendothelial microfibrils. These investigators found that her platelet membranes were deficient in GpIa, which together with GpIIa forms the integrin $\alpha_2\beta_1$ (VLA-2), an important collagen receptor (Table 25.4).³⁰ Although no corresponding abnormality could be found in the platelets of this patient's parents, sister or son, the defect seems likely to have been genetically determined. A similar patient has subsequently been described with a lifelong bleeding tendency and a decreased reaction with collagen, in whom GpIa deficiency was associated with a lack of platelet thrombospondin.³¹ The symptoms and platelet defect disappeared at the time of the menopause, perhaps suggesting that they were related to hormonal influences.

P2Y₁₂ deficiency

Platelets possess two receptors for ADP: P2Y₁, which mediates ADP-induced Ca²⁺ mobilization and shape change; and P2Y₁₂, which results in stabilization of platelet aggregation.³⁰

Both P2Y₁ and P2Y₁₂ belong to the seven-transmembrane-domain family of G protein-linked receptors. Deficiency of the P2Y₁₂ receptor has been reported (Table 25.4).³² Such patients are of particular interest because their platelets show identical functional changes to those of normal platelets treated with clopidogrel or ticlopidine, suggesting that P2Y₁₂ is the molecular target for these antiplatelet drugs. So far, no human pathology of the P2Y₁ receptor has been reported.

Thromboxane A₂ receptor deficiency

Defective platelet aggregation to TXA₂ resulting from an Arg⁶⁰→Leu mutation in the TXA₂ receptor has been reported (Table 25.4).³³

Defective response to epinephrine

The aggregatory response of normal platelets to epinephrine is variable and decreased responsiveness may be inherited without conferring any hemostatic failure.^{34,35} It can therefore be argued that tests of epinephrine-induced aggregation are best avoided in the investigation of bleeding disorders, or at least discounted in the absence of other demonstrable abnormalities. However, Stormorken *et al.*³⁶ reported a 16-year-old boy who had had frequent bleeding episodes since early childhood and whose platelets completely failed to aggregate in response to epinephrine. Like the hemostatically normal subjects studied by Scrutton *et al.*,³⁴ his platelets had normal α_2 -adrenergic receptors. The exact nature of the defect was not established.

Signaling pathway defects

Platelet pathologies may also be present in the intracellular signal transduction pathways into which surface receptors are locked.²² This heterogeneous group of disorders (see Tables 25.2 and 25.4) present as mild bleeding disorders and defects of platelet aggregation that affect individual stimuli more than others. For example, patients have been reported with impaired Ca²⁺ mobilization, defective inositol 1,4,5-trisphosphate production, and reduced phosphorylation of the protein pleckstrin by protein kinase C. One patient was selectively deficient in the phospholipase C β_2 isoform, thereby highlighting its role in platelet activation. Another patient had a specific decrease in platelet membrane G_{oq} and platelets that responded less well to several agonists including decreased activation of $\alpha_{IIb}\beta_3$.³⁷ Rare patients with congenital deficiencies of cyclooxygenase, prostaglandin H synthetase 1, thromboxane synthetase, lipooxygenase, glycogen 6 synthetase, or ATP metabolism have been reported and lead to platelet function abnormalities that often resemble those seen in storage pool disease or after aspirin ingestion (see Tables 25.2 and 25.4).²² These reports of abnormalities in signaling pathways represent the first of what may

eventually prove to be a long list of rare congenital disorders of platelets. The key to identifying these disorders will be improved diagnostic methods, perhaps including the simultaneous assessment of a wide range of genes by microarraybased technology.²²

Secretion defects

Storage pool disease

This term was first applied to deficiency of the platelet dense bodies, the site of the storage pool of adenine nucleotides and of 5-HT (serotonin). Following the suggestion of Weiss *et al.*,³⁸ its use has been extended to include deficiency of the α -granules. Pure dense body deficiency is therefore now designated δ -storage pool deficiency (δ -SPD), pure deficiency of α -granules (gray platelet syndrome) α -SPD, and combined deficiency of both types of organelle $\alpha\delta$ -SPD.

Dense body deficiency

Laboratory diagnosis

The definitive diagnosis of δ -SPD depends on demonstration of the dense body deficiency, biochemically, morphologically or by flow cytometry. The bleeding time, or PFA-100 closure time, is usually moderately prolonged, and the platelet aggregation pattern commonly reflects the defect of secretion, although it will not clearly distinguish dense body deficiency from other secretory disorders. The typical features are normal primary aggregation in response to ADP and epinephrine, but without a second wave, a marked defect of aggregation and ATP secretion in response to collagen, and a normal response to arachidonic acid, which serves to exclude a defect of thromboxane generation.³⁹ However, this typical pattern may not be seen in milder cases: Nieuwenhuis *et al.*¹³ studied over 100 patients with long bleeding times and a deficiency of total platelet ADP and 5-HT, of which about half were congenital in origin, and found that about one-quarter had a normal aggregation pattern with ADP, epinephrine and collagen, while only one-third showed a pattern completely typical of a secretory defect. The hallmarks of δ -SPD are therefore actual deficiency of the dense bodies and their contents. Dense bodies can be enumerated in platelets by either electron microscopy or fluorescence microscopy after incubation with the fluorescent dye mepacrine, which is taken up and localized in the dense bodies.⁴⁰ δ -SPD can be accurately diagnosed by a simple, rapid, one-step flow cytometric assay for mepacrine uptake.^{14,15} Biochemical evidence of dense body deficiency depends on measurement of the platelet content of adenine nucleotides and 5-HT and their uptake and secretion. The storage pool of nucleotides in the dense bodies (which is largely deficient in δ -SPD) has an ATP/ADP ratio of about 2 : 3, while that of the metabolic pool in the cytosol is about 8 : 1. In δ -SPD,

therefore, the ATP/ADP ratio of whole platelets (normally 1.5–2.5 : 1) is much increased, approximating to that of the metabolic pool alone of normal platelets.⁴¹ The defective secretion of adenine nucleotides can also be demonstrated by lumiaggregometry after thrombin activation.

Clinical associations

Dense body deficiency has been observed in a number of families as an isolated platelet defect, and also occurs as an integral part of two well-defined syndromes in association with albinism and lysosomal abnormalities: Hermansky–Pudlak and Chédiak–Higashi syndromes. The nonalbino group (idiopathic δ -SPD) shows considerable heterogeneity with respect to both heredity and the degree of dense body deficiency, and patients are usually more mildly affected than albino patients. While in several families the isolated defect appears to be transmitted as an autosomal dominant trait, others exhibit recessive inheritance. In contrast to the albino patients, whose platelets are profoundly deficient in both dense body membranes and contents, the idiopathic nonalbino group shows various degrees of dissociation between these two features.

Hermansky–Pudlak syndrome is an autosomal recessive disorder characterized by the triad of tyrosinase-positive oculocutaneous albinism, a lifelong moderate bleeding tendency, and the presence of ceroid-like pigment in cells of the reticuloendothelial system (see Table 25.4). The pigment was first observed in bone marrow macrophages but may also be deposited in the lungs and intestine, where it leads to pulmonary fibrosis and inflammatory bowel disease, as well as in the buccal mucosa and urinary bladder. The bleeding tendency is primarily attributable to the deficiency of platelet dense bodies. The dense body deficiency is more severe than that in nonalbino patients and affects both membranes and contents,^{42,43} suggesting that the defect is a structural one, involving dense body formation in the megakaryocyte. Heterozygotes are clinically unaffected, and their platelets contain normal amounts of adenine nucleotides and aggregate normally. Hermansky–Pudlak syndrome is common in Puerto Rico. The defect is in the *HPS1* or *HPS2* genes.²²

Chédiak–Higashi syndrome, an autosomal recessive disorder of lysosome formation in neutrophils and other cells (Table 25.4). Thrombocytopenia is common and is the chief cause of the bleeding tendency, but dense body deficiency is also characteristic.²² As in Hermansky–Pudlak syndrome, granulophysin (CD63) is deficient, indicating a defect of dense body membrane formation. Like the neutrophils, the platelets contain large abnormal granules. The defect is in the *CHS* gene on chromosome 13.²²

Wiskott–Aldrich syndrome is an X-linked recessive disorder characterized by thrombocytopenia, small platelets, eczema, and recurrent infections secondary to immune deficiency (see Table 25.4).²² In addition, the platelets also have a dense body deficiency.²² The genetic defect in Wiskott–Aldrich

syndrome results from a defect in the 502-amino acid protein termed WASP (Wiskott–Aldrich syndrome protein). Wiskott–Aldrich syndrome is more fully described in Chapter 19.

α -Granule deficiency (gray platelet syndrome)

Unlike dense body deficiency, a pure deficiency of α -granules occurs in only a single hereditary disorder, named by Raccuglia⁴⁴ as gray platelet syndrome (Table 25.4), based on the appearance of the agranular platelets on a stained blood smear. This extremely rare hereditary platelet disorder, which shows either autosomal recessive or autosomal dominant inheritance, is sometimes surprisingly mild clinically, considering the profound nature of the structural and biochemical platelet defect. Epistaxes, menorrhagia and prolonged bleeding after serious injury are the commonest symptoms.

Laboratory findings

The bleeding time is usually moderately prolonged. Unlike most other defects of platelet function, the first diagnostic clue comes from examination of the blood film, which reveals the characteristic gray agranular platelets. The platelet count is usually slightly below normal and mean platelet volume is increased. The profound α -granule deficiency can be confirmed by electron microscopy, which also shows normal numbers of dense bodies and mitochondria and numerous large vesicles. The latter probably represent both abortive α -granules and elements of the open canalicular system. Small abnormal granules may also be seen, recognizable as α -granule precursors by their content of fibrinogen and VWF, and also by the specific proteins, including P-selectin, in their membranes.⁴⁵

Gray platelets have been shown to be profoundly deficient in many of the proteins normally contained in α -granules, including 2-TG, PF4, thrombospondin, PDGF, VWF and factor V,^{46,48} all of which are synthesized within the megakaryocyte. The defect is one of packaging of these endogenous proteins within the organelles rather than of protein synthesis, as shown by normal or even slightly elevated plasma levels of 2-TG and PF4. It has been suggested that this failure of packaging may lead to the premature release of PDGF and PF4 from the megakaryocyte, so accounting for the myelofibrosis observed in some of these patients,⁴⁹ and perhaps for the pulmonary fibrosis which has also been described.⁵⁰ However, this failure of packaging does not extend to the plasma proteins, including fibrinogen, fibronectin, immunoglobulins and albumin, which are taken up essentially normally into α -granule precursors.

Gray platelets typically show a partial defect of aggregation and dense body secretion, particularly in response to thrombin and collagen. This appears to be due to a defect of phosphoinositide hydrolysis and cytosolic calcium transport,^{51,52} associated with an increased rate of transport of calcium into membrane vesicles;⁵³ this in turn may be

related to an abnormality of the monomeric GTP-binding protein Rap-1, which is normally expressed in intracellular membranes from gray platelets but abnormally phosphorylated by cAMP.⁵⁴

Gray platelet syndrome has not yet been diagnosed prenatally, but Wautier and Gruel⁵⁵ were able to exclude the condition in the 19-week fetus of a woman with gray platelet syndrome by demonstrating normal platelet β -TG content and ultrastructure.

Combined storage pool deficiency

A proportion of patients with the nonalbino variety of hereditary dense body deficiency also have various degrees of α -granule deficiency, i.e., $\alpha\delta$ -SPD.⁵⁶ The clinical severity does not appear to be significantly greater in patients with the combined deficiency than in those with pure δ -SPD. An apparent association with acute myeloid leukemia has been reported in two families with SPD: two affected members of the family with mild $\alpha\delta$ -SPD had leukemia,⁵⁶ while a large family with apparent δ -SPD (in whom α -granules were not studied) included seven patients with myeloid leukemias, of whom at least four had a preexisting platelet disorder.⁵⁷ It may be that both these families were expressing defects in a protooncogene that regulates the maturation of both granulocytes and megakaryocytes.

Quebec syndrome

Quebec syndrome (see Table 25.4) is an autosomal dominant bleeding disorder that was first described in two French-Canadian families.⁵⁸ Originally thought to involve factor V, Quebec syndrome platelets in fact have a severe deficiency of multimerin, a high-molecular-mass multimeric protein that is stored as a complex with factor V in α -granules. In this syndrome, platelets typically show protease-related degradation of many α -granule proteins (including P-selectin) even though α -granule ultrastructure is preserved.⁵⁹ Platelets in this disorder have unusually large amounts of urokinase-type plasminogen activator that is released on platelet activation, and whose presence in excess of the natural inhibitors of this protease accounts for the *in situ* protein degradation in the α -granules.⁶⁰ For unknown reasons, the platelet aggregation deficiency is most striking with epinephrine. Thrombocytopenia is sometimes observed.

Aggregation defects

Glanzmann thrombasthenia

In 1918, Glanzmann provided the first description of a hereditary disorder of platelet function, characterized by a prolonged bleeding time and impaired clot retraction in the presence of a normal platelet count.⁵⁸ The defect is now

known to be characterized by a global defect in platelet aggregation as a result of a deficiency of integrin $\alpha_{IIb}\beta_3$ (GpIIb-IIIa, CD41/CD61).

Clinical features

Glanzmann thrombasthenia is an autosomal recessive disorder, rare in a global context but relatively more common in those communities where consanguineous marriages are frequent. It cannot be distinguished on clinical grounds alone from other congenital platelet disorders or severe von Willebrand disease. It commonly presents in infancy or early childhood with multiple bruises following minimal or unrecognized trauma, or with crops of petechiae or ecchymoses. George *et al.*⁶¹ reported the incidence and severity of bleeding symptoms in a series of 177 patients. Epistaxes are very common, and may be difficult to control with local measures, and may even be life-threatening. Gingival hemorrhage is a frequent result of the shedding of deciduous teeth, or even of tooth brushing, and is likely to lead to iron deficiency. Large muscle hematomas and hemarthroses seldom occur, but menorrhagia is virtually inevitable and may present a serious hazard in pubertal girls. Serious accidental and surgical trauma can be life-threatening. Although the failure of platelet aggregation *in vitro* is always virtually complete, clinical severity correlates poorly with the nature and degree of the molecular abnormality, with even siblings sometimes being very differently affected.⁶¹

Laboratory diagnosis

The essential diagnostic features are normal platelet count and morphology associated with a complete failure of platelet aggregation in response to all agonists (e.g., ADP, epinephrine, collagen, arachidonic acid, thrombin); this is because Glanzmann thrombasthenia is the result of a defect in integrin $\alpha_{IIb}\beta_3$ which, as the fibrinogen receptor, is the final common pathway for platelet aggregation.⁵⁸ However, platelet agglutination with ristocetin is normal because this process is not dependent on integrin $\alpha_{IIb}\beta_3$ interactions with fibrinogen but on GpIb-IX-V interactions with VWF. After the platelet aggregation defect has been demonstrated, the diagnosis of Glanzmann thrombasthenia can be confirmed, and in the case of unusual variants extended, by measuring the amounts of integrins α_{IIb} and β_3 in the platelet surface membrane. The methods available for this include one- and two-dimensional polyacrylamide gel electrophoresis, crossed immunoelectrophoresis using specific antibodies, and binding assays or flow cytometry with monoclonal antibodies to the constituent glycoproteins. The last of these has the advantage of being simply performed on very small volumes of whole blood,⁶² making it particularly appropriate for prenatal diagnosis (see below) or the investigation of small children. Clot retraction, platelet fibrinogen and PF3 availability are all defective in Glanzmann thrombasthenia, but contribute no more to the diagnosis when the defective

platelet aggregation and deficiency of integrin $\alpha_{IIb}\beta_3$ has been demonstrated.

Molecular genetics

A normal tertiary structure of integrin $\alpha_{IIb}\beta_3$ is required for its receptor activity, as demonstrated by patients with variant forms of Glanzmann thrombasthenia who have qualitative defects of $\alpha_{IIb}\beta_3$ that result in an inability to bind fibrinogen. Nevertheless, the majority of patients have severely decreased platelet surface expression of $\alpha_{IIb}\beta_3$.⁵⁸ Large gene deletions are rare, while splice defects and nonsense mutations in the α_{IIb} and β_3 genes are common. The gene encoding α_{IIb} spans 17 kb and comprises 30 exons. The gene encoding β_3 spans 46 kb and is composed of 15 exons. The genes co-localize to 17q21-23.

Detection of heterozygotes

Heterozygotes for Glanzmann thrombasthenia usually have no significant bleeding symptoms and no demonstrable defect of platelet aggregation. However, their platelet surface expresses about half the normal number of copies of integrin $\alpha_{IIb}\beta_3$, thus providing a means of carrier detection by flow cytometry, gel electrophoresis, or fibrinogen binding. None of these methods is completely reliable, but in kindreds in which the precise genetic defect has been identified, unequivocal carrier detection can be provided using DNA probes specific for the abnormal DNA sequence or by the detection of deletions by polymerase chain reaction analysis.⁶³

Prenatal diagnosis

Since platelet integrin $\alpha_{IIb}\beta_3$ has reached adult levels by 18 weeks of gestation, its expression and functional integrity can be determined on fetal blood samples.^{64,65} These methods are applicable to families with the classical form of the disease, characterized by integrin $\alpha_{IIb}\beta_3$ deficiency, and can even detect the heterozygous state *in utero*,⁵⁵ but are less appropriate for the prenatal diagnosis of disease variants. In such cases, prenatal blood testing depends on the demonstration of a defect in aggregation⁶⁶ or fibrinogen binding.⁶⁷ When the molecular genetic abnormality is known, diagnosis can be performed at 8–10 weeks' gestation by chorionic villous sampling and the use of appropriate DNA probes. Fetal sampling for the prenatal diagnosis of Glanzmann thrombasthenia carries a high risk to the affected fetus of death from continuing hemorrhage.^{66,68}

Abnormalities of platelet coagulant activity

Scott syndrome

Scott syndrome is a rare inherited disorder of Ca^{2+} -induced phospholipid scrambling, leading to abnormal assembly of the prothrombinase complex on blood cells including platelets (see Table 25.4).⁵⁸ When activated, Scott syndrome

platelets are unable to translocate phosphatidylserine from the inner to the outer phospholipid leaflet of the membrane bilayer, with the result that they cannot assemble the prothrombinase (factors Va/Xa) and tenase (factors VIIIa/IXa) enzyme complexes. The resultant lack of thrombin generation is sufficient to induce a bleeding diathesis. Stimuli that induce this phosphatidylserine translocation under physiologic conditions include a thrombin and collagen mixture and complement C5b–9. Microvesiculation and the diffusion of the procoagulant activity into the circulation may accompany surface phosphatidylserine expression, which can be readily measured by flow cytometry using fluorescein isothiocyanate (FITC)-conjugated annexin V. Microvesicle formation is also deficient in Scott syndrome. The defect in Scott syndrome may be related to capacitative Ca^{2+} entry into cells, and the subsequent regulated activation of the scramblase enzyme thought to be responsible for phosphatidylserine mobilization.^{69–71}

MYH9-related disease

May–Hegglin anomaly, Sebastian syndrome, Fechtner syndrome, and Epstein syndrome are autosomal dominant macrothrombocytopenias distinguished by different combinations of clinical and laboratory signs, such as sensorineural hearing loss, cataract, nephritis, and polymorphonuclear Döhle-like bodies (see Table 25.4). Mutations in the *MYH9* gene encoding nonmuscle myosin heavy chain IIA have recently been identified in all these syndromes.⁷² May–Hegglin anomaly, Sebastian syndrome, Fechtner syndrome, and Epstein syndrome are therefore not distinct entities but rather a single disorder with a continuous clinical spectrum, varying from mild macrothrombocytopenia with leukocyte inclusions to a severe form complicated by hearing loss, cataracts, and renal failure. For this new nosologic entity, the term “MYH9-related disease” has been proposed,⁷² which identifies patients at risk of developing renal, hearing, and/or visual defects.

Miscellaneous disorders

Various platelet abnormalities have been reported in hereditary disorders of connective tissue, including Ehlers–Danlos and Marfan syndromes and osteogenesis imperfecta, but the bleeding tendency in these disorders is more likely to result from the connective tissue abnormality. In Ehlers–Danlos syndrome, for example, skin collagen has been shown to be defective in aggregating normal platelets.⁷³ The bleeding tendency is most severe in type IV Ehlers–Danlos syndrome, in which type III collagen, the most potent type of collagen in activating the platelets, is deficient.⁷⁴ Defective platelet aggregation has been described in Bartter syndrome but is due to a plasma factor, the probable consequence of the underlying metabolic disturbance.⁷⁵ Biochemical and/or

functional abnormalities of the platelets have been described in Down syndrome, adenosine deaminase deficiency and idiopathic scoliosis, but none of these conditions is associated with abnormal bleeding.

Acquired disorders of platelet function

Abnormalities of platelet function occur in a wide range of acquired conditions, often in association with other hemostatic defects including both thrombocytopenia and disorders of blood coagulation. It may therefore be difficult to assess the relative importance of several observed abnormalities in the pathogenesis of the bleeding tendency. In most acquired disorders of platelet function, the nature of the platelet abnormality is much less clear-cut than in the genetic disorders of platelet function. A predominantly clinical rather than pathogenetic classification is therefore appropriate (see Table 25.3).

Drugs and other agents

Aside from the deliberate use of platelet inhibitory drugs as antithrombotic agents, interference with platelet function may occur as a side-effect of drugs used for other purposes. The defects induced are usually of minor degree and observed only on laboratory testing. The following account is largely confined to those drugs and agents that have been recognized as potential causes of clinical bleeding (Table 25.5).

Cyclooxygenase inhibitors

Aspirin irreversibly acetylates serine 529 of cyclooxygenase (COX)-1, resulting in inhibition of TXA_2 generation by platelets and prostacyclin by endothelial cells.⁷⁶ Because platelets lack the synthetic machinery to generate significant amounts of new COX, aspirin-induced COX-1 inhibition lasts for the lifetime of the platelet. In contrast, endothelial cells retain their capacity to generate new COX and recover normal function shortly after exposure to aspirin. Aspirin results in absence of the second wave of aggregation with ADP and failure of aggregation and secretion in response to collagen and arachidonic acid. It is therefore important to ensure abstinence from aspirin for at least 10 days before platelet function testing for diagnostic purposes. Aspirin ingestion is a common cause of platelet dysfunction, and may occasionally precipitate gastrointestinal or other hemorrhage, particularly in susceptible individuals. Aspirin is therefore contraindicated in patients with known bleeding disorders. Since aspirin crosses the placenta and can contribute to neonatal bleeding,⁸ it should if possible be withheld during the week before delivery. Compared with aspirin, other NSAIDs, including indometacin,

phenylbutazone and sulfinpyrazone, have a similar but reversible, and therefore less prolonged, effect on platelet function.

ADP receptor antagonists

The thienopyridines clopidogrel (Plavix) and ticlopidine (Ticlid) inhibit platelet function by antagonism of the P2Y₁₂ ADP receptor.⁷⁷ In patients treated with a thienopyridine, platelet aggregation responses to several agonists, including ADP, collagen, epinephrine, and thrombin, are inhibited to various extents depending on agonist concentrations. Significant inhibition of platelet aggregation is observed after 2–3 days of therapy with a maximal effect at 4–7 days.⁷⁷ The platelet inhibitory effect persists to some extent for 7–10 days after therapy is discontinued. Because of this prolonged effect, these drugs need to be discontinued for 7–10 days prior to elective surgery. Ticlopidine and, to a lesser extent, clopidogrel are rarely associated with thrombotic thrombocytopenic purpura.⁷⁷

GpIIb–IIIa antagonists

GpIIb–IIIa antagonists abciximab (ReoPro), eptifibatide (Integrilin) and tirofiban (Aggrastat) inhibit fibrinogen binding to GpIIb–IIIa (integrin $\alpha_{IIb}\beta_3$, CD41/CD61), the final common pathway of platelet aggregation.⁷⁸ Platelet aggregation induced by all agonists (with the exception of ristocetin, which is not a true agonist) is therefore inhibited. Abciximab may have additional mechanisms of action through binding to integrins $\alpha_v\beta_3$ (vitronectin receptor) and $\alpha_M\beta_2$ (Mac-1, CD11b/CD18).⁷⁸ Bleeding secondary to these intravenous drugs is responsive to platelet transfusion, but this is usually unnecessary with eptifibatide and tirofiban because of their shorter half-life.⁷⁹ In addition to their platelet inhibitory effect, thrombocytopenia is a potential side-effect of GpIIb–IIIa antagonists.⁷⁹

Antimicrobials

Many of the β -lactam antibiotics, particularly the penicillins, can cause a bleeding tendency by interfering with platelet function. This side-effect, which may persist for up to 12 days after withdrawal of the drug,⁸⁰ is seen only with high-dosage regimens. Patients in renal failure are at particular risk, since high drug concentrations resulting from impaired clearance may coexist with other hemostatic defects. Thrombocytopenia-induced bleeding in patients on chemotherapy for malignant disease may be exacerbated by antibiotic-induced platelet dysfunction. Both penicillins and cephalosporins have been shown to inhibit platelet adhesion, aggregation and secretion *in vitro*: the underlying mechanisms appear to involve the inhibition of agonist binding to membrane receptors and impairment of thromboxane synthesis and calcium mobilization.^{81,82} The platelet inhibitory effect of β -lactam antibiotics

is influenced by plasma albumin concentration: platelet binding of the antibiotic and the impact on platelet responses are inversely related to albumin concentration.⁸³ In addition to the β -lactam antibiotics, other antimicrobials shown to inhibit platelet function include nitrofurantoin,⁸⁴ hydroxychloroquine,⁸⁵ and miconazole.⁸⁶

Cardiovascular drugs

The following cardiovascular drugs have been reported to inhibit platelet function: β -blockers (propranolol, pindolol, atenolol, metoprolol), furosemide, nitroprusside, nitroglycerin, isosorbide dinitrate, and quinidine.¹²

Heparin

The main platelet-related complication of heparin therapy is heparin-induced thrombocytopenia (see Chapter 31).⁸⁷ In addition, unfractionated heparins have been found to bind to the platelet membrane and to inhibit platelet function in certain experimental systems, possibly by inducing a refractory state following partial activation. These effects might contribute to the bleeding tendency of heparin overdosage. Heparin fractions of low molecular weight and high antithrombin affinity are the least likely to bind to platelets⁸⁸ and interfere with platelet function,⁸⁹ and this may partly account for the lower incidence of bleeding complications seen with low molecular weight than with unfractionated heparin.⁹⁰

Thrombolytic agents

The major complication following the administration of thrombolytic agents (streptokinase, urokinase, recombinant tissue plasminogen activator (rt-PA)) is hemorrhage, which arises from multiple mechanisms including the effect of plasmin on the plasma coagulation system and platelets, and the dissolution of blood clots providing local hemostasis.¹² The bleeding time in patients receiving rt-PA may be prolonged.⁹¹ *In vitro*, plasmin induces several effects in platelets: initial platelet activation followed by inhibition, cleavage of membrane glycoproteins, inhibition of TXA₂ production, and disaggregation of platelet clumps.⁹² Urinary metabolites of TXA₂ are increased during thrombolytic therapy with rt-PA or streptokinase, indicating *in vivo* activation of platelets.^{93,94} Other factors contributing to platelet inhibition in patients receiving thrombolytic therapy include radiographic contrast media and elevated levels of fibrin(ogen) degradation products.¹²

Miscellaneous agents

Other drugs that have been reported to inhibit platelet function include tricyclic antidepressants (imipramine, amitriptyline,

nortriptyline), phenothiazines (chlorpromazine, promethazine, trifluoroperazine), chemotherapeutic agents (mithramycin, BCNU, daunomycin), local anesthetics, halothane, sodium valproate, dextrans, hydroxyethyl starch, aminocaproic acid, antihistamines, ethanol, and radiographic contrast agents.¹² The following food items and supplements have been reported to inhibit platelet function: ω -3 fatty acids, vitamin E, onions, garlic, ginger, cumin, turmeric, clove, black tree fungus and *Ginkgo*.¹²

Uremia

Although coagulation defects and thrombocytopenia may both occur in patients in renal failure, defective platelet function is the main cause of bleeding. This commonly presents as purpura, epistaxis or bleeding from the gums, although serious internal hemorrhage may also occur, and renal biopsy or surgical procedures present a special hazard. The bleeding time is typically prolonged, and abnormalities have been reported in a variety of aspects of platelet function, including aggregation,⁹⁵ adhesion to subendothelium⁹⁶ (perhaps related to reduction in platelet membrane GpIb⁹⁷), elevation of cytoplasmic free calcium,⁹⁸ and thromboxane formation.⁹⁹ The aggregation defect correlates poorly with the severity of the renal failure, but can be at least partially corrected by hemodialysis or peritoneal dialysis.^{100,101} No general agreement has been reached on the identity of the dialysable component responsible for the effect on the platelets; urea,¹⁰² guanidinosuccinic acid,¹⁰³ and phenolic acids¹⁰⁴ have all been incriminated. Various defects of arachidonate metabolism have been described in uremic patients, leading to both impaired generation of TXA₂⁹⁹ and increased prostacyclin production.¹⁰⁵

Liver disease

The hemostatic failure of liver disease results chiefly from defective synthesis of clotting factors, but low-grade intravascular coagulation and increased fibrinolysis may also occur. Defective platelet aggregation may be another contributory factor: acquired storage pool deficiency is a likely mechanism, and defects of thromboxane synthesis¹⁰⁶ and membrane glycoproteins¹⁰⁷ have also been reported. Although patients with liver disease usually have normal or raised levels of VWF, desmopressin has been found to shorten the prolonged bleeding time¹⁰⁸ as well as improving the results of coagulation tests.

Extracorporeal perfusion

Bleeding during and after cardiopulmonary bypass has many contributory causes, including defective surgical hemostasis, but transient thrombocytopenia and platelet dysfunction are important in the etiology.¹⁰⁹ The platelet dysfunction results

in marked prolongation of the bleeding time during the procedure, with gradual normalization during the subsequent 2–4 hours. The platelet dysfunction is attributable to a combination of platelet activation and membrane damage from contact with the bypass apparatus, decreased available thrombin, contact activation, complement activation, plasmin, fibrin(ogen) degradation products, hypothermia, and heparin.¹⁰⁹ Excessive perioperative bleeding can be reduced by aprotinin, (to a lesser extent) desmopressin, and (possibly) platelet transfusions.¹⁰⁹

Acquired storage pool deficiency

An acquired storage pool deficiency has been reported in a number of different clinical settings including autoimmune disease, disseminated intravascular coagulation, hemolytic-uremic syndrome/thrombotic thrombocytopenic purpura, severe burns and valvular heart disease.¹²

Antiplatelet antibodies

Many patients with immune thrombocytopenic purpura have autoantibodies directed against determinants on GpIIb–IIIa or GpIb. Such antibodies have also been detected in patients with acquired bleeding disorders and long bleeding times but normal platelet counts, resulting in platelet function defects resembling those of Glanzmann thrombasthenia¹¹⁰ and Bernard–Soulier syndrome.¹¹¹ Similarly, acquired antibodies directed against GpIa can result in a platelet function defect.¹¹² In patients with immune thrombocytopenic purpura, the antibody-induced functional defect can persist after recovery of the platelet count.

Acute leukemias and myelodysplastic syndromes

Platelet dysfunction can occur in acute leukemias (especially myeloid) and myelodysplastic syndromes.¹² Defects of aggregation and secretion have been described and attributed variously to storage pool deficiency and defects of secretory mechanisms,¹¹³ impaired thromboxane production,¹¹⁴ and deficiency of thrombin-binding sites on the platelet membrane.¹¹⁵

Myeloproliferative disorders

Hemorrhagic symptoms and arterial thromboses are common in adults with myeloproliferative disorders, and both may occur in the same patient.¹² The most common bleeding symptoms are large superficial ecchymoses, epistaxes and hemorrhage from the gastrointestinal tract. Thrombosis usually involves either the cerebral arteries or the peripheral arteries of the limbs. The platelet defects that have been described are not specifically associated with any one of the adult myeloproliferative disorders; similar defects have been

observed in essential thrombocythemia, polycythemia vera, chronic granulocytic leukemia, and myelofibrosis.¹² All these conditions are rare in childhood, particularly the first two, but when they do occur they may also be associated with functional platelet disorders. Structural platelet abnormalities are commonly seen in the myeloproliferative disorders, and among the disturbances of platelet function that have been described are:

- defects of aggregation, particularly in response to epinephrine;¹¹⁶
 - storage pool deficiency;¹¹⁷
 - defects of arachidonate metabolism;¹¹⁸
 - defects of platelet coagulant activities;¹¹⁹
 - resistance to the action of the antiaggregatory prostaglandin D₂.¹²⁰
 - various abnormalities of platelet membrane glycoproteins.¹²¹
- Michelson¹²² studied four children with juvenile (Ph-negative) chronic myeloid leukemia (CML) and with Ph-positive adult CML, all of whom (in contrast to age-matched controls and adults with Ph-positive CML) showed two subpopulations of platelets, positive and negative respectively, for both GpIb and GpIIb–IIIa. Berndt *et al.*¹²³ described the case of a 9-year-old girl with a myelodysplastic syndrome characterized by monosomy 7, thrombocytopenia and giant platelets, who had had a bleeding tendency from the age of 5. She was also found to have two populations of platelets, the majority being large and deficient in GpIb–IX complex and the minority normal. Some of the platelet abnormalities that have been observed in myeloproliferative disorders would be expected to lead to abnormal bleeding and others to predispose to thrombotic episodes, but in practice the laboratory findings have been found to correlate poorly with the clinical course of the disease.

Treatment of platelet function disorders

General principles

Platelet function disorders are often mild bleeding disorders. The general principles of treatment of platelet function defects are as follows.

- Avoidance of major body contact activities.
- Avoidance of drugs that interfere with platelet function (e.g., aspirin and other NSAIDs) and other components of the hemostatic system.
- Avoidance of intramuscular injections.
- Good dental care (to minimize gum bleeding and avoid tooth extraction).
- Local hemostatic measures.
- Oral iron (to prevent or treat iron deficiency secondary to blood loss).
- Oral contraceptive pills may be necessary for the control of menorrhagia.

- Immunizations can be given subcutaneously with direct pressure using ice. If necessary, Stimate can be given (see below).
- Consideration should be given to the wearing of a medical bracelet or necklace with the words “platelet function defect” inscribed and/or the patient should carry an information card to that effect.

Antifibrinolytic agents

- Oral aminocaproic acid, an inhibitor of plasminogen activator, is often useful for oral bleeding.
- In Quebec syndrome, the bleeding responds to antifibrinolytic agents rather than to platelet transfusions, because platelets in this disorder have unusually large amounts of urokinase-type plasminogen activator that is released on platelet activation, and whose presence in excess of the natural inhibitors of this protease accounts for the *in situ* protein degradation in α -granules.⁶⁰

Desmopressin (DDAVP)

- Desmopressin, either intravenously or by nasal spray (Stimate), is often helpful for patients with a platelet function defect.¹²⁴
- There should be a major response by 30 min with a maximum response at 90 min.
- Plasma levels last at least 8–10 hours.
- Desmopressin can be repeated every 12 hours, but tolerance may occur after 72 hours.
- The beneficial effect of desmopressin in platelet function disorders may be related to increased release of factor VIII and VWF from endothelial Weibel–Palade bodies and/or a poorly characterized direct effect on platelets.¹²⁴

Activated factor VII

- NovoSeven (intravenous activated factor VII) is effective in many platelet function disorders.^{125,126}
- The beneficial effect of activated factor VII may be via a tissue factor-dependent mechanism and/or a tissue factor-independent, platelet-dependent mechanism.¹²⁵

Platelet transfusion

- If necessary, platelet transfusions (preferably HLA-matched) can be given for major bleeding episodes. The platelet transfusion will temporarily correct the platelet function defect.
- Platelets should be available for transfusion during any surgery.
- There is evidence that leukocyte depletion of platelet and red cell concentrates by filtration reduces the likelihood of alloimmunization as well as of febrile transfusion reactions.¹²⁷

- A major problem with platelet transfusion in Bernard–Soulier syndrome and Glanzmann thrombasthenia is alloimmunization, with patients forming antibodies against the glycoproteins missing from their own platelets. Some of these antibodies may recognize epitopes on active sites of the glycoproteins involved in adhesion and aggregation, thus rendering transfused platelets refractory as well as leading to their accelerated destruction. Therefore, platelet transfusions in Bernard–Soulier syndrome and Glanzmann thrombasthenia should be reserved for life-threatening emergencies.

- Platelet concentrates are the treatment of choice in platelet-type von Willebrand disease, because the defect is in the platelets. Both desmopressin and cryoprecipitate should be avoided in platelet-type von Willebrand disease because the resultant increase in circulating large VWF multimers may result in worsening thrombocytopenia.

Treatment of the platelet function defect of uremia

- The most effective therapeutic measure is correction of the hematocrit, either by red cell transfusions¹²⁸ or by administration of human recombinant erythropoietin.¹²⁹ The beneficial effect on hemostasis of correcting the anemia in uremic patients remains to be fully explained; the mechanical effect of red cells in influencing flow conditions so as to promote interaction of platelets with the vessel wall¹³⁰ is probably part of the explanation, but erythropoietin treatment also appears to diminish the inhibitory effect of uremic plasma on platelet adhesion and aggregation.^{131,132}
- Conjugated estrogens have also been shown to correct the bleeding time of uremic patients.^{133,134} The effect lasts for several days and appears to depend on reduction of endothelial synthesis of nitric oxide.¹³⁵
- The platelet aggregation defect correlates poorly with the severity of the renal failure, but can be at least partially corrected by hemodialysis or peritoneal dialysis.^{100,101}

Bone marrow transplantation

- Bone marrow transplantation is used in children with severe diseases such as Chédiak–Higashi syndrome,¹³⁶ Wiskott–Aldrich syndrome¹³⁷ and, occasionally, Glanzmann thrombasthenia.¹³⁸
- The risks of bone marrow transplantation confine its use to cases in which severe bleeding cannot be adequately controlled by more conservative measures.

Gene therapy

Diseases such as Bernard–Soulier syndrome and Glanzmann thrombasthenia are good candidates for gene therapy and progress is being made in this regard.¹³⁹

Hemophilia A and B

Judith Smith and Owen P. Smith

Introduction

Hemophilia is unique among diseases for two main reasons. Firstly, it is generally well known to members of the public because of its connection with the royal families of Europe, in particular those descendants of Queen Victoria who were associated with the Russian and Spanish royal families. The presence of this genetic defect within these families subsequently had catastrophic social, personal and political effects. Secondly, the history of hemophilia shows that there was parallel progress in understanding the causes of the disease, diagnosis of the disease as well as improved therapy, and indeed cure of the disease, a situation unrivalled in any other human illness.

Historical perspective

The word "hemophilia" is derived from two Greek words, *haima* meaning blood and *philein* meaning to love.¹ Despite the inappropriateness of this description of excess bleeding, the word "hemophilia" continues to be used in patients with an inherited predisposition to blood loss. It is interesting that this inherited blood disease is not mentioned in early Egyptian, Roman and Greek medical literature.²

The first documented account of an inherited bleeding disorder was in the 2nd century AD. The Babylonian Talmud describes the decision of Rabbi Juddah that the son of a woman whose three previous sons had bled to death following circumcision be excused from the rite.³ Although further descriptions by Arabic physicians appear in the 12th century, it was not until the 18th century that the first reports on a possible genetic basis and effective treatment with blood transfusion appeared.⁴ By the 1950s fresh frozen plasma was the main step in treatment, and then in the mid 1960s Poole and Shannon made the first major advance in hemophilia treatment care with the discovery that factor (F)VIII was

concentrated in cryoprecipitate.⁵ This discovery made it possible for blood banks to prepare a potent "wet" concentrate and, together with the advances made by the plasma industries in preparing coagulation factor concentrate, hemophilia care was thus dramatically altered from solely hospital-based management to one where treatment could be administered at home immediately following trauma or at the first sign of bleeding. The next major innovation was prophylaxis, which resulted in markedly reduced hospitalizations and the incidence of crippling deformities in children and adolescents with hemophilia A and B. Advances in recombinant DNA technology led to the cloning of the FVIII and FIX genes in the early 1980s. Today we have several recombinant FVIII and one FIX gene products and all have been shown to be safe, effective and extremely well tolerated in children. The next milestone in the history of hemophilia treatment clearly will be cure of the disease with gene therapeutics.

Hemophilia A and B (factor VIII and factor IX deficiency)

The term "hemophilia", originally applied to a lifelong hemorrhagic disorder, was by the early 1950s classified into two distinct disease types based on specific plasma protein deficiencies. FVIII deficiency (hemophilia A) and FIX deficiency (hemophilia B) are inherited as sex-linked recessive disorders, with a prevalence in all racial groups of approximately 1 in 10 000 and 1 in 50 000 respectively.⁶

After von Willebrand's disease, hemophilia A and B are considered the commonest but also the most severe forms of congenital bleeding disorder, with FVIII deficiency being five times more prevalent than FIX deficiency. The reason for the relatively high incidence of FVIII deficiency is partly due to the high mutation rate and the X-linked pattern of inheritance. In approximately one-third to half of newly diagnosed infants with hemophilia A there is no family history of the disorder and the hemophilia has resulted from spontaneous

(*de novo*) mutations. Following activation by FXa and thrombin, FVIIIa acts as a cofactor for FIXa in the formation of FXa. It is not surprising therefore that the clinical syndromes associated with hemophilia A and B are phenotypically identical.

Laboratory criteria have varied in different classifications and in an effort to standardize this the Scientific and Standardization Committee of the International Society of Thrombosis and Haemostasis recently recommended revised criteria for the classification of hemophilia based on biological FVIII:C and FIX:C levels as follows.⁷

- Severe hemophilia: FVIII/FIX concentration < 0.01 IU/mL (<1% of normal).
- Moderate hemophilia: FVIII/FIX concentration 0.01–0.05 IU/mL (2–5% of normal).
- Mild hemophilia: FVIII/FIX concentration 0.05–0.4 IU/mL (5–40% of normal).

Clinical presentation

The clinical manifestations of both hemophilia A and B are similar, depending on the concentration of the deficient clotting factor (Table 26.1). Patients with severe hemophilia (FVIII:C or FIX:C levels < 0.01 IU/mL) usually present in the first 2 years of life with spontaneous bleeding involving joints and muscles. Spontaneous bleeding involving the central nervous system, head and neck, and the gastrointestinal tract are well-recognized but less frequent complications. Children with severe hemophilia may also present with excessive bleeding after minor trauma, postoperatively (Fig. 26.1), or after intramuscular childhood vaccinations. Moderate hemophilia (FVIII:C or FIX:C levels 0.01–0.05 IU/mL) usually results in bleeding at time of hemostatic challenge (trauma, surgery or dental extractions) but occasionally spontaneous

bleeding occurs. The bleeding that occurs in mild hemophilia (FVIII:C or FIX:C > 0.05 IU/mL) is usually restricted to hemostatic challenge and these patients are often not diagnosed until teenage years or adulthood.

Making the diagnosis

FVIII and FIX deficiency are associated with prolongation of the activated partial thromboplastin time, which corrects on mixing studies. The prothrombin time and thrombin clotting time are normal. The diagnosis is made on specific clotting assays that assess the activity of FVIII (FVIII:C) or FIX (FIX:C). These assays should be repeated on separate occasions to confirm the diagnosis. A variant of FVIII deficiency is associated with normal FVIII:C as measured by the standard (one-stage) clotting assay but reduced FVIII by alternative assays (chromogenic or two-stage clotting assay).^{8,9} The measurement of FVIII by chromogenic assay is becoming part of first-line investigation in most hemophilia comprehensive care centers. In centers where this practice is not established, the chromogenic assay should be considered in children in the following situations: (i) a family history of FVIII deficiency where the affected individuals have a normal one-stage FVIII:C assay, or (ii) children with a normal one-stage FVIII:C assay where there is a high clinical suspicion of hemophilia.

Differential diagnosis

The differential diagnosis of FVIII deficiency includes von Willebrand's disease (vWD). One of the functions of von Willebrand factor (vWF) is to bind and protect circulating FVIII from proteolytic degradation. vWD is caused by a defect in vWF and consequently these patients may have a

Type of bleeding	IU/mL		
	Severe (<0.1)	Moderate (0.1–0.4)	Mild (0.5–4.0)
Age of onset	<1 year	<2 years	>2 years
Hemarthroses			
Spontaneous	++++	++	–
Following minor trauma	++++	+++	–
Muscle hematoma	++++	++	–
Central nervous system	++*	+	–
Hematuria	++++	++	–
Surgery	++++	+++	++
Dental extraction	++++	+++	++
Trauma to soft tissue			
Mild	++++	++	–
Significant	++++	+++	+

++++, usual; +++, common; ++, not unusual; +, can occur; –, rare.

(b)

Fig. 26.1 Hemophilia A. (a) Postcircumcisional hematoma in an infant with no family history of hemophilia. Mutational analysis showed the presence of IVS 22. (b) Full hematoma resolution 1 week later following replacement with recombinant FVIII.

reduced FVIII:C level. vWD is assessed by the measurement of vWF antigen and function. The gold standard vWF functional assay is the ristocetin cofactor assay. This measures the ability of the patient's vWF to agglutinate normal platelets in the presence of ristocetin.

Occasionally children may have vWD despite normal vWF assays. This occurs in a subtype of vWD called type 2 Normandy, which is caused by an isolated defect in the ability of vWF to bind circulating FVIII. These patients have normal vWF as measured by standard vWF antigen and functional (ristocetin cofactor) assays. The diagnosis of type 2 Normandy vWD is made on the basis of an assay that assesses the ability of the patient's vWF to bind to FVIII, with or without the identification of a mutation within the relevant region of the vWF gene.

Genetics, carrier testing and genetic counseling

Hemophilia is inherited in an X-linked recessive manner. If a male with hemophilia has children, all the daughters will be carriers and no son will be affected. If a female hemophilia carrier has children, there will be a 50% chance that each male child will have hemophilia and a 50% chance of a female child being a carrier. It should be noted that female carriers of severe hemophilia mutations frequently have reduced FVIII:C or FIX:C levels (0.2–0.5 IU/mL, normal > 0.5 IU/mL). Rarely, females who are carriers of hemophilia mutations may have levels as low as affected males within the family due to nonrandom inactivation of the X chromosome, inheritance of a mutated FVIII gene from both maternal and paternal chromosomes, or Turner syndrome.

FVIII and FIX gene defects may be divided into several categories: (i) gross gene rearrangements, (ii) insertions/deletions, and (iii) single-base substitutions resulting in missense mutations, nonsense mutations or mRNA splicing defects. There are in excess of 2500 reported mutations in FVIII and FIX genes. The single most important defect is an inversion involving the noncoding sequence (intron) 22 of the FVIII gene that results in approximately 50% of all cases of severe FVIII deficiency. This intron contains a CpG island associated with two additional transcripts, F8A and F8B. F8A is transcribed in the opposite direction to the FVIII gene and there are two additional copies of the F8A transcript approximately 400 kb telomeric of the FVIII gene. Homologous recombination occurs between the F8A transcript within intron 22 and one of the two extragenic homologs of this sequence. The recombination occurs during the meiotic division of spermatogenesis. This results in the translocation of the gene sequences involved in exons 1–22 away from exons 23–26. The most common type of the inversion involves the distal homolog.

An additional inversion is responsible for 5% of cases of severe FVIII deficiency. This occurs as a result of homologous

recombination between a sequence within intron 1 and a similar sequence telomeric of the FVIII gene. There is evidence to suggest that large deletions, nonsense mutations and gross gene rearrangements such as the inversion 22 mutation are associated with a higher risk of inhibitor formation.¹⁰

Strategies for the identification of carrier status include family pedigree, measurement of FVIII:C and FIX:C levels, linkage analysis and direct mutation analysis. A detailed family pedigree may identify obligate carriers. Daughters of men with hemophilia are obligate carriers, as are women with two children with hemophilia, or one child with hemophilia and another maternal relative with hemophilia. FVIII:C or FIX:C levels should be measured in the potential carrier to identify those at risk of bleeding. However, the measurement of factor levels alone is an unreliable guide to carrier status. Direct mutation analysis has now replaced linkage analysis as the investigation of choice when the mutation can be identified in affected males within the family. The identification process is simplified by the common occurrence of an inversion within intron 22 in severe FVIII deficiency. When direct mutation analysis is unavailable, linkage analysis may be informative in the determination of carrier status. Antenatal diagnosis using chorionic villous sampling at 10–14 weeks or amniocentesis at 15–20 weeks can be used to determine both the sex and presence of the family-specific hemophilia mutation if known.¹¹

With recent advances in molecular laboratory techniques, it is now possible to give each individual patient and family member very reliable genetic information. To enable these genetic data to be used for the benefit of the patient with hemophilia or to influence reproductive choices, genetic counseling should be initiated as early as possible. Comprehensive genetic counseling addresses a wide range of issues, but different levels of genetic counseling can be provided according to circumstances. According to Miller,¹² the basic requirements for providing genetic counseling in hemophilia include knowledge of inheritance patterns, what tests are available, and personnel able to interpret results. The main aims of genetic counseling are to help people make informed choices about their own and their family's well-being, ensure informed consent for testing is obtained, and that the discussion includes information about:

- hemophilia, its prognosis and therapeutic options;
- inheritance pattern of hemophilia;
- tests for diagnosing hemophilia and carrier status;
- implications for future and existing children.

The importance of informed consent is particularly relevant when discussing the issue of genetic testing in children. It is recognized that genetic tests can only be performed on people who give informed consent after appropriate counseling. It is recommended that all children with hemophilia have their phenotype established as this provides valuable information regarding the risk of developing inhibitors and may allow information to be given to different family members.¹³

The area of particular difficulty revolves around testing female children who are potential carriers of hemophilia. This subject raises ethical conflict about who should give consent, when it should be raised, and how to consider the child's best interests. The 1989 Children's Act in the UK states that the child's views should be taken into consideration along with his/her intellectual capacity to give informed consent. In some circumstances it may be appropriate to carry out genetic testing for hemophilia in a child younger than 16 years providing the implications of the test are understood. If young children are genetically tested for hemophilia before they are competent to give informed consent, they are denied the right to refuse the test and the knowledge gained from that test. Despite these possible pitfalls, every opportunity should be taken to discuss carrier status with potential carriers and their families. What is more straightforward and agreed is that all potential carriers of hemophilia have their coagulation factor levels tested in infancy. This information will determine if the child is at increased risk of bleeding and treatment plans can be put in place.

Treatment

Development of factor concentrates

Although the first description of effective treatment of hemophilia with blood transfusion is as far back as 1840,¹⁴ it was not until the 1950s that the widespread use of plasma pioneered by McFarlane and his colleagues at Oxford came into being. Prior to this, plasma from pigs and cows was used with good effect, although allergic reactions were frequent and often severe and thus limited its widespread use. The main problem with human plasma is that it contains only small amounts of antihemophilic globulin (FVIII) and therefore large quantities of plasma needed to be infused in order to achieve a desired effect. The early work of Cohn in developing fractionation of plasma with variation in temperature and concentrations of saline and alcohol led to the development of fairly crude concentrates of human FVIII and these were used by a number of hemophilia physicians in Europe and North America.

In 1964, Judith Poole serendipitously discovered "cryoprecipitate", which she found to be rich in antihemophilic factor.⁵ This simple process involved the rapid freezing of fresh plasma, which was then allowed to thaw at 4°C; this results in the formation of a sludge called cryoprecipitate. The reason why hemophilia physicians were excited about cryoprecipitate was that a small volume contained high concentrations of antihemophilic globulin and thus made it possible for blood banks to prepare it and patients to store it in their homes. Hemophilia care was dramatically altered from hospital-based management to one where treatment could be administered at home immediately following trauma or at the first sight of bleeding. This major therapeutic innovation

markedly reduced hospitalization and the incidence of crippling deformities. Following this discovery the plasma fractionation industry went a step further, developing lyophilized clotting factor concentrates. These concentrates were now in powder form and could be stored in the home; when needed for active treatment, the addition of water was all that was required prior to administration. Again, a very small volume of concentrate was needed to arrest bleeding and this was very important when dealing with small children. The initial big drawback of this high-technology blood product was cost. The thousands of donors that needed to be recruited to supply the plasma essential for producing these lyophilized concentrates had to be paid.

By the early 1970s, the widespread availability of lyophilized FVIII concentrates offered considerable advantages in terms of storage and ease of administration and this had a dramatic effect on the natural history of the disease. The median life expectancy for people with severe hemophilia was 11 years in the 1920s; by the 1970s the median life expectancy approached that of normal males. The following decade saw the arrival in the developed world of ultra-pure forms of FVIII and FIX. These newer concentrates were produced from even larger numbers of donors. Soon complications became apparent, particularly viral transmission. The first case of acquired immunodeficiency syndrome (HIV) in hemophilia patients was reported in 1982. Prior to the mid 1980s most patients who received factor concentrates developed hepatitis C. The scientific response, driven by the biotechnology industry, to this disastrous happening was swift. The aim was to develop recombinant FVIII as it was felt that a synthetic product would solve not only the problem of contaminating viruses but also the problems of quality and supply, especially to developing countries. Remarkably, within 18 months of beginning this work two large scientific teams using two different cloning strategies not only cloned the FVIII gene but also demonstrated expression of the gene and the recombinant protein had the same biologic function as FVIII derived from human plasma.

Treatment with factor concentrates

Acute bleeds

Hemorrhagic complications in moderate and severe hemophilia may become obvious after birth, especially if the child is circumcised. Severity and type of bleeding is related to the absolute concentration of circulating plasma VIII:C (Table 26.1). A minimum effective level of FVIII and FIX for hemostasis is about 30–50%. Those with severe deficiency (<1%) usually experience repeated and often spontaneous hemorrhages, most commonly hemarthroses; if not treated adequately, this will develop into chronic synovitis, resulting in target joint formation with eventual crippling arthropathy. While muscular skeletal bleeding is by far the commonest clinical event, other spontaneous hemorrhagic

manifestations occur frequently and may be life-threatening (Table 26.1).

Successful treatment in acute or potentially acute (pre surgery) bleeding is usually achieved with adequate and prompt factor replacement therapy. The level of factor concentrate required to achieve adequate hemostasis will depend on the type of bleeding. It should be remembered that the initial plasma half-life of infused FVIII:C is 3–6 hours during equilibration with the extravascular space; thereafter the plasma half-life will be approximately 12 hours. As stated above, the amount of factor concentrate given will depend on the type of bleed and also on the weight of the child: FVIII 1 IU/kg raises plasma FVIII:C by 2% so that

Units of FVIII concentrate required = weight (kg) × desired level (%) × 0.5.

For the majority of soft tissue bleeds and hemarthroses, FVIII levels of around 50% may be adequate. If the bleed is more severe and a longer period of treatment is anticipated, then the desired level should be around 70%. Increasing the level above 50% is sufficient to treat major soft tissue or visceral bleeds and cover minor surgical procedures. With major surgery, a preoperative level of 100% is considered mandatory by most hemophilia physicians and thereafter daily prophylactic levels of 50–100% for approximately 7–12 days are sufficient to facilitate wound healing. With severe or pharyngeal and central nervous system bleeding, 100% correction is also required, and treatment is usually continued for a more protracted period of time. Indeed, in patients with an intracerebral bleed it may be necessary to continue treatment until imaging reveals that the brain lesion has fully resolved (Table 26.2).

As with FVIII treatment, the dosage and frequency of FIX administration is governed by the type of bleeding and its plasma half-life (18–24 hours). Unlike FVIII, recovery of infused FIX is lower than expected, presumably because FIX is absorbed at sites in the vascular endothelium recently shown to be collagen IV. Thus these patients require approximately twice the amount per dose once daily to treat bleeding, i.e., weight (kg) × desired level (%) × 1. The exception is on the first day of surgery, when a twice-daily dose is usually administered to achieve the desired level.

It is important to note that the recovery of recombinant FIX (BeneFIX, Genetics Institute-Baxter Hyland) is less than that of plasma-derived FIX. Thus, to raise a given individual's plasma concentration by 1% the recombinant product should be given in doses of 1.2 IU/kg and not 1 IU/kg as for the plasma-derived products.

Prophylaxis

Recurrent hemarthroses are the major cause of morbidity in children with severe FVIII and FIX deficiency. For children with severe hemophilia and no evidence of inhibitors, the unwanted musculoskeletal complications of severe

Type of bleed	Desired plasma level after treatment	Duration of treatment
<i>Major bleed</i>		
CNS or bleed involving peripheral nerve	100% rise + commence CI	See note
Ileopsoas/retroperitoneal		
Tongue/neck/retropharyngeal	100% rise + commence CI	
Gastrointestinal		
Preoperative treatment		
Joint (hemarthrosis)	50–70%	See note
Muscle		
Mucosal	50–70% and tranexamic acid	
<i>Minor bleed</i>	50%	
Dental extraction	50% and tranexamic acid	
Dental filling	30%	
Laceration requiring sutures	40% until sutures removed	
Hematuria	High fluid intake \pm 50%	

Note: duration of treatment depends on the severity of the injury, type of surgery and the clinical findings on daily examination.

CI, continuous infusion.

Fig. 26.2 Hemophilia B. Chronic severe hemophilic arthropathy of the right knee joint. The quadriceps muscle is severely wasted. This adolescent was only treated intermittently with plasma throughout the first 5 years of life.

Table 26.2 Treatment of specific bleeds: desired factor levels in plasma after treatment.

hemophilia can be effectively prevented by the early initiation of a program of long-term prophylaxis. Prophylactic factor concentrates given on a regular basis significantly reduce the incidence of hemarthrosis,^{16,17} and when commenced early in life long-term joint damage (Fig. 26.2) can be avoided¹⁸ or in some cases reversed.¹⁷ Although there is still some debate with regard to prophylaxis versus on-demand treatment, more long-term studies are now available to support the benefits of an early initiated prophylaxis program.^{19,20} The World Health Organization²¹ and the World Federation of Hemophilia therefore now recommend that primary prophylaxis be commenced between 1 and 2 years of age in those with severe hemophilia and should continue until around 20 years of age.

The primary prophylaxis regimen (Malmö protocol) was pioneered and tested in Sweden in the 1960s and involves the infusion of FVIII 20–40 IU/kg on alternate days (minimum three times per week) for FVIII deficiency, and FIX 20–40 IU/kg twice weekly for FIX deficiency. The treatment is usually commenced at around 1 year of age and continued until at least 20 years but usually lifelong. The results of this protocol have been reported^{14,21} and demonstrate that all children treated with this regimen maintained perfect musculo-skeletal status. Outcome measures included orthopedic and radiologic joint scores. Although very effective, this protocol is demanding on peripheral veins, is very time-consuming for families, may result in compliance issues, and is very expensive. Many modifications have been made to this protocol, such as starting primary prophylaxis with once-weekly infusions and dose escalation based on frequency of bleeds and tolerance of the child.²⁰

The efficacy of such an approach is largely influenced by the level of compliance. Compliance with any long-term medical regimen is challenging and in pediatrics especially, noncompliance can be a major barrier to successful treatment outcomes. Hacker *et al.*²² demonstrated a 58.8% compliance rate in a group of 38 children with hemophilia who had commenced prophylaxis. The major barrier to compliance in this cohort, as self-reported by the families, was the time-consuming nature of prophylaxis (52%); the uncooperative nature of the child was cited as the most significant challenge in 16% and venous access was reported as the most significant barrier in 13% of participants.

It is important when discussing the issue of prophylaxis with parents that they are aware of the potential problems associated with this therapy and that this is balanced with the evidence supporting prophylaxis. Due to the advances in pediatric hemophilia care, both life-threatening bleeding and chronic bleeding are preventable. Consequently, the traditional approach of measuring morbidity and mortality are no longer practical in the design of clinical trials for children with hemophilia. One option is to use more subjective constructs with direct relevance to patients, such as health-related quality-of-life measurements. Much work has been done to develop quality-of-life assessment tools in children with hemophilia^{23–26} and this would certainly seem to be the most appropriate way of measuring the impact of medical advances and treatment outcomes in children with hemophilia.

Desmopressin

Desmopressin (1-deamino-8-D-arginine vasopressin, DDAVP) is a synthetic analog of L-arginine vasopressin that produces a two- to eight-fold increase in circulating plasma FVIII:C levels.²⁷ The mechanism responsible for this effect is unclear but most likely includes the release of vWF from endothelial stores (Weibel–Palade bodies), with subsequent stabilization of plasma FVIII:C. The therapeutic efficacy of desmopressin in reducing blood product requirements in patients with mild hemophilia was first reported over 20 years ago.²⁸ Concerns about viral transmission associated with blood products have resulted in desmopressin becoming the therapeutic treatment of choice for patients with mild FVIII deficiency. However, the increase in endogenous plasma FVIII:C to therapeutic levels does not occur in all patients and cannot be predicted. Nolan *et al.*²⁹ report a response rate of 77% in children, while Revel-Vilk *et al.*³⁰ report a response rate of 57%. It is therefore now considered mandatory that all patients with mild or moderate FVIII deficiency be assessed for desmopressin responsiveness at the time of diagnosis to decide whether it will provide a therapeutic response in the event of bleeding or surgery.^{31–35} Revel-Vilk *et al.* also point out that the association between desmopressin response and age is unclear; they report a lower response rate in younger

children (<6 years), and in the younger nonresponders a subsequent response to rechallenge with desmopressin after a mean of 6.3 years.³⁰ They conclude that in their study group repeating the desmopressin challenge increased the response rate from 57 to 71%.

We believe that it is clearly preferable to assess desmopressin response at diagnosis so as to facilitate the development of a treatment strategy for each patient. Failure to adhere to these guidelines will likely increase the risk of morbidity or mortality associated with surgical intervention or bleeding episodes in patients who have a suboptimal response to desmopressin.

Desmopressin can be administered intravenously (0.3 µg/kg), subcutaneously (0.3 mcg/kg) or intranasally (150–300 µg), with peak values occurring at 60, 90 and 120 min respectively after treatment. Contraindications are a history of seizures, congestive heart failure, polydipsia and type 2B vWD. The commonest side-effects of desmopressin are facial flushing, mild headache and minor changes in blood pressure. More serious side-effects include fluid retention, hyponatremia and seizures.³⁶ It has been suggested that desmopressin is dangerous in children under 18 months old³⁷ as there is increased risk of cerebral irritation. However, Revel-Vilk *et al.*³⁰ would advocate the use of desmopressin in this age group where there is a reasonable chance of benefit and that fluid intake be minimized.

The use of desmopressin in FIX deficiency has been reported.^{38,39} Both these groups show that desmopressin appears to be useful in preventing and treating bleeding episodes in FIX deficiency despite the fact that plasma FIX levels are not increased by desmopressin. Ehl's hypothesis that desmopressin could cause changes that bypass the need for normal FIX levels, namely supraphysiologic levels of FVIII and stimulation of vWF, remains open to debate.³⁸

Central venous access devices

As outlined above, the World Health Organization/World Federation of Hemophilia now recommend that prophylaxis with FVIII and FIX concentrate be commenced in children with severe hemophilia between 1 and 2 years of age. The intravenous administration of factor concentrate twice or three times per week is fraught with difficulty in the majority of young children when using only peripheral veins. Similarly, immune tolerance therapy using large doses of factor concentrate, up to twice daily for 12–24 months for children with inhibitors to FVIII/FIX (see below), is almost impossible without the use of central venous access devices. These can be fully implantable (Port-a-Cath, Deltac, USA) or partly externalized (single or double lumen Quintan Catheters). The use of a port is preferable to an external device because it causes fewer limitations to the child's lifestyle and it has been suggested that there is a lower infective risk.^{40,41} However, despite the obvious attractions of these

devices, their routine use for prophylaxis and immune tolerance therapy has not gained universal acceptance because of the potential risks of hemorrhage,⁴¹ thrombosis,⁴² and infection,^{43–46} all of which may lead to a high rate of morbidity and permanent removal of the device. Infection is cited as the reason for removal of a port in up to 69.9% of all port removals.⁴⁸ The rate of infection is higher in children with inhibitors according to Ljung,⁴⁹ and a reasonable conclusion that he and others make based on different experience is that patients with inhibitors can expect one Port-a-Cath infection per 6–12 months of use. He goes on to conclude that in the best of hands, the patient with a Port-a-Cath, without inhibitors and on regular prophylaxis, will have a maximum of one catheter-related infection in approximately 10 years.

Although there is no consensus on their use, it is our practice that long-term indwelling devices are necessary to facilitate the modern intensive treatment of congenital coagulation disorders. There are complications, as outlined above, particularly infections, but with improved management of the perioperative period and regular frequent reeducation, particularly in those children with inhibitors, many of these complications may be avoided.

The decision to use an indwelling port to facilitate venous access merits careful and individual discussion. As well as explaining the benefits and complications to the parents and child, an indication should be given as to the amount of instruction necessary to ensure competency in caring for the port. Parents and, if relevant, the child need to be taught appropriate sterile techniques to ensure safe access of the device. General consensus with regard to catheter-site sterile technique or catheter flushing have not been reached and most institutions follow local policy. However, there are a number of general issues regarding care of the access device that have been recognized.

- Strict handwashing procedure and aseptic technique should be followed.⁵⁰
- If a local anesthetic cream is used, this should be removed with soap and water prior to aseptic technique being performed.⁵¹
- Cleansing of the skin prior to puncture should be with 2% chlorhexidine as this has been shown to be a more effective cleansing agent than povidone-iodine or 70% alcohol.^{50,52,53}
- Ports must be flushed after each use or at least monthly⁵⁴ with either saline^{55,56} or heparin in the lowest concentration possible. Baranowski⁵⁷ recommends 5 mL of heparin 10 units/mL solution to be safe and effective.
- Once the port is accessed, the needle should not be rocked or tilted. Needles should be removed as soon as possible after every infusion. If the needle is left in place, it should be changed every 7 days.⁵⁷
- To reduce potential for blood backflow when de-accessing the port, positive pressure should be maintained on the syringe while clamping the infusion set.⁵⁸
- Syringes smaller than 10 mL should not be used as they

generate pressures greater than 172 kPa (~25 pounds per square inch) and this can cause venous damage and catheter rupture.^{58,59}

More recently Santagastino *et al.*⁶⁰ have reported on the use of arteriovenous fistulae (AVF) as a reliable means of vascular access in children with hemophilia. They report on the creation of 31 proximal AVF in 27 children with severe hemophilia. Complication rates were minimal, with bleeding in 16%, thrombotic complications in 3% and infections in none. This group report that 96% of their study cohort achieved functional AVF that are still regularly used for home treatment over a median period of 29 months. The results of this study would support and encourage the creation of AVF as the first option for achieving permanent venous access in children with severe hemophilia, although longer follow-up is warranted to determine the potential development of late complications.

Complications of treatment

The risk of blood-borne infections associated with plasma-derived products was demonstrated to have a catastrophic effect with the infection of the hemophilia population with HIV and hepatitis C in the 1980s. This risk relates to the fact that these products are produced from plasma pools containing up to 20 000 donors.^{61,62} Plasma-derived factor concentrates are currently tested for a variety of known infectious agents, such as HIV, hepatitis C, hepatitis B, hepatitis A and parvovirus, and usually undergo dual and complementary viral inactivation steps. However, there is a residual risk of infection from nonenveloped viruses (which are not effectively inactivated by current viral inactivation steps), variant Creutzfeldt–Jakob disease (CJD) and unknown infectious agents. Due to the residual risk of blood-borne infections associated with factor concentrates and blood transfusions, it is recommended that all nonimmune patients with inherited bleeding disorders are vaccinated against hepatitis A and B.

Variant CJD is caused by an abnormal prion protein and is likely to have resulted from the consumption of beef infected with a related prion disease called bovine spongiform encephalopathy (BSE). At present, 170 people have died from variant CJD, the vast majority of cases occurring in UK residents. The risk of variant CJD is currently the subject of concern for hemophilia populations in the UK, France and other European countries. This is due to the development of vCJD in British and French donors whose plasma was used in the production of factor concentrates. There have been two probable cases of variant CJD transmission by blood transfusion, although there have been no reports of either variant CJD in patients with hemophilia or transmission of variant CJD by factor concentrate.⁶³

One of the most serious complications of hemophilia is the development of an inhibitor, which is usually an IgG antibody with the capacity to neutralize the function of FVIII

or FIX. The prevalence of inhibitors is approximately 30% in severe hemophilia and 1–7% in severe FIX deficiency. Inhibitor development is a well-recognized but uncommon complication of mild and moderate FVIII deficiency, and represents only 10% of inhibitors seen with FVIII deficiency.

Inhibitors and their treatment

The development of inhibitors to therapeutic factor concentrates in children with hemophilia A and B is a troublesome complication, with an incidence approaching 33% of those with hemophilia A and 3% of those with hemophilia B.⁶⁴ The median age for the development of inhibitors in severe FVIII deficiency is approximately 2 years after a median of 9–12 days of exposure. The first 50 exposure days represent the most significant inhibitor risk and thereafter there is a continuous but low risk of subsequent inhibitor formation. Risk factors for inhibitor development include race (black population have a higher risk than white), genotype (large gene deletions, major gene rearrangements or nonsense mutations), and family history.⁹ Recent studies have suggested that both early exposure to FVIII and the use of recombinant rather than plasma-derived FVIII is associated with a higher risk of inhibitor formation.^{65,66} However, further studies are required to validate these data.

The development of inhibitors may be detected by routine laboratory screening for inhibitor or by the identification of a poor clinical or routine laboratory response to factor replacement therapy. The Bethesda assay is the standard for the measurement of inhibitor titer. FVIII inhibitors are measured using a Nijmegen modification of the Bethesda assay. Patients should be screened for inhibitors every 6 months, or in the setting of a poor clinical or laboratory response to therapy. Inhibitors are classified as low or high responding. A low-responding inhibitor is defined as a peak historical inhibitor titer of < 5 Bethesda units (BU)/mL with a low or very attenuated response to FVIII/FIX administration. These patients frequently continue to respond to factor therapy, albeit at higher or more frequent dosing schedules. Conversely, high-responding inhibitors are defined as a peak historical inhibitor titer of > 5 BU/mL or a brisk anamnestic response to FVIII challenge. These patients will usually not respond to FVIII replacement therapy at times of bleeding and alternative treatments are required, such as FVIIa or activated prothrombin complex concentrates. Patients can convert from low- to high-titer inhibitor over time.

The management of acute bleeding episodes in children with inhibitors depends on the severity of bleed and whether they are low- or high-responding inhibitors. In low-responding inhibitors the use of FVIII and FIX at higher doses and more frequent intervals may be effective. Otherwise, recombinant FVIIa (90 µg/kg every 2 hours) or activated prothrombin complex concentrates (FEIBA 50–100 IU/kg every 6–12 hours) is usually effective in achieving hemostasis. It should be

stated that recombinant FVIIa, at least in the developed world, has revolutionized the treatment of patients with severe FVIII deficiency and high-responding inhibitors.⁶⁷ Hemostasis is achieved by promoting tissue factor–FVIIa assembly at the site of vessel injury. Recombinant FVIIa may also cause activation of FIX and FX on the surface of activated platelets.⁶⁸ Effective hemostasis occurs without significant activation of the systemic coagulation cascade unlike other FVIII and FIX bypassing agents. Recombinant FVIIa has been used successfully in adults for the treatment of serious bleeding disorders and in the prevention of surgical bleeding. Few adverse events have been reported with therapy.⁶⁹

As is the case in FVIII deficiency, most inhibitors in severe FIX deficiency occur after relatively few exposure days. A unique feature of FIX inhibitors is the association with allergic reactions (including anaphylaxis) in response to FIX infusion. The risk of allergic reaction is higher in patients with large gene deletions or rearrangements, and those who have or may have these mutations usually receive the first 20 treatments in hospital.⁷⁰ The principles of management of bleeding episodes in these patients include the use of FIX concentrate (for low-titer inhibitors in the absence of allergic reactions), FVIIa and activated prothrombin complex concentrates (in the absence of allergic reactions and anamnestic responses).⁷¹ The response to immune tolerance therapy in children with FIX inhibitors is inferior to that for FVIII inhibitors.

Early recognition of the presence of an inhibitor allows a planned treatment program, avoiding further use of FVIII or FIX concentrate until the inhibitor has reached its nadir and then initiating immune tolerance therapy. Immune tolerance protocols have been developed that are successful in approximately 80% of children.^{72–75} Higher success rates are seen when the inhibitor titer is allowed to decline to a low level, preferably < 10 BU, before commencing immune tolerance therapy. In addition, central venous access is necessary to facilitate the administration by parents of frequent high-dose factor concentrate.^{46,76,77} Recombinant FVIIa has been used successfully in adults and children with severe FVIII deficiency and inhibitors who are undergoing surgery.^{78,79} It is crucial that perioperative hemostasis is achieved with an agent that is safe and effective.

The optimal dose and interval for immune tolerance has not been determined and different regimens have been used, varying from 50 IU/kg three times per week to 300 IU/kg daily. Adjunctive therapies may be used and include any or all of the following: intravenous immunoglobulins, cyclophosphamide and protein A immunoadsorption. The most important predictor of success is the inhibitor titer prior to commencing immune tolerance, with a titer of < 10 BU/mL associated with a higher and quicker response rate.⁸⁰ Time to tolerance ranges from a few months to 2 years. If no response has been achieved at 2 years, then treatment is usually discontinued. Immune tolerance is continued until there is

no evidence by inhibitor titer, recovery, and half-life.⁸¹ Successful immune tolerance with a return to standard FVIII or FIX prophylaxis has been shown to be cost-effective when analyzed as part of total lifetime treatment costs.⁸² The use of recombinant FVIIa in patients with high-responding inhibitors has been shown to significantly increase the cost of treatment.⁸³ However, this must be counterbalanced by the efficacy of recombinant FVIIa in preventing serious morbidity and mortality from bleeding episodes.^{82,83} A significant minority of patients will fail immune tolerance therapy and recombinant FVIIa will continue to be the treatment of choice in these patients for the management of surgery and acute bleeding.

The use of rituximab (a monoclonal antibody against CD20)⁸⁴ or intermediate-purity FVIII (i.e., containing vWF) may prove effective in patients unresponsive to standard immune tolerance regimens. At present their use is deemed experimental.

Inhibitory activity in patients with hemophilia usually occurs on a background of severe disease. However, when it occurs in the setting of mild or moderate disease there are a number of unique features. The development of inhibitors usually occurs outside the pediatric age group, with a median age of 30 years. The presence of the inhibitor usually results in a change in the bleeding phenotype. Patients experience severe spontaneous bleeding whereas previously they only bled after trauma or surgery. This is caused by the cross-reactivity of the inhibitor against endogenous mutated FVIII, which frequently results in a reduction of baseline FVIII to <1%, although occasionally FVIII levels may remain unchanged despite laboratory evidence of inhibitor and the onset of more severe bleeding symptoms.⁸⁵ Another distinctive feature of the bleeding phenotype of these patients is that they frequently have a bleeding profile similar to acquired hemophilia, with a higher incidence of soft tissue, gastrointestinal or urogenital bleeding. The response to immune tolerance is inferior to that of patients with severe hemophilia; at present the role of immune tolerance is a controversial issue in these patients, especially in the older age group. The management of acute bleeding episodes is similar to that in patients with severe hemophilia who develop inhibitors. However, desmopressin may be effective especially in patients whose baseline factor level does not reduce and in whom the inhibitor does not appear to cross-react with endogenous FVIII.

Comprehensive care approach

In order to improve the quality of life of patients with bleeding disorders, with their great variety of other clinical problems, hemostatic treatment alone is far from sufficient and a more comprehensive approach involving a multidisciplinary team is now considered best practice. The team is composed of diverse specialists and health-care professionals delivering

comprehensive care on a 24-hour basis. In practice this involves a core team of hemophilia center medical staff, hemophilia nurses, hemophilia physiotherapist, hemophilia social worker and hemophilia center laboratory.⁸⁶ To deliver comprehensive care effectively, the involvement of other specialist services is also necessary, i.e., dental surgery, general surgery, counseling services and clinical psychology, and genetics service. It is advisable that all children with severe and moderate hemophilia have access to comprehensive care services and that these children must have a comprehensive care review at least every 6 months.

Social care

Hemophilia identification cards

In conjunction with a diagnosis, a patient with hemophilia should be issued with a registration card that states the type and severity of disorder that the child has and contact details of their hemophilia treatment center.

Vaccinations

Children with hemophilia can be vaccinated like other children but the vaccinations must be given subcutaneously not intramuscularly.⁸⁷ If there is concern regarding the efficacy and uptake of specific vaccinations given via the subcutaneous route, then the vaccine should be administered after the child has received prophylaxis or treatment. It is recommended that all children with hemophilia be vaccinated against hepatitis A and B.⁸⁸

School

It is important that parents inform school staff that a child has hemophilia. The staff from the hemophilia center can help to support the parents with this if necessary. If the child is on an adequate prophylaxis program, there should be no need for further resources within the school.

Leisure activities

A child with hemophilia who is on an adequate prophylaxis program can enjoy most sporting activities. Despite this some parents are apprehensive about allowing their children to play sports. Legitimate concerns do arise, especially in competitive or team events, but it is important to remember that participation in sports is an important part of an individual's life. Being active contributes to physical fitness and can influence the psychologic and emotional development of a growing child.

The National Hemophilia Foundation⁸⁹ has classified different sporting activities into three categories in order to help evaluate their risk–benefit in children with hemophilia.

- Category 1: most individuals with hemophilia can safely participate in these sports (e.g., cycling, fishing, hiking, swimming, tai chi).
- Category 2: the physical, social and psychologic benefits often outweigh the risks in these sports. The majority of sports fall into this category (e.g., basketball, karate, mountain biking, roller-blading, rowing, skiing, soccer, tennis, weight-lifting).
- Category 3: the risks outweigh the benefits in these sports. The nature of these activities make them dangerous even for those without hemophilia (e.g., boxing, hockey, lacrosse, motorcycling, rock climbing, rugby, wrestling).

Transition from pediatric to adult services

The adolescent years are full of tremendous social, psychological and emotional changes. Transition from a pediatric to an adult care setting should be the purposeful and planned movement of adolescents and young adults with hemophilia from child to adult-centered health-care systems. The timing of this transfer depends on physical and psychological maturity because adolescence, despite the familiarity of the term, proves difficult to define. Adolescence is a critical juncture for the development of positive health behaviors and it is important that certain barriers to adolescent independence are recognized and addressed. These barriers may be personal (i.e., maturity level, self-image, self-confidence, gaps in education), family-related (i.e., cultural, sibling issues, parental issues), or institutional (i.e., learned dependence, lack of formalized transition programs or family-centered care).

Conclusions

Significant advances in hemophilia A and B over the past quarter of a century have made hemophilia the paradigm of a human disease, where the application of not only molecular genetics but also innovations in medical, surgical and psychosocial practices have had significant impact in terms of diagnosis, treatment and, hopefully in the next decade, cure. By then gene therapeutics will have become a reality.

von Willebrand disease

David Lillicrap

Introduction

The disorder now recognized to be the most common inherited bleeding condition in humans, von Willebrand disease (VWD), was originally described by Erik von Willebrand in 1926.¹ He described a severe mucocutaneous bleeding problem in a large family residing in the Aland Islands in the Gulf of Bothnia. The propositus was a 5-year-old girl who later bled to death during her fourth menstrual period. An investigation of this disorder revealed a normal coagulation time, a normal platelet count and a prolonged bleeding time. During the next four decades, it was believed that this condition was most likely due to either a vascular defect or to some form of platelet dysfunction. It was not until the 1960s that an abnormality in von Willebrand factor (VWF) was implicated in the pathogenesis of the disorder, and even then the failure to differentiate VWF from factor VIII (FVIII) further complicated studies until their eventual definitive separation through genetic cloning in the mid-1980s.^{2,3}

Estimates of the prevalence of VWD have varied from about 1% of the general population⁴ to 125 clinically relevant cases per million population. Nevertheless, even in the surveys in which the higher prevalence figures have been obtained, the affected individuals have been documented to have some, albeit mild, clinical evidence of a hemostatic defect.⁴ VWD has been reported in subjects from all ethnic backgrounds, although several localized concentrations of severe disease have been documented in, for example, Israel, Sweden and Iran.

In surveys performed on VWD populations, about 80% of cases have the mild type 1 form of the disorder. The remainder have various type 2 forms of the condition (Table 27.1). The severe type 3 form of the disease is rare, with a prevalence of about 1 per million.

As more is learned about the underlying genetic pathogenesis of VWD, the inheritance pattern of the condition continues to be revised. Most cases of types 1, 2A, 2B and 2M

Table 27.1 Classification of von Willebrand disease (VWD) subtypes based on the 1994 recommendations of the VWD Subcommittee of the Scientific and Standardization Committee of the International Society on Thrombosis and Haemostasis.

Type of VWD	Definition and prevalence
Type 1 (~80%)	Partial quantitative deficiency of normal von Willebrand factor (VWF)
Type 2 (~20%)	Qualitative defects of VWF
Type 2A	Qualitative variants with decreased platelet-dependent function associated with the absence of high-molecular-weight multimers
Type 2B	Qualitative variants with increased binding affinity for platelet glycoprotein Ib
Type 2M	Qualitative variants with decreased platelet-dependent function associated with normal VWF multimer pattern
Type 2N	Qualitative variants with reduced binding of FVIII
Type 3 VWD (prevalence ~1 per million)	Complete absence of VWF

Reproduced with permission from Ref. 5.

disease represent autosomal dominant conditions with type 1 disease exhibiting incomplete phenotypic penetrance and variable expressivity. In contrast, types 2N and 3 VWD are recessive conditions with patients having been documented to be either homozygous or compound heterozygous for mutations within the VWF gene.

Biosynthesis and function

The gene that encodes VWF is located on the short arm of chromosome 12.³ The VWF gene is a large and complex locus encompassing 175 kb of DNA and comprising 52 exons.⁶ A further level of genetic complexity is introduced by the presence of a partial pseudogene sequence on chromosome 22,

Fig. 27.1 Multiple binding partners for von Willebrand factor (VWF) and the functional role of these interactions.

corresponding to the region between exons 23 and 34 on chromosome 12. Expression of the gene is limited to two cell types, vascular endothelial cells⁷ and megakaryocytes.⁸ The primary translation product of the gene is a pre-pro-VWF protein that has a short amino-terminal signal peptide, an approximately 100-kDa propeptide involved in multimer assembly, and a mature subunit composed of 2050 amino acid residues. The pro-VWF molecule consists of four repeated domains (A–D) that constitute more than 90% of the sequence.⁹

Following translation, the pre-pro-VWF molecule undergoes a series of complex posttranslational modifications. These include signal peptide cleavage, dimerization, glycosylation, sulfation and eventual multimerization and propeptide cleavage in the Golgi. The fully processed protein is then sorted into one of two pathways involving either constitutive secretion from the cell of synthesis or storage in specialized organelles, the Weibel–Palade bodies of endothelial cells or α -granules of platelets. Following appropriate stimuli, such as thrombin deposition or platelet activation, VWF is released from these storage sites into the plasma, where it circulates with a molecular mass ranging from 500 to 20 000 kDa depending on the extent of subunit multimerization.¹⁰ Following secretion, VWF is tethered to cell surface P-selectin where, under the influence of shear flow, the high-molecular-weight VWF multimers undergo partial proteolysis by the ADAMTS13 protease between amino acid residues tyrosine 1605 and methionine 1606 in the A2 domain of the protein.¹¹

VWF is a multifunctional adhesive protein that binds to several different ligands in plasma and the subendothelial matrix (Fig. 27.1). It has two major physiologic roles.

1 As a carrier protein for the procoagulant cofactor FVIII. This has the consequence that low levels of VWF result in correspondingly low levels of FVIII due to its accelerated proteolytic degradation by activated protein C.¹²

2 It has an essential role in the initial cellular stages of the hemostatic process, platelet adhesion, platelet aggregation and eventual platelet plug formation (Fig. 27.2). VWF secreted from the basolateral surface of endothelial cells is adherent to

Fig. 27.2 Role of von Willebrand factor (VWF) in mediating the initial events in the hemostatic process. Platelets, rolling along the endothelial cell surface, are tethered to the site of endothelial cell injury through the binding of subendothelial VWF to the glycoprotein (Gp)Ib receptor. The platelets are subsequently activated and the GpIIb–IIIa complex is exposed on the platelet surface. Interaction of fibrinogen and VWF with GpIIb–IIIa consolidates the platelet adhesive event and initiates platelet aggregation.

the subendothelial matrix and interacts with the platelet receptor glycoprotein (Gp)Ib to initiate platelet adhesion and platelet activation.¹³ The GpIIb–IIIa complex is then exposed and VWF plays an additional role in binding to this receptor and facilitating the process of platelet aggregation.¹⁴

Laboratory evaluation

The laboratory findings of this common bleeding condition are highly variable, ranging from the complete absence of VWF in type 3 VWD to minimal alterations in VWF and FVIII levels in patients with type 1 VWD. Indeed, due to the incomplete penetrance and variable expressivity of this trait, many individuals may have inherited mutant VWF alleles but fail to manifest any clinical or laboratory abnormalities.

Screening tests for von Willebrand disease

A number of rapid and inexpensive hematologic screening studies should be performed in the initial evaluation for possible VWD. The complete blood count may show evidence of iron-deficiency anemia due to chronic blood loss, and type 2B VWD is often associated with a mild thrombocytopenia. If the plasma VWF level is significantly reduced (below about 0.35 units/mL), the correspondingly low level of FVIII may result in a prolonged activated partial thromboplastin time (APTT).

Finally, the bleeding time may be prolonged.¹⁵ However, it is important to note that many patients with proven VWD have a normal APTT and bleeding time and that the results

of these screening studies must be interpreted in the context of the patient's clinical history. Although some hematologists no longer use the bleeding time in their diagnostic work-up of potential VWD, its use is still justified to evaluate the presence of one of the differential diagnoses for VWD, platelet dysfunction. Recently, a new analyzer that evaluates platelet function under conditions of high shear stress, the PFA-100, has also been incorporated into the screening investigations for VWD diagnosis.¹⁶

Tests for the VWF–FVIII complex

VWF and FVIII circulate in plasma as a noncovalent bimolecular complex, and the critical laboratory tests for VWD must include an evaluation of both these proteins. Plasma FVIII coagulant levels are measured using a standard APTT-based assay, utilizing FVIII-deficient plasma. Plasma VWF should be assessed in two ways: a quantitative immunologic assay and a functional test that evaluates its platelet-dependent interaction.

The two common VWF immunoassays (measuring VWF:Ag) used in clinical laboratories involve either a Laurell rocket immunoelectrophoretic assay or an enzyme-linked immunosorbent assay (ELISA). The former protocol is limited by a sensitivity of about 0.1 units/mL and a tendency to over-estimate the levels of VWF in type 2 variants due to the excess of low-molecular-weight forms of the protein. In comparison, most ELISA assays detect to a level of 0.01 units/mL and are unaffected by type 2 variant plasmas.

The functional activity of plasma VWF can be evaluated by testing its interactive role with platelets or collagen. The antibiotic ristocetin induces the binding of VWF to the GpIb receptor on platelets and is used in the laboratory to quantify the functional activity of plasma VWF in the ristocetin cofactor assay (VWF:RCo).¹⁷ Ristocetin was withdrawn from clinical use because of its *in vivo* association with thrombocytopenia, presumably due to the clearance of ristocetin-induced platelet aggregates.¹⁸ The other test that utilizes ristocetin is the ristocetin-induced platelet agglutination (RIPA) assay that evaluates the sensitivity of a patient's platelets to low-dose ristocetin. This test is especially useful in identifying individuals with type 2B VWD in whom the platelet membranes are 'overloaded' with the high-affinity mutant VWF resulting in increased sensitivity to ristocetin concentrations below 0.6 mg/mL.¹⁹ In some laboratories, the binding of VWF to collagen is quantified in an ELISA as the functional test of choice.²⁰ This test has been shown to be highly dependent on, among other things, the type of collagen used in the assay.

The normal plasma level of VWF is about 10 µg/mL (equivalent to 1 unit/mL), with a wide normal population range of 50–200% of the mean value (0.5–2.0 units/mL). Several important genetic and environmental influences must be kept in mind when interpreting the results of VWF plasma

Table 27.2 Influence of ABO blood group on factor VIII (FVIII) and von Willebrand factor (VWF) levels: 95% lower confidence limits in 58 children with group O and nongroup O blood types.

	Group O	Nongroup O
FVIII:C (units/mL)	0.57	0.80
VWF:Ag (units/mL)	0.37	0.50
VWF:RCo (units/mL)	0.42	0.51

Data derived from Ref. 22.

estimations. The best-characterized genetic influence relates to an ABO blood group effect;²¹ FVIII and VWF levels of blood group O individuals are approximately 25% lower than those with blood groups A, B and AB (Table 27.2). The major environmental influence on VWF and FVIII levels is their involvement in the acute-phase response. The plasma levels of both proteins will increase by three- to five-fold during acute physiologic stress and at times such as the later stages of pregnancy. The plasma levels of these proteins can vary so widely over time from a variety of influences (e.g., hormone levels in women) that at least two (and optimally three) sets of laboratory results should be obtained from patients prior to confirming or refuting the diagnosis of VWD (Fig. 27.3).

The final laboratory evaluation required to characterize VWD involves the assessment of the circulating molecular weight profile of VWF.²³ As mentioned above, VWF circulates in the plasma in the form of a heterogeneous mixture of multimers ranging in size from 500 to 20 000 kDa. The high-molecular-weight multimeric forms of the protein are the most effective in mediating the platelet interactive functions of VWF and it is these forms that are absent in some type 2 forms of VWD. The molecular weight profile of plasma VWF is most often evaluated using an SDS-PAGE electrophoretic assay (Fig. 27.4). The most recent advances in this assay have combined nonradioactive chemoluminescent detection of VWF multimers with densitometric analysis of multimer bands in efforts both to simplify and enhance the objectivity of the assay.

Von Willebrand disease classification

The VWD Subcommittee of the Scientific and Standardization Committee of the International Society of Thrombosis and Haemostasis proposed the currently accepted classification of VWD in 1994 (see Table 27.1).⁵ This involves three major categories.

- Type 1 disease comprises about 80% of cases and presents with a partial, mild-to-moderate quantitative reduction of VWF levels. The VWF in type 1 disease is qualitatively normal.
- Type 3 disease, the other quantitative defect, occurs with a frequency of about 1 per million and represents a virtual absence of VWF.

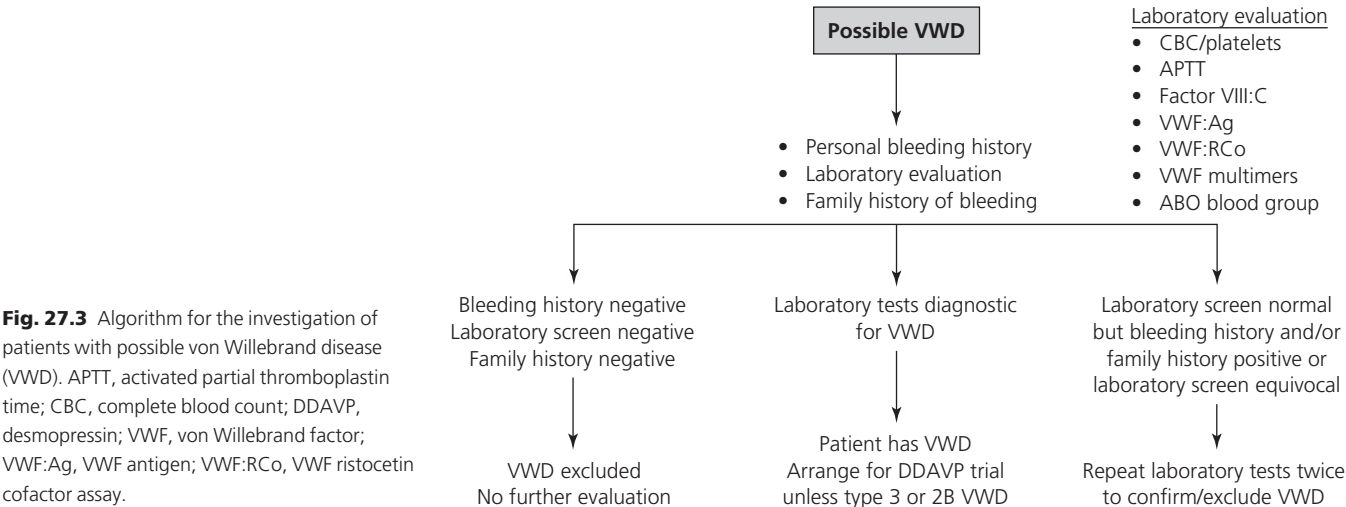

Fig. 27.4 Multimer analysis in two patients with type 2 von Willebrand disease (VWD). Lanes 1 and 4 represent normal plasma multimer patterns. Lane 2 shows the plasma von Willebrand factor (VWF) multimers for a patient with type 2A VWD and lane 3 the plasma VWF multimers for a patient with type 2B VWD. HMW, high molecular weight; LMW, low molecular weight.

	1	3	2A	2B	2M	2N
VWF:Ag	↓	↓↓↓	↓	↓	↓	↓
VWF:RCo	↓	↓↓↓	↓↓	↓↓	↓↓	↓
FVIII:C (units/mL)	↓	0.05–0.1	↓	↓	↓	0.1–0.4
VWF:RCo/VWF:Ag ratio	>0.6	–	<0.6	<0.6	<0.6	>0.6
Multimers	Normal	–	Abnormal	Abnormal	Normal	Normal
RIPA	Normal	–	Normal	↑	Normal	Normal

Fig. 27.5 Classification and results of laboratory studies in the common forms of von Willebrand disease. RIPA, ristocetin-induced platelet agglutination; VWF, von Willebrand factor; VWF:Ag, VWF antigen; VWF:RCo, VWF ristocetin cofactor assay.

• The various type 2 forms of the disease involve the synthesis of qualitatively mutant forms of the protein that manifest abnormalities in multimerization, platelet and FVIII binding (Fig. 27.5). Type 2 forms of VWD account for about 20% of diagnosed cases.

Type 1 von Willebrand disease

While this is clearly the most common form of the disease, it is also the most problematic to diagnose with certainty. Plasma levels of VWF (both VWF:Ag and VWF:RCo) and FVIII can range from about 0.05 to 0.45 units/mL in this condition and the caveat raised above concerning acute-phase influences is especially pertinent to the diagnosis of this subtype of VWD. The situation concerning the role of blood group O in type 1 VWD remains controversial, but it may be

that this is one of several genetic modifiers that contribute to this phenotype. It is important to note that only some patients with this disorder will have abnormal hemostatic screening studies (i.e., prolonged APTT and bleeding times). Recent attempts to clarify the diagnosis of this condition have focused on three factors:

- a personal history of excessive mucocutaneous bleeding;
- evidence of a family history of the condition;
- laboratory demonstration of VWF deficiency.

Without documentation of all three of these features, the diagnosis of type 1 VWD is rendered less definitive, although with the incomplete penetrance of the phenotype it should be recognized that lack of a family history is not unusual.

The genetic basis for type 1 VWD is currently under intense investigation and recent information suggests that the phenotype is most often due to a large variety of missense

Table 27.3 Clinical definitions of a significant bleeding trait.

Recurrent nosebleeds requiring medical treatment (packing, cautery, desmopressin, etc.) or leading to anemia
Oral cavity bleeding lasting for at least 1 hour, restarting over the next 7 days or requiring medical treatment
Bleeding from skin lacerations lasting for at least 1 hour, restarting over the next 7 days or requiring medical treatment
Prolonged bleeding associated with, or following, dental extraction or other oral surgery
Menorrhagia requiring medical attention or leading to anemia
Spontaneous gastrointestinal bleeding requiring medical treatment or leading to anemia, unexplained by local causes
Prolonged bleeding from other skin or mucous membrane surfaces requiring medical treatment

mutations within the VWF gene. The most common of these changes appears to be a tyrosine to cysteine mutation at codon 1584 that is present in 10–20% of type 1 patients.²⁴ A variety of transcriptional and splicing mutants have also been documented in type 1 patients. In contrast to these findings, some type 1 VWD patients have no obvious mutations in their VWF genes and may have mutations at other genetic loci implicated in VWF biosynthesis.

Patients with type 1 VWD exhibit an increase in mucocutaneous bleeding. The most common features are nosebleeds, easy bruising, bleeding from trivial cuts and excessive menstrual bleeding. Prolonged and delayed-onset bleeding following tooth extractions and oral surgery is also a common feature. Bleeding into soft tissues and joints does not occur unless provoked by trauma. Unfortunately, as with many aspects of this disease, definitive documentation of these clinical characteristics is not always straightforward, and an attempt should be made to enhance the objectivity of these historic details with the use of a validated bleeding questionnaire (Table 27.3).

Type 3 von Willebrand disease

Unlike most other forms of the disease (aside from type 2N), the inheritance pattern of type 3 disease best fits that of a recessive condition, with both carriers being asymptomatic. However, there is a growing realization that in some type 3 families, one parent has documented evidence of type 1 VWD, illustrating the heterogeneous nature of the inheritance of this disease subtype.

Type 3 patients manifest a clinically severe phenotype. Not only do they exhibit the same mucocutaneous bleeding features seen in type 1 disease (in a more pronounced fashion) but, due to their very low levels of plasma FVIII

(<0.10 units/mL), they also experience the joint and soft tissue bleeds seen in patients with hemophilia A. In the laboratory, this condition is characterized by prolongation of the APTT and bleeding time, undetectable levels of VWF:Ag and VWF:RCO, and FVIII levels < 0.10 units/mL.

Molecular genetic studies of type 3 patients indicate that this phenotype is the result of a variety of null mutations including gross deletions, frameshift and nonsense mutations in their VWF genes. In some instances, these mutations are associated with the development of alloantibodies to VWF that seriously complicate treatment.^{25,26}

Type 2 von Willebrand disease

The current classification divides these qualitative variants into those that affect the platelet-dependent function of VWF and those that reduce binding to FVIII. The clinical features are similar to those seen in type 1 disease.

Type 2A

Type 2A disease is characterized by the presence of VWF that lacks the large- and intermediate-sized multimers of the protein. This defect appears to result from either an inherent inability to form the higher molecular-weight multimers (Group I mutations) or the synthesis of multimers that are more susceptible to ADAMTS13-mediated proteolysis (Group II mutations).²⁷ This subtype accounts for approximately 15% of VWD cases in most populations and segregates within families as an autosomal dominant trait.

Type 2A disease can initially be suspected from a disproportionately low VWF:RCO level relative to the VWF:Ag (ratio <0.6). The FVIII level may be low or normal. Ristocetin-induced platelet agglutination is reduced and the multimer profile will show a loss of high, and sometimes intermediate, molecular-weight forms in both the plasma and platelet lysates.

The molecular genetic basis of type 2A VWD has been well characterized, with the majority of mutations being missense changes in the region of the VWF gene encoding the A2 protein domain (Fig. 27.6).²⁸ The remainder of the type 2A mutations disrupt the generation of dimers or multimers.

Type 2B

Type 2B VWD represents an interesting gain-of-function mutant form of the disease. In this condition, the mutant form of VWF binds with greater affinity to the GpIb receptor on platelets, resulting in the selective depletion from the plasma of the highest multimeric forms of VWF.^{18,29} The increased binding of the mutant VWF to platelets also results in the formation of circulating platelet aggregates and subsequent thrombocytopenia. Thus, type 2B VWD should be

Fig. 27.6 Repeating multidomain structure of the von Willebrand factor (VWF) protein. The regions of the protein comprising the pre-pro-peptide and mature VWF subunits are indicated at the bottom of the diagram (numbers refer to amino acid residues). Regions of the protein where the causative mutations for types 2A, 2B, 2M and 2N von Willebrand disease are found are shown above the protein diagram.

considered in the differential diagnosis of inherited forms of thrombocytopenia.

As with type 2A disease, in patients with type 2B VWD the VWF:RCo will likely be disproportionately low relative to the VWF:Ag, but with this subtype there is increased sensitivity to low-dose ristocetin-induced platelet agglutination (ristocetin concentrations <0.7 mg/mL). On multimeric analysis, the highest molecular-weight forms are absent from the plasma, while in platelets the multimer pattern is normal (reflecting increased binding of the mutant VWF to the platelet surface).

Also like type 2A disease, this variant exhibits an autosomal dominant mode of inheritance. The mutations in type 2B disease have been well characterized and represent a variety of different missense mutations in the region of the VWF gene encoding the GpIb binding region of the protein, the A1 domain.³⁰

A disorder known as platelet-type VWD (PT-VWD) exhibits identical clinical and laboratory features to those of type 2B VWD.³¹ This condition is caused by mutations in the GpIb α gene that affect the region of the receptor that binds to VWF.³² Type 2B VWD and PT-VWD can be differentiated either by specialized tests that distinguish enhanced ristocetin-induced binding of VWF to washed patient platelets or by genetic analysis of the A1 domain-encoding region of the VWF gene (exon 28) and the GpIb α gene. Because of the identical nature of the screening laboratory studies in these conditions, their relative frequencies are unknown, although it is assumed that PT-VWD is significantly less prevalent in most populations.

Type 2M

This type 2 variant form of VWD is characterized by the same disproportionate reduction in VWF:RCo levels relative to VWF:Ag seen in type 2A and 2B disease, but in type 2M VWD the plasma and platelet multimers are normal and ristocetin-induced platelet agglutination is reduced. In those cases in which the disease-causing mutation has been identified, this has been a missense alteration in the same region of the VWF gene in which the type 2B mutations are localized, the A1 domain.³³ Thus, type 2M VWD represents the result of loss-of-function mutations that adversely influence the binding of VWF to the platelet GpIb receptor.

Type 2N

This VWD subtype represents an important patient population that can be confused with other conditions in which the only laboratory abnormality is a low plasma FVIII level. Unlike the other type 2 forms of VWD, type 2N VWD exhibits a recessive mode of inheritance.

Type 2N disease has been described as an autosomal form of hemophilia A.³⁴ The bleeding tendency is relatively mild and on laboratory investigation often the only abnormality is a low FVIII level of 0.10–0.40 units/mL. The definitive diagnosis of type 2N disease requires one of two strategies:³⁵ the demonstration of reduced FVIII binding in a microtiter plate-based assay or demonstration of the disease-causing mutations in the regions of the gene encoding the N-terminal D'/D3 FVIII-binding domain of the protein (exons 18–25).

Clinical management

As this is the most common inherited bleeding condition, with a prevalence of up to 1% of the population, physicians of all types are faced with the management of patients with VWD. It should be evident from the discussion of the laboratory features of the disease and its classification that one of the most problematic areas of management is definitive diagnosis of the disorder. While type 3 and type 2 forms of the disorder should be readily identifiable (with access to an experienced coagulation laboratory), the diagnosis of type 1 disease still poses significant problems.³⁶ Assigning an incorrect diagnostic label of VWD to a patient can be difficult to revise and may result in confusion and inappropriate management decisions. In addition, the wider implications of this diagnostic label, including its potential social stigma and health insurance implications, should be considered before pronouncing any individual to be affected with VWD. The converse of this problem concerns the young child or male individual (no menstrual experience) who has yet to undergo a sufficient hemostatic challenge to manifest a bleeding tendency that would suggest the diagnosis of VWD.

VWD is an inherited disorder and, as such, genetic counseling is appropriate in affected families. However, the incomplete penetrance and variable expressivity of the disorder

significantly complicate the prediction of phenotypic consequences. Furthermore, the relatively mild nature of the bleeding problems, except in type 3 disease, obviates the need to consider prenatal testing. Although there is no suggestion that infants who have potentially inherited VWD need to be delivered routinely by cesarean section, they should not be subjected to prolonged or complicated (vacuum extraction or mid-cavity forceps) vaginal deliveries.

Prophylactic and therapeutic treatment of bleeding

Adjunctive therapies

In addition to treatments that specifically address the VWF deficit, there are several adjunctive therapies that are effective at reducing blood loss in these patients. The antifibrinolytic agents, tranexamic acid and aminocaproic acid, have been used as highly efficacious agents either alone or as complements to desmopressin (DDAVP) and blood component therapy in both prophylactic and therapeutic situations. They should be administered 2 hours prior to an anticipated hemostatic challenge and continued for 7–10 days after the challenge. The therapeutic oral doses are 25 mg/kg every 6–8 hours for tranexamic acid and 100–200 mg/kg every 6 hours for aminocaproic acid. Both agents are also available as intravenous preparations and tranexamic acid has also been demonstrated to be effective as a mouthwash.³⁷ Both drugs are usually well tolerated, aside from occasional mild gastrointestinal upset. Estrogen therapy has also been shown to be an effective measure in reducing menstrual bleeding and the frequency and magnitude of nosebleeds.

Desmopressin

Desmopressin (1-deamino-8-D-arginine vasopressin, DDAVP) is a synthetic analog of the antidiuretic hormone vasopressin.³⁸ Its infusion increases plasma VWF and FVIII levels by two- to eight-fold within 1 hour of administration.³⁹ This effect is presumed to be due to the release of VWF from endothelial cell stores (Weibel–Palade bodies) with secondary stabilization of additional FVIII.

Desmopressin can be administered by the intravenous, subcutaneous or intranasal route.⁴⁰ Peak responses will be achieved within 30 and 90 min with the intravenous and intranasal routes, respectively. The usual parenteral dose is 0.3 µg/kg (to a maximum of 20 µg), infused intravenously in 10–50 mL of normal saline over about 20 min. The dose of the highly concentrated intranasal preparation is 150 µg for children under 50 kg and 300 µg for larger children. It should be noted that another intranasal preparation of desmopressin is available for the treatment of diabetes insipidus. However, this is a low-concentration compound and does not result in significant increments to the plasma VWF and FVIII levels.

Desmopressin is a safe and generally very effective hemostatic agent. Its only common side-effects are facial flushing, mild headache and minimal changes to blood pressure and heart rate. All these effects can be minimized by increasing the duration of the infusion and administering the drug with the patient lying down. The most serious side-effects that can develop are severe hyponatremia and seizures.^{41,42} Children under 2 years of age are especially prone to this complication and their fluid intake should be reduced to maintenance levels for the 24 hours following desmopressin administration. In addition, with repeated doses of the drug, serial monitoring of the serum sodium should be undertaken.

The other limitation to this agent is the development of tachyphylaxis with repeated administration. When given at repeated intervals of 24 hours or shorter, the magnitude of VWF and FVIII increments achieved often falls to approximately 70% of that documented with the initial dose.⁴³ This is presumably related to a partial “exhaustion” of the endothelial cell stores. The reduced VWF increments obtained with repeated desmopressin infusion are only a relative limitation to its use for several consecutive days and it will often still be effective in this clinical setting.

The plasma VWF and FVIII response should be evaluated in every patient with a therapeutic trial of the agent, preferably prior to the first treatment. This is necessary as not all patients, particularly those with severe type 1 or type 2 VWD, respond adequately to this therapy.⁴⁴ This therapeutic trial should also include testing for VWF and FVIII levels at 4 hours post administration as some VWF mutants may show a significantly reduced plasma half-life.

Desmopressin can be used as a prophylactic or therapeutic agent in a wide variety of clinical circumstances, including the treatment of epistaxis and menstrual bleeding, and prior to dental procedures and minor surgery. Major surgical procedures and life-threatening bleeds should be treated with blood component therapy (see below).

Most patients with mild/moderate type 1 VWD should respond satisfactorily to desmopressin infusion, and for this common form of the disease the concomitant use of desmopressin and antifibrinolytic therapy should be sufficient for most clinical situations. In contrast, desmopressin has only been reported very rarely to be effective in type 3 patients and should not be considered the treatment of choice for this population. The therapeutic effect of desmopressin in the type 2 variant forms of VWD is variable. Some type 2A patients are very adequately treated and this patient group will be evident from a therapeutic trial infusion. In type 2B patients the situation is more controversial. While infusion of desmopressin consistently results in transient thrombocytopenia in these patients, several investigators have documented an excellent hemostatic effect from this treatment.^{45,46} In addition, the theoretical concern of desmopressin-induced thrombosis due to potential platelet aggregate formation has not been documented. Finally, desmopressin has been used in

type 2N VWD patients where it has been found to increase both VWF and FVIII levels between two- and nine-fold.⁴⁷ However, due to the fact that the VWF being released is a FVIII-binding mutant, the duration of the FVIII increment is only about 3 hours. This suggests that for type 2N patients, desmopressin should only be used in clinical situations where a brief transient rise in FVIII is required.

Blood component therapy

Treatment of VWD with blood component transfusion is required for major dental and surgical procedures, following trauma and to treat life-threatening bleeding. Cryoprecipitate, the standard component used for VWD therapy during the 1970s and 1980s, is no longer the material of choice. No effective viral attenuation process has yet been devised for cryoprecipitate and thus the risk of viral transmission has relegated this blood component to a rare alternative therapy in this condition.

The blood components currently used are plasma-derived, intermediate-purity FVIII concentrates (i.e., Humate-P and Alphanate) that have undergone a variety of viral inactivation steps to prevent viral infection.^{48–50} The latest high-purity and ultra-high-purity FVIII concentrates, such as the monoclonally purified concentrates and recombinant FVIII, have a very low VWF content and are not useful in this context. Interestingly, although these intermediate-purity FVIII concentrates are frequently used with good effect in VWD, their regulatory approval for this purpose is highly variable.

Most dosing recommendations for the treatment of VWD with blood component infusions are based on FVIII unit increments (intermediate-purity FVIII concentrates are now often labeled with both FVIII:C and VWF:RCO potencies). This practice relates to the demonstration that FVIII replacement appears to be critical for hemostasis in most surgical bleeding situations. The dose of the intermediate-purity concentrate required to elevate plasma FVIII to the required level is calculated in the same way as recommended for hemophilia A (i.e., desired FVIII increment \times weight in kg \times 0.4) (see Chapter 26). A FVIII level of 1 unit/mL should be the target for major surgery and life-threatening bleeds and 0.5 unit/mL for minor surgical and dental procedures. Plasma FVIII levels can be monitored to assess treatment response and, with a VWF half-life of ~18 hours, repeat infusions should be given every 12–24 hours. Repeat infusions of these concentrates in VWD patients can result in supra-physiologic FVIII levels and there has been a suggestion that these high FVIII levels may contribute to a risk for venous thrombosis in this setting.⁵¹ Dosing recommendations for the prevention or treatment of mucocutaneous bleeding are less well resolved, but might be better based on VWF:RCO unit dosing. Unfortunately, there are no studies that demonstrate the benefit of follow-up after therapy using any particular laboratory test.

In the rare event that infusion with an intermediate-purity concentrate is ineffective at stopping bleeding, transfusion with either platelet concentrates⁵² or cryoprecipitate has been used as an effective second-line treatment.

Finally, there have been successful preclinical trials of recombinant VWF and interleukin-11 preparations, but at this stage it is too early to assess the relative advantages and likely clinical application of these compounds.

Rare congenital hemorrhagic disorders

Nigel S. Key and Margaret A. Heisel-Kurth

Introduction

The focus of this chapter is the inherited coagulation disorders associated with factor deficiency states that may produce bleeding from inadequate thrombin generation and/or inadequate inhibition of fibrinolysis. The more prevalent disorders hemophilia A and B and von Willebrand disease are discussed separately in Chapters 26 and 27, respectively. Inherited defects of platelet number or function, which may similarly present with hemorrhagic manifestations, are also addressed separately in Chapter 25.

In considering these rare factor deficiency states, a number of common themes emerge.

1 Bleeding is generally less severe than the hemophilias at an equivalent factor activity level.

2 The pattern of bleeding may have a somewhat different anatomic distribution than the hemophilias (Fig. 28.1).¹ Some types of bleeding may be characteristic of a particular deficiency state, for example postsurgical bleeding on mucosal surfaces in factor (F)XI deficiency or intracranial bleeding and impaired wound healing in FXIII deficiency.

3 The prevalence of these disorders individually is substantially lower than that of the hemophilias, and generally in the order of 1 in 500 000 to 1 in 2 million of the population (Table 28.1). Since even large hemophilia centers are unlikely to follow more than a handful of patients, only cooperative national registries and surveys can adequately address the clinical manifestations and outcomes in these patients.

4 Unlike the X-linked recessive mode of inheritance of the hemophilias, the majority of these disorders are inherited in an autosomal recessive fashion. In certain cultures where

Table 28.1 Characteristics of coagulation factors and their deficiency states.

	Chromosomal location	Molecular mass (kDa)	No. of chains (active)	Half-life	Plasma concentration (µg/mL)	No. of Gla domains	No. of described mutations	Prevalence	Hemostatic levels (% reference range)
FVII	13	50	2	4–6 h	0.5	10	>130	1 in 500 000	15–20
FX	13	59	2	40–60 h	10	11	~70	1 in 1 million	15–20
FII	11	72	2	3–4 days	100	10	~40	1 in 2 million	20–30
FV	1	330	2	36 h	10	–	~30	1 in 1 million	15–25
FV/FVIII									
ERGIC-53	18	330 (FV)	2 (FV)	36 h (FV)	10 (FV)		>15 (ERGIC)	1 in 2 million	15–20
MCFD2	2	330 (FVIII)	2 (FVIII)	10–14 h (FVIII)	0.1 (FVIII)		>5 (MCFD2)		
FXI	4	160	2	52 h	5	–	>50	1 in 1 million	15–20
FXIII (2 genes)	6 (A chain) 1 (B chain)	320	4	11–14 days	60	–	>50	1 in 2 million	2–5
Fibrinogen (3 genes)	4 (α, β, and γ chains)	340	6	2–4 days	3000	–	>300 (dysfibrinogenemia) >30 (hypofibrinogenemia)	1 in 1 million	50 mg/dL

Fig. 28.1 Bleeding symptoms in patients with recessively inherited coagulation disorders (RICD) versus patients with hemophilia. Percentage of Iranian patients ($n = 750$) presumably homozygous for RICD who experienced a given bleeding symptom at least once (open bars) compared with Iranian hemophilia A patients with comparable factor VIII deficiency ($<10\%$ in plasma) (shaded bars). CNS, central nervous system; GI, gastrointestinal; n.a., not applicable. Reproduced with permission from Ref. 1.

consanguineous marriage is practiced, the prevalence may be higher. Additionally, in certain populations a founder effect for a particular genotype encoding deficiency and/or dysfunction of an individual clotting factor may account for a higher regional prevalence of that disorder, as may be the case for example with FXI deficiency.

5 The range of factor concentrates available to treat patients with rare bleeding disorders is limited, and when available is usually limited to plasma-derived products. Therefore, all patients should receive prophylactic hepatitis A and B vaccination, and all treatment decisions should be weighed against the risk of contracting blood-borne infection from fresh frozen plasma (FFP) or cryoprecipitate that have not undergone bactericidal or virucidal treatment.

6 In some disorders, a paradoxical thrombotic propensity has been identified with distinct genotypes, and occasionally a thrombotic and hemorrhagic phenotype (e.g., in certain forms of dysfibrinogenemia) may coexist.

Unlike the hemophilias, where the classification system of mild, moderate and severe cases is defined by and correlates with baseline FVIII:C or FIX:C levels, no similar categorization exists for the other rare bleeding disorders. Indeed, in some rare inherited deficiency states, such as FVII or FXI deficiency, there is rather poor correlation between plasma clotting factor activity and clinical manifestations. Thus, there is a tendency to resort to the mendelian terminology of

heterozygote for those presumed to carry one affected allele, and homozygote/compound heterozygote for those presumed to carry two affected alleles. Somewhat arbitrarily, circulating plasma activity levels of less than 20% (0.20 units/mL) for FII:C, FVII:C, FV:C, FX:C, or FXI:C are often assumed to represent homozygosity or compound heterozygosity.² Conversely, it may be very difficult to distinguish a heterozygote carrier from an unaffected individual on the basis of clotting factor level alone. These difficulties are compounded by the imprecision of the assay at low levels of clotting factor activity and by potential variability between assays depending on the particular reagents, as illustrated by the one-stage assay for FVII:C, where vastly different results may be seen depending on whether a human or nonhuman thromboplastin is used. Although simultaneous measurement of immunologic levels of the deficient factor in plasma may help to minimize these discrepancies, an accurate diagnosis of “heterozygote” or “homozygote” (e.g., for genetic counseling purposes) will ultimately depend on genotype analysis. Globally speaking, heterozygous carriers of these rare coagulation factor deficiency states tend to be asymptomatic and may be undetectable by routine coagulation screening assays since, as a rule, the prothrombin time (PT) and activated partial thromboplastin time (APTT) assays are prolonged only with deficiency of the constituent clotting factor activity of 30% or less of the normal reference range. Here again,

however, there are some notable exceptions, such as dysfibrinogenemia, which may be clinically manifest in heterozygotes and thus by definition is considered to follow an autosomal dominant pattern of inheritance. Heterozygotes for dysfibrinogenemia may also be apparent on screening assays such as the thrombin clotting time (TCT).

Deficiency states for essentially all individual clotting factors have been created in laboratory mice using gene knockout technology. In many cases, the human phenotype is recapitulated, although there are several notable discrepancies. For example, while FV gene knockout mice (FV^{-/-}) do not survive to birth, the analogous defect in humans is apparently compatible with life.

Influence of developmental hemostasis on the presentation of congenital hemorrhagic disorders

A child with an inherited hemorrhagic disorder may come to medical attention in several ways. First, a positive family history may prompt the clinician to order the appropriate screening assay(s). However, since the majority of these disorders adhere to an autosomal recessive pattern of inheritance, they are much more likely than the hemophilias to present unexpectedly. A hemorrhagic event is thus a frequent mode of presentation, as is the incidental discovery of abnormal coagulation screening tests prior to a planned procedure. In the latter instance, it is important to be aware of the physiologic differences in coagulation factor levels between newborns and older infants. A number of coagulation factors are physiologically decreased at birth, and may not reach adult levels for several months or years.³ Since coagulation proteins do not cross the placenta, fetal and newborn levels of these proteins are dependent on the fetus for synthesis. The first coagulation protein levels may be detected at 10 weeks' gestation and gradually increase with gestational age. At birth, newborns have normal adult plasma levels of fibrinogen, FV, FVIII, FXIII, and von Willebrand antigen. Essentially all the other coagulation factors, inhibitors and fibrinolytic factors are decreased at birth and variably increase in the first days and months of life to normal adult levels.³ Administration of vitamin K in the neonatal period is critical to ensure prompt normalization of the vitamin K-dependent factors. Premature infants can be expected to have lower plasma levels of all coagulation factors compared with term newborns. The physiologic decreased synthesis associated with prematurity is frequently complicated by accelerated consumption of coagulation factors related to the postnatal complications that are so prevalent in these babies.

For all these reasons, it may be extremely difficult to determine whether there is a true inherited deficiency state in very young children with abnormal screening coagulation assays and low factor levels. This dilemma may only be resolved by

repeated testing over a period of weeks or months. For a more detailed treatise on assessment of bleeding in the neonate, the reader is referred to Chapter 30.

Congenital deficiency states producing isolated prolongation of the prothrombin time

The PT measures what was formerly known as the "extrinsic" pathway of coagulation, in addition to the final common pathway. "Thromboplastin", consisting of re-lipidated full-length tissue factor (TF) apoprotein and anionic phospholipid vesicles, is added to citrated platelet-poor plasma; on recalcification, coagulation is initiated and the clotting time recorded optically or mechanically. TF binds to plasma FVIIa; this "extrinsic tenase" complex then activates both FIX and FX to initiate coagulation both *in vitro* and *in vivo*. Sequestration of TF by confinement to the surface of cells in the extravascular space is one mechanism by which the initiation of coagulation is regulated *in vivo*. Recently, however, evidence exists that very small quantities of intravascular TF may be present even in healthy subjects, where it may play a role in propagating the growth of a hemostatic plug.⁴ So far, no TF deficiency states have been identified in humans.

Causes of a prolonged PT associated with a normal APTT and TCT include vitamin K deficiency, ingestion of oral anti-coagulants/rodenticides that act as vitamin K antagonists, and liver disease. Once these acquired disorders have been ruled out and it has been demonstrated that a 1 : 1 mix of patient plasma and normal plasma leads to correction of the PT, FVII deficiency is a likely possibility. Acquired isolated FVII deficiency is very rare but has been reported.

Factor VII deficiency

Structure and function

The gene for FVII is located on chromosome 13. FVII zymogen is synthesized in the liver as a single polypeptide chain, and is converted to the active two-chain protease (FVIIa) as the result of cleavage of a single bond, Arg¹⁵²-Ile¹⁵³. In contrast to TF^{-/-} animals, which do not survive to term due to abnormal embryonic vascular development and hemorrhage, FVII^{-/-} mice develop normally *in utero*. However, intraabdominal bleeding within the first 24 hours of life leads to the demise of about half these animals, and the survivors usually succumb to intracranial bleeding shortly thereafter, with none surviving longer than 45 days.

Approximately 1% of the total FVII in plasma circulates in the active serine protease form (FVIIa, 10–100 pmol/L). Controversy still exists as to which enzyme is responsible for basal activation of FVII *in vivo*, although there is evidence

implicating FIXa. In the absence of its cofactor TF, FVIIa is a very weak enzyme. Moreover, unlike other similar vitamin K-dependent serine proteases (e.g., FXa, thrombin), FVIIa is not rapidly inactivated in plasma by antithrombin, and has a circulating half-life that varies from 1.5 hours in children to 2.5 hours in adults. The relatively long half-life was a critical factor in the clinical development of recombinant (r)FVIIa for therapeutic management of bleeding in the hemophilias, and more recently in other noncoagulopathic conditions associated with excessive bleeding.

Inheritance and prevalence

FVII deficiency is inherited as an autosomal recessive disorder. Homozygotes or compound heterozygotes for approximately 130 described mutations in the FVII gene, the majority of which are missense, may manifest a bleeding tendency. Several polymorphisms in the human FVII gene may also contribute to lowering of plasma FVII:C levels. For example, homozygotes for the Arg353Gln polymorphisms are typically found to have about half-normal FVII:C levels.

Among the rare inherited hemorrhagic disorders, FVII deficiency is considered to be one of the more common, with an estimated prevalence of 1 in 300 000 to 1 in 500 000. FVII deficiency accounted for almost half of the 294 cases reported to the North American Rare Bleeding Disorders Registry.²

Clinical and laboratory features

There is a relatively poor correlation between FVII:C and the clinical bleeding manifestations. In general, however, individuals with FVII:C < 1% will usually manifest abnormal bleeding, although not necessarily in early life. Individuals with FVII:C > 15–20% (0.15–0.20 units/mL) are frequently asymptomatic even after surgery or trauma, indicating that the levels of FVII required to maintain hemostasis are less than for FVIII or FIX. For this reason, FVII deficiency is not uncommonly diagnosed incidentally as the result of a prolonged PT rather than because of bleeding manifestations.

For many years, it was thought that certain genotypes encoding FVII deficiency might paradoxically predispose to thrombosis, possibly through defective inhibition of the complex of TF with mutant FVIIa by the TF pathway inhibitor (TFPI). However, subsequent data from the International Registry of FVII Deficiency comprising more than 500 patients suggest that while thrombosis may occur, it is not associated with any particular genotype and is rather uncommon. The conclusion seems to be that although FVII deficiency does not necessarily predispose to thrombosis, neither does it protect affected individuals from thrombosis during times of high risk.⁵

Laboratory diagnosis of FVII deficiency is established by finding a low plasma FVII:C in a one-stage assay using

FVII-deficient substrate plasma (preferably using a human thromboplastin) and/or by quantification of FVII antigen by an immunologic method such as enzyme-linked immunosorbent assay (ELISA). Both type I (CRM⁻) and type 2 (CRM⁺) variants may be encountered. In the North American registry, the median FVII:C in 49 presumed homozygotes was 0.08 units/mL. Bleeding events, 84% of which were spontaneous, were predominantly mucocutaneous (60%), followed by musculoskeletal (21%), gastrointestinal (16%) or genitourinary (3%).² Epistaxis and menorrhagia were particularly common.^{2,5} Interestingly, these registries failed to confirm the observation reported in earlier series that neonatal intracranial hemorrhage is a common manifestation of FVII deficiency.

Treatment

Possible treatment options for bleeding in FVII-deficient patients include FFP, prothrombin complex concentrates (PCCs), plasma-derived FVII concentrates, and rFVIIa. Fibrin glues and antifibrinolytic agents may also be used for topical bleeding control and for bleeding affecting mucosal surfaces, respectively. Several plasma-derived FVII concentrates that are subjected to viral inactivation are available in Europe but not the USA.^{6,7} The recommended dose is 20–40 units/kg. Virally inactivated FFP at a dose of 10 mL/kg every 6 hours is a reasonable alternative but, here again, these products are no longer available in the USA. Perhaps the most logical and attractive option is rFVIIa. The usual recommended dose is 15–25 µg/kg every 4–6 hours. Trough FVII:C levels should be maintained above 15–20% to ensure adequate hemostasis. PCCs are generally not recommended for the treatment of FVII-deficient patients, primarily because of concerns for thrombosis.⁸ The development of an inhibitor to FVII as a result of treatment is a very rare occurrence, but has been described in a few patients with FVII deficiency treated with rFVIIa.

Congenital deficiency states producing isolated prolongation of the activated partial thromboplastin time

The APTT is performed by incubating the test plasma with an inert negatively charged substance (e.g., kaolin, celite, or ellagic acid) that acts as an activator for the contact system, ultimately generating FXIa. Negatively charged phospholipids, devoid of TF (i.e., “partial thromboplastin”), are then added, the sample is recalcified, and the clotting time recorded. The contact system comprises three zymogen serine proteases (FXII, prekallikrein, and FXI) and one cofactor molecule, high-molecular-weight kininogen. In plasma, FXI circulates in a complex with high-molecular-weight kininogen. The APTT is sensitive to deficiencies of all four components of the contact pathway, and to deficiencies of the

components of the “intrinsic tenase” complex (i.e., FVIII and FIX). It is also sensitive to more significant deficiencies of clotting factors in the final common pathway.

The APTT may be prolonged by lupus inhibitors, auto-antibodies to a specific procoagulant (e.g., FVIII), circulating anticoagulants (e.g., heparin, low-molecular-weight heparins, direct thrombin inhibitors), and acquired causes of multiple coagulation factor deficiencies such as disseminated intravascular coagulation (DIC), liver disease, and oral anticoagulants/vitamin K deficiency. Commercial APTT reagents vary in their sensitivity to heparin, lupus inhibitors, and individual factor deficiency states. The initial evaluation of a prolonged APTT should include a 1 : 1 mixing study. Correction during this step rules out a lupus inhibitor or circulating anticoagulant and points toward a single or multiple clotting factor deficiency state. It is imperative to correlate the results of laboratory studies with the patient's clinical manifestations (or lack thereof) in reaching a final diagnosis as to the cause of a prolonged APTT.

Factor XII, prekallikrein and high-molecular-weight kininogen deficiency

Deficiency of any one of these factors may be associated with an incidentally discovered prolonged APTT, but in all cases there is no associated bleeding disorder. This observation implies that these molecules must have an alternative function. Indeed, the kininogens (high- and low-molecular-weight) are needed for the generation of the vasoactive peptide bradykinin. The contact activation system may also play profibrinolytic and antithrombotic roles in vascular biology. However, since they are not associated with a bleeding diathesis, further discussion of these functions is beyond the scope of this chapter.

Factor XI deficiency

Previously, the term “hemophilia C” was used to describe FXI deficiency, although this is now obsolete. It has been suggested that because some heterozygotes may experience bleeding despite seemingly adequate factor levels, the term “partial deficiency” for FXI should be used to describe these subjects.

Structure and function

FXI is a 160-kDa homodimer consisting of two 80-kDa polypeptides connected by a single disulfide bond. Activation occurs following a single proteolytic cleavage at Arg³⁶⁹–Ile³⁷⁰ in each chain, but FXIa remains a dimeric molecule, with each monomer comprising a heavy and a light chain. Although this activation step can be executed by FXIIa *in vitro*, it is believed that activation by thrombin on the surface of platelets is the more important physiologic mechanism *in*

vivo. FXIa activates FIX, ultimately leading to more thrombin generation. Thus, the role of FXI is to sustain thrombin formation after the initiation phase of coagulation (i.e., TF–FVIIa complex formation) has been extinguished by TFPI. The high concentration of thrombin generated in this FXI-dependent manner is also necessary to activate the inhibitor known as thrombin-activated fibrinolysis inhibitor (TAFI). Activated TAFI inhibits the breakdown of fibrin clots by plasmin; thus, the second function of FXIa is antifibrinolytic.

Inheritance and prevalence

FXI deficiency is usually considered to be inherited as an autosomal recessive disorder. The gene for FXI is located on chromosome 4. Although the liver is probably the primary site of synthesis, other cells including megakaryocytes may contribute. About 50, predominantly missense, mutations in the FXI gene have been identified. The vast majority of affected individuals have a type I deficiency phenotype with concordant reduction of FXI:C and FXI:Ag; dysfunctional molecules causing a type II pattern are rather uncommon. Individuals who are homozygous or compound heterozygous usually have FXI:C levels that range from < 1 to 20%, whereas heterozygotes express FXI:C activities in the 20–70% range.

FXI^{−/−} mice are born in the expected numbers, mature normally, and enjoy a normal lifespan. Despite the expected APTT prolongation, they do not experience spontaneous bleeding, and it is difficult to demonstrate that bleeding is excessive even after standard hemostatic challenges, such as tail transection.

FXI deficiency occurs at a frequency of about 1 per million of the general population. However, in several ethnically distinct populations, it may be found with much greater frequency due to a founder gene effect. Most informative among these is the Ashkenazi (European origin) Jewish population, in which the prevalence of heterozygosity for FXI deficiency is 8–9%, with a homozygote frequency of 0.2%. Although there are four well-defined “Jewish” mutations, the Jewish type II and Jewish type III mutations are the most common. Type II is a nonsense mutation (Glu117Stop) leading to a stop codon in exon 5, whereas type III is a missense mutation (Phe283Leu) in exon 9. Compound heterozygosity for type II and type III mutations is the most common genotype in severely affected individuals, and homozygosity for either type II or type III accounts for the majority of the remaining cases in this ethnic group. Type II homozygotes typically express FXI:C levels of ≤ 1%, type III homozygotes a level of ≈ 10%, and compound II/III heterozygotes a level of 3–5%. Interestingly, while the type III mutation is largely confined to Ashkenazi Jews, the type II mutation is found in both Ashkenazi and Iraqi Jews. It has been suggested that the latter mutation arose in a single ancestral population, probably in the era between the 6th century BC and the 1st

century AD, whereas the type III mutation probably arose no earlier than the 15th century AD.⁹ Other founder mutations have been described in French Basques and in England.

Clinical and laboratory features

It has been repeatedly recognized that there is a lack of correlation between FXI:C levels and the severity of bleeding manifestations, with many mildly deficient patients exhibiting as many symptoms as severely deficient patients. This may be explained by (i) the coexistence of phenotypic modifiers of the bleeding tendency such as von Willebrand disease; (ii) the presence of small quantities of FXI synthesized in platelets; or (iii) the fact that FXI:C assays based on the APTT may be insensitive to the other functions of FXI, such as in fibrinolysis. That being said, FXI deficiency leads to injury-related bleeding in most patients with severe deficiency and in about half of patients with a partial deficiency. Surgery or injury at sites with high fibrinolytic activity, including the oropharynx, nasal cavity and urinary tract, are particularly likely to be complicated by bleeding. It has been estimated that about 70% of FXI-deficient patients (~90% with severe deficiency and ~60% with partial deficiency) will experience excessive bleeding after tonsillectomy in the absence of prophylactic therapy.¹⁰ This observation is probably explained by a partial or complete absence of the antifibrinolytic contribution of FXI described above. Unlike the hemophilias, spontaneous bleeding such as hemarthrosis and intramuscular hemorrhage are uncommon, although affected women (of any severity) may experience menorrhagia. However, the risk of maternal bleeding during vaginal delivery may not be invariable, and it may be reasonable to withhold prophylactic plasma replacement therapy unless bleeding occurs. Acquired auto-antibodies causing FXI deficiency are very rare but have been described and should also be considered in the differential diagnosis.

Patients with previously recognized FXI deficiency may present with bleeding after surgery or injury, associated with a prolonged APTT that corrects on mixing with normal plasma. In this situation, one-stage assays for FVIII:C and FIX:C will usually be indicated in addition to FXI:C, but the likelihood of FXI deficiency is increased in a patient of Ashkenazi Jewish ancestry, and when bleeding is from the oropharynx, nose, or urogenital tract following surgery. Increasingly, however, the diagnosis of FXI deficiency is made on an asymptomatic individual with a prolonged APTT. In areas with a high Ashkenazi Jewish population, routine pre-operative screening using the APTT has been advocated.

Until recently, little was known about the epidemiology of inhibitor formation in FXI deficiency. However, among Ashkenazi Jews, one-third of patients homozygous for the type II (Glu117stop) mutation developed FXI inhibitors following treatment with plasma, whereas no inhibitors were identified in patients with other genotypes.¹¹

Treatment

One implication of the lack of correlation of FXI:C levels with bleeding tendency is that prophylactic hemostatic therapy is indicated for invasive procedures in the majority of patients, especially if these procedures involve an anatomic site with a high intrinsic fibrinolytic potential. Against this has to be balanced the risk of inhibitor formation in patients known to be homozygous for the Glu117Stop mutation, where plasma products should be used judiciously to minimize the risk of inhibitor formation.¹¹

Currently available options for raising plasma FXI levels include FFP (preferably a virally inactivated product) and FXI concentrates, two of which are manufactured in Europe but not available in the USA.^{6,7} A reasonable target FXI:C for surgery is > 30% for minor procedures and > 45% for more invasive procedures. This may entail the administration of quite large volumes of FFP. These guidelines may have to be adjusted according to a given individual's history of bleeding propensity with surgery. Of note, FXI concentrates, while offering the advantage of a lesser risk of viral transmission, have been associated with arterial and venous thrombosis and DIC, particularly when given at doses greater than the recommended maximum of 30 units/kg, and to elderly patients.

Antifibrinolytic agents such as ϵ -aminocaproic acid and tranexamic acid are excellent choices for dental work and other mucosal surface procedures, either administered alone or in combination with FFP. As always, however, antifibrinolytic agents should be avoided when bleeding originates from the upper urinary tract. Similarly, there may be a role for topical fibrin administered at the time of surgery. Finally, there have been anecdotal reports of the successful use of rFVIIa to control bleeding in FXI-deficient patients who have developed inhibitors to FXI.

Congenital deficiency states affecting the final common pathway of coagulation

The final common pathway of coagulation begins with the enzymatic conversion of FX to FXa, either via the intrinsic tenase complex, consisting of FIXa and its cofactor FVIIIa, or via the extrinsic tenase complex, comprising FVIIa and TF. During physiologic hemostasis, the initial activation of FX is mediated by the TF-FVIIa complex. After this burst of FXa formation has been extinguished by TFPI, further propagation of coagulation via additional FX activation is dependent on the intrinsic tenase (FIXa-FVIIIa) complex. Thereafter, activated FX, in association with its cofactor FVa, forms the "prothrombinase complex" which proteolytically cleaves and activates prothrombin to thrombin. All these enzymatic reactions depend on the presence of a suitable anionic phospholipid surface, generally provided by the activated platelet membrane, and on calcium. Thrombin has many important

functions in hemostasis, including platelet activation, feed-back activation of FV, FVIII and FXI, and activation of fibrinogen and FXIII.

The TCT is the simplest of the coagulation screening assays. Excess human or bovine thrombin is added to citrated platelet-poor plasma in order to convert fibrinogen to fibrin, and the clotting time is recorded. Notably this reaction is neither phospholipid nor calcium dependent. Possible causes of a prolonged TCT include congenital or acquired quantitative or qualitative fibrinogen disorders (afibrinogenemia, hypofibrinogenemia, or dysfibrinogenemia), direct and indirect thrombin inhibitors (including heparin), acquired inhibitory antibodies to thrombin, and inhibition of fibrin polymerization by monoclonal immunoglobulin or light chains or fibrin degradation products. Notably, vitamin K antagonists and lupus inhibitors do not influence the TCT.

Screening laboratory evaluation in deficiencies affecting the final common pathway will therefore be reflected by a prolonged PT and APTT but normal TCT (FX, FV, prothrombin deficiency), or by a prolonged PT, APTT and TCT (quantitative or qualitative fibrinogen defects). The Russell viper venom time (RVVT) is a useful adjunctive assay in this situation. Russell viper venom is a metalloproteinase found in the venom of *Vipera russelli* that enzymatically activates FX in a phospholipid and Ca^{2+} -dependent fashion. Therefore, the RVVT is prolonged in deficiencies affecting all the final common pathway factors (fibrinogen, prothrombin, FV, FX) but is normal in deficiencies of contact factors (FXII, FXI, prekallikrein, high-molecular-weight kininogen) or factors in the intrinsic (FVIII/FIX) or extrinsic (FVII) tenase complexes.

Factor X deficiency

Structure and function

FX is synthesized in the liver as a 59-kDa two-chain zymogen. Posttranslational modifications include vitamin K-dependent γ -carboxylation of 11 Glu residues in the membrane-binding (Gla) region of the light chain. Like other vitamin K-dependent factors, this step is essential for full procoagulant function and may be inhibited by oral anticoagulants, in dietary vitamin K deficiency, or in hemorrhagic disease of the newborn. The gene for FX is located on the long arm of chromosome 13, close to that for FVII.

Both the extrinsic and intrinsic tenase complexes activate FX by cleavage of the Arg¹⁹⁴–Ile¹⁹⁵ bond, concurrently releasing an activation peptide of 52 amino acids from the heavy chain. The primary substrate for FXa is prothrombin, but activation of FV, FVIII, and FVII may also be partially dependent on FXa generation *in vivo*.

Approximately 30% of FX^{−/−} embryos die *in utero* in mid-gestation. Although the remaining animals are born alive, they die in the perinatal period from intraabdominal

bleeding or in the neonatal period from intracranial hemorrhage. Thus, complete FX deficiency does not appear to be compatible with survival into adulthood.

Inheritance and prevalence

FX deficiency is inherited in an autosomal recessive fashion, and affects about 1 per million of the population. Heterozygotes are generally asymptomatic. About one-third of affected individuals exhibit a type 1 deficiency, while the rest have a type 2 pattern, with FX:Ag levels that are preserved or at least significantly above the level of FX:C. This finding is explained by the fact that missense mutations, frequently affecting the catalytic domain, tend to predominate. Although a small number of mutations leading to stop codons have been identified, nonsense mutations are not reported, suggesting that like the murine model a total absence of FX may be incompatible with life. Perhaps for the same reason, the development of an alloantibody inhibitor to FX as a result of exposure to FX concentrates or plasma has not been reported.

Clinical and laboratory features

Patients with severe FX deficiency tend to be among the most, if not the most, severely affected of the rare coagulation deficiency states. In the Iranian series of 32 patients, 18 had “severe” disease (FX:C <1%), nine had “moderate” disease (FX:C 1–5%), and five had “mild” disease (FX:C 6–10%).¹² Mucosal bleeding, especially epistaxis, was prevalent (72% of the entire cohort). Menorrhagia occurred in about 50% of affected women, and gastrointestinal bleeding was reported by about two-thirds of patients with severe disease. Umbilical cord bleeding, typically occurring at 7–10 days after birth, was reported in about 30%, predominantly in patients with severe disease. Central nervous system (CNS) bleeding was reported in about 10%. Unlike many of the other rare factor deficiency states, hemarthroses and muscle hematomas were relatively common (~75%) in those with moderate or severe disease, and in this respect the disorder is more similar to the hemophilias. In the North American Registry, the type of bleeding manifestations were similar, although patients were defined as “homozygotes” when FX:C was <20% (in fact, more than half of these had a FX:C of <1%, and the median for the whole group was 13%).² This registry did emphasize that 80% of bleeding episodes were spontaneous rather than traumatic in origin. Women with severe FX deficiency may experience recurrent miscarriage, and uterine bleeding and premature labor during pregnancy, but successful outcomes are also reported.

The major differential diagnosis of isolated FX deficiency is an acquired deficiency occurring as a complication of AL (light chain) amyloidosis. This interesting association appears to be explained by adsorption of FX to amyloid

fibrils, and is described in 10–15% of patients with this disorder. Bleeding may be severe but generally responds to splenectomy. While very rare, acquired inhibitors to FX have been described, often as a complication of a respiratory infection. Here again, bleeding complications may be severe.

Laboratory evaluation in patients with FX deficiency reveals prolongation of PT, APTT, and RVVT, all of which correct on mixing. The TCT is normal. In addition to functional clotting assays, it is recommended that an immunologic assay for FX be performed to distinguish type 1 and type 2 deficiency states.

Treatment

Treatment options for patients with FX deficiency include FFP or PCC; there is no purified FX concentrate. FFP can be administered at a dose of 10–15 mL/kg, followed by 5–10 mL/kg every 24 hours, monitoring trough FX:C levels. Nonactivated PCCs (for specific products see ref. 7) may be preferable to activated PCCs that contain both FX and FXa, but are more expensive. The target FX:C for hemostasis is generally 15–20% and because of the exceptionally long half-life of FX (40–60 hours), alternate-day treatment may be adequate. The FX content of PCCs is variable but generally in the range 50–150 units per 100 units of FIX;⁶ 1 unit/kg of FX is expected to elevate FX:C by about 1.5%. Perhaps somewhat surprising from a mechanistic standpoint, rFVIIIa has been shown to be effective in anecdotal cases of bleeding in acquired FX deficiency. Particularly for mucosal bleeds, antifibrinolytic agents, alone or in combination with FFP, may be useful, although their use with PCCs is discouraged due to increased thrombotic risk. Fibrin glues are a reasonable option for topical bleeding in a temporarily dry field.

Factor V deficiency

Structure and function

FV is a pro-cofactor that circulates in plasma at a concentration of 20 nmol/L (10 µg/mL). FV is a large molecule (330 kDa) that shares significant structural homology with FVIII and ceruloplasmin. The FV gene is located on chromosome 1, and FV is principally synthesized by hepatocytes. About 20% of the total FV in blood is stored in α -granules of platelets. Platelet-associated FV is both synthesized in megakaryocytes and taken up from plasma by megakaryocytes. On activation by thrombin, FVa (consisting of heavy and light chains) functions as the cofactor for FXa in the membrane-bound prothrombinase complex. FVa is inactivated by activated protein C in the presence of its cofactor, protein S. This inactivation process is slowed by the substitution of Glu for Arg⁵⁰⁶ in the FVa molecule, known as the FV Leiden mutation, which leads to a prevalent thrombophilic phenotype in Caucasian populations.

Deletion of the FV gene in knockout mice is incompatible with life. About half of FV^{-/-} embryos die *in utero* as a result of an abnormality in the yolk sac vasculature, while the remainder die from massive neonatal hemorrhage. In humans, however, FV:C levels <1% appear to be compatible with survival into adulthood. It has been argued that there may be residual trace amounts of functional FV in severely affected individuals, although major homozygous deletions affecting large portions of the FV molecule have been described. Overall, it remains unresolved whether complete FV deficiency is compatible with survival in humans.

Inheritance and prevalence

Factor V deficiency is a rare autosomal recessive disorder that affects about 1 per million of the population. The number of described discrete mutations underlying FV deficiency is still relatively small (in the order of 30), and no founder mutations have been described. About three-quarters of affected patients have a type 1 deficiency.

Clinical and laboratory features

Severe FV deficiency (formerly referred to as “parahemophilia”) is a moderately severe bleeding disorder that, like most of the recessively inherited deficiencies, is not associated with as much musculoskeletal morbidity as severe hemophilia A or B. Bleeding events are frequently spontaneous. Homozygotes generally manifest very low FV:C levels, usually < 5% and frequently < 1%. Heterozygotes will generally have FV:C levels in the range 20–55%.²

In the Iranian series of 35 patients with FV:C levels between 1 and 10%, mucocutaneous bleeding events were the most frequent complication, with epistaxis, menorrhagia and oropharyngeal bleeding in 50–60%.¹³ Postoperative and postpartum bleeding were reported by about 40%, while hemarthrosis and muscle hematomas were reported by 25–30% of subjects. CNS bleeding was recorded in only two patients (6%) and gastrointestinal, genitourinary, and umbilical cord bleeding were quite uncommon, occurring in < 10%.¹³ A very similar distribution of bleeding was reported in 37 patients with FV deficiency in the North American Registry.² A recent series describing the outcome of pregnancy in five homozygous and 17 heterozygous females with FV deficiency reported that significant postpartum bleeding requiring FFP was relatively common in the severely affected, but not in the heterozygous carriers. Fetal outcomes were generally excellent.¹⁴ Oral contraceptives were beneficial in modulating the severity of menorrhagia in affected homozygous women.

Inhibitors to FV may occur in FV-deficient patients who have been exposed to FFP. In the North American Registry, an inhibitor was reported in 1 of 37 (3%) subjects.² Distinct

from the entity of acquired alloantibodies to FV in patients with severe inherited deficiency is acquired FV deficiency due to an acquired autoantibody to FV in previously normal individuals. The incidence of these antibodies may be underappreciated. Classically, development of these inhibitors has been linked to exposure to topical bovine thrombin contaminated by immunogenic bovine FV, usually following cardiac surgery, and particularly when there have been multiple or recurrent exposures. The resulting cross-reactive anti-human FV inhibitory antibodies may be associated with anti-bovine prothrombin, thrombin, and/or FV inhibitors. However, they may also develop after surgery in the absence of topical thrombin exposure, with underlying malignancy, or with no identifiable precipitating factors. Although very rare in children, acquired FV autoantibodies have been described and should be considered in the differential diagnosis of inherited deficiency.

Laboratory evaluation of FV deficiency reveals prolongation of both APTT and PT but normal TCT. The RVVT is also prolonged. In the absence of a FV inhibitor, mixing studies with normal plasma demonstrate full correction. One-stage clotting assays and immunoassays demonstrate reduction in FV:C and FV:Ag, respectively. It is important to be aware of the entity of combined FV and FVIII deficiency (see below). In these patients, both FV:C and FVIII:C are typically in the 5–20% range. Therefore, it is worthwhile to consider measuring the FVIII:C level to rule out this disorder.

Treatment

No FV concentrate is available. Therefore, FFP 15–20 mL/kg is usually recommended for treatment of bleeding or surgical prophylaxis, followed by 5 mL/kg every 12–24 hours.⁶ The target FV:C for hemostasis is 15–25%. Antifibrinolytic agents may be used alone or with FFP if needed for mucocutaneous bleeding episodes, such as nosebleeds. Platelet transfusions may be used as a source of FV, and may be particularly useful in patients with FV inhibitors, in whom soluble FV may be rapidly inactivated.

Prothrombin (factor II) deficiency

Structure and function

Prothrombin is a 72-kDa protein containing 10 γ -carboxyglutamic acid residues that is synthesized in the liver and in very small amounts in the brain. Activation of prothrombin by FXa results in the cleavage of two peptide bonds (after residues 271 and 320), with release of thrombin from the amino-terminal membrane-binding portion of the molecule that remains attached to the cell. Thrombin may then activate fibrinogen, FV, FVIII, FXI, FXIII, TAFI and platelets. Recently, it was demonstrated that thrombin also has a myriad of

functions in inflammation, vascular reactivity, cell mitogenesis, and tissue repair mediated through a family of transmembrane protease-activated receptors expressed on platelets, leukocytes, endothelial cells, and smooth muscle cells.¹⁵ Finally, thrombin, once bound to the endothelial cofactor thrombomodulin, loses its procoagulant activity and instead becomes an anticoagulant via activation of zymogen protein C.

The gene encoding prothrombin is on chromosome 11. The majority of FII^{-/-} mice die *in utero*, and the few surviving to term die very shortly after birth from hemorrhage into the abdominal cavity and elsewhere.

Inheritance and prevalence

Prothrombin deficiency is very rare, occurring at an estimated frequency of 1 per 2 million of the population. Two major phenotypes can be defined by measurement of FII:C and FII:Ag levels. Firstly, the type 1 deficiency, with concomitantly reduced activity and antigen levels, is usually referred to as hypoprothrombinemia, whereas type 2 deficiency, characterized by reduced activity with normal to borderline low antigen, is known as dysprothrombinemia.¹⁶ However, like FX deficiency, no individuals with a complete FII deficiency have been described, consistent with the murine model suggesting that total prothrombin deficiency is incompatible with life.

Like most of the rare coagulation factor deficiencies, patients with more severe deficiencies of prothrombin are either homozygous for a particular mutation or compound heterozygous for two distinct mutations. Patients who are compound heterozygotes for hypoprothrombinemia and dysprothrombinemia are also described. Mutation homozygosity tends to be more common in the offspring of consanguineous marriages and/or when there is a founder effect in a remote or isolated population.

Clinical and laboratory features

In the North American Registry, 10 subjects who were presumed to be “homozygous” for prothrombin deficiency were described.² Median FII:C was 3%, with a range from < 1 to 18%. Whether these patients had a type 1 or type 2 phenotype was not described. Parenthetically, other authorities consider that FII:C and FII:Ag levels should be < 10% in patients who are homozygotes/compound heterozygotes for hypoprothrombinemia, and that FII:C levels should be in the range 1–20% for homozygotes/compound heterozygotes for dysprothrombinemia.¹⁶ The North American Registry reported that 60% of bleeding events were unprovoked, with mucocutaneous sites (40%) and hemarthroses/muscle hematomas (26%) being approximately equally represented.² Intracranial bleeds were recorded in 20% of those with FII:C levels < 1%, although numbers were small. The propensity of

prothrombin-deficient patients to develop musculoskeletal hemorrhage was also reported in the Italian/Iranian series¹⁷ and in an earlier summary of reported cases.¹⁶ Both series also noted that severe umbilical cord bleeding may occur, often as a presenting feature.

Bleeding manifestations may occur in less severely affected individuals. Mucocutaneous hemorrhage was experienced by 83% of presumed heterozygotes (median FII:C of 25%, range 21–35%).²

Laboratory evaluation reveals prolongation of the PT, APTT and RVVT with a normal TCT. The abnormal screening tests may in fact be relatively modestly prolonged compared with FV or FX deficiency of the same degree. The *Echis carinatus* assay utilizes the venom from the saw-scaled viper to activate prothrombin in a FV- and phospholipid-independent manner. It is abnormal in hypoprothrombinemia and in the majority of dysprothrombinemias. A one-stage clotting assay and immunologic prothrombin assay should be performed to establish the diagnosis, and to distinguish hypoprothrombinemia and dysprothrombinemia.

The principal condition to be considered in the differential diagnosis of congenital prothrombin deficiency is the (acquired) lupus anticoagulant–hypoprothrombinemia syndrome. In this disorder, patients (particularly children) may present with acute bleeding manifestations, frequently mucocutaneous, following a viral infection. The PT, APTT, and RVVT are prolonged and the APTT does not correct on mixing, with further evaluation revealing the presence of a lupus anticoagulant. However, since lupus anticoagulants are generally not associated with hemorrhagic manifestations *per se*, the clinician should measure factor activity levels, which will demonstrate an isolated prothrombin deficiency that is occasionally very profound. Both FII:C and FII:Ag are equally reduced. These prothrombin autoantibodies both possess lupus anticoagulant activity and lead to accelerated clearance of prothrombin *in vivo*. However, since they are nonneutralizing *in vitro*, a quantitative Bethesda inhibitor assay is usually uninformative. Most patients spontaneously improve over several weeks, but occasionally intervention with immunosuppressives (e.g., steroids and/or immunoglobulin) or hemostatic agents (e.g., PCC with or without plasma exchange) may be required.

Treatment

There is no purified prothrombin concentrate, but FFP or PCC are suitable alternatives. The hemostatic level of FII:C is probably somewhat higher than FVII or FX, and a target of 30% is appropriate for most situations. Like FX, prothrombin has a long half-life in plasma so that after an initial loading dose, daily or even alternate-day dosing is sufficient. As a guideline, it can be assumed that the prothrombin content in PCC is about 1 unit per unit of FIX, and that 1 unit/kg of prothrombin will raise the FII:C level by 1%.⁸

Fibrinogen abnormalities

Structure and function

Fibrinogen (sometimes referred to in older literature as “factor 1”) circulates in plasma as a 340-kDa homodimer. It is also found in platelet α -granules. Each fibrinogen monomer consists of three structurally distinct polypeptides, known as the $A\alpha$, $B\beta$, and γ chains. Although a separate gene codes for each polypeptide, all three genes are located in close proximity on chromosome 4. All three peptides are synthesized in the liver and, to a lesser extent, megakaryocytes.

Thrombin cleaves and releases fibrinopeptides A and B from the $A\alpha$ and $B\beta$ chains respectively. The fibrin monomers so formed can then begin to polymerize to form an insoluble fibrin gel. Finally, fibrin polymers are stabilized by FXIIIa-mediated cross-linking of fibers. The TCT detects fibrin polymerization well before the onset of action of FXIIIa; therefore the TCT is normal in patients with FXIII deficiency. Fibrinogen has another important function in hemostasis, namely to act as the cross-linking ligand for glycoprotein IIb–IIIa on activated platelets during aggregation.

Mice lacking the $A\alpha$ chain of fibrinogen (Fib^{-/-}) are unable to assemble functional fibrinogen molecules and are phenotypically afibrinogenemic with markedly abnormal clotting studies, yet they survive to adulthood. This observation is likely explained by a degree of inherent redundancy in this arm of the hemostatic system, whereby other ligands, such as von Willebrand factor, are able to substitute for fibrinogen in platelet adhesion and aggregation. It is furthermore presumed that thrombin-dependent activation of platelets to form platelet-rich hemostatic plugs can compensate for the lack of fibrin formation *in vivo*. It has been shown that the sequence of cellular infiltration into wounds is abnormal in Fib^{-/-} mice, and the tensile strength of wounds is diminished, even though wound healing does ultimately occur.

Inheritance and prevalence

Afibrinogenemia is inherited in an autosomal recessive manner with an estimated prevalence of about 1 per million. In humans, the vast majority of afibrinogenemic patients have been found to have truncating mutations in the gene for the fibrinogen α -chain. Hypofibrinogenemia and dysfibrinogenemia represent heterozygous carrier states and therefore may be inherited from generation to generation in the absence of consanguinity. Only a few patients with dysfibrinogenemia are homozygotes. Genetic mutations leading to dysfibrinogenemia result in alterations of fibrinopeptide release, fibrin polymerization, fibrin cross-linking, or resistance to plasmin digestion during fibrinolysis.¹⁸ The latter mutations tend to be associated with a thrombotic phenotype, as expected. As an example of the complexity of the dysfibrinogenemias, some mutations can result in the formation of abnormal fibrin

(leading to bleeding) while at the same time rendering the fibrin resistant to fibrinolysis (leading to thrombosis). In all, more than 300 mutations accounting for dysfibrinogenemia have been described.

Clinical and laboratory features

Although perhaps representing a continuum with hypofibrinogenemia from a clinical standpoint, afibrinogenemia is usually defined as a condition in which plasma fibrinogen levels are undetectable both by a functional assay (most commonly the Clauss method) and an immunoreactive assay. The sensitivity of these assays is generally in the order of 5–10 mg/dL. However, in the North American Registry, afibrinogenemia was defined as fibrinogen activity < 50 mg/dL.² Hypofibrinogenemia refers to a disorder in which there is a quantitative reduction in the amount of circulating fibrinogen, below the usual reference range of 150–350 mg/dL. As alluded to above, however, there may be overlapping definitions of patients with fibrinogen levels in the range 5–50 mg/dL, depending on the study. In hypofibrinogenemia, there is a parallel reduction in functional and immunoreactive fibrinogen levels, whereas dysfibrinogenemia refers to the presence of abnormal fibrinogen molecules in the circulation. In this disorder, the functional (Clauss) fibrinogen level is generally significantly lower than the fibrinogen antigen level. If the antigen level is itself below the normal range, the terminology “hypodysfibrinogenemia” has been used by some authors. Also, in contrast to the other rare inherited coagulation disorders, dysfibrinogenemia is considered to be inherited in an autosomal dominant fashion.

In afibrinogenemia, all routine screening assays (PT, APTT, RVVT and TCT) are abnormally prolonged. In hypofibrinogenemia, the PT is usually more likely to be prolonged than the APTT, but the TCT and reptilase time are generally the most sensitive screening assays. Reptilase (batroxobin) is a snake venom from the South American pit viper *Bothrops atrox*. It converts fibrinogen to fibrin but, unlike thrombin, it only cleaves and releases fibrinopeptide A, and is insensitive to the presence of heparin, heparin-like compounds or direct thrombin inhibitors in the test sample. This property can be exploited to distinguish contaminating anticoagulants from a true fibrinogen abnormality, since only in the latter instance will the reptilase time be prolonged.

Platelet aggregation studies using standard reagents may be abnormal in patients with severe reductions in plasma fibrinogen. This is explained by insufficient cross-linking of aggregating platelets *in vitro*. It is likely, however, that other ligands such as von Willebrand factor are capable of substituting for fibrinogen in this role *in vivo*.

Patients with afibrinogenemia, who are genetically homozygous or compound heterozygous for mutations in one or more fibrinogen chains, tend to have more severe manifestations than hypofibrinogenemic individuals, many

of whom are asymptomatic unless subjected to trauma or surgery.² Overall, like *Fib*^{-/-} mice, afibrinogenemic humans experience a bleeding disorder that is significantly milder than severe hemophilia. In the Iranian series of 55 patients with afibrinogenemia,¹⁹ bleeding from the umbilical cord was found to be the most common site of hemorrhage (85%), followed by muscle hematomas, epistaxis, menorrhagia, and oral cavity bleeding (all ~70%). Hemarthrosis occurred in 54%, while CNS bleeds occurred in 10%. Gastrointestinal and genitourinary bleeding was notably absent. Hemorrhagic corpus luteal cysts and recurrent abortion are relatively frequent in afibrinogenemic women, and placental abruption may be a problem even if implantation has been successful. Thrombotic episodes, a recurring observation in several studies of afibrinogenemia, were recorded in only 4% of patients in the Iranian series.¹⁹ Thromboses may occur independently of fibrinogen replacement therapy. It has been postulated that the lack of a “fibrin sink” for thrombin clearance leads to high circulating thrombin and a tendency to induce thrombosis via platelet activation.

The clinical manifestations of dysfibrinogenemia are protean and frequently difficult to predict. About half of affected individuals remain asymptomatic while one-quarter develop thrombotic manifestations, and the remainder have a tendency to bleed abnormally.¹⁸ Both arterial and venous thrombotic events have been reported in dysfibrinogenemia. In yet other patients, bleeding and thrombosis can both occur at different times. To some extent, genotyping of the mutation in a specialized facility can assist in predicting the clinical phenotype, if the patient presents incidentally.¹⁸ If, on the other hand, the patient has come to attention because of a clinical history of bleeding or thrombosis, it is likely that their future risk with surgery will be somewhat easier to predict, and will dictate the need for appropriate hemostatic or antithrombotic prophylaxis.

The differential diagnosis of inherited fibrinogen abnormalities include acquired forms of hypofibrinogenemia and dysfibrinogenemia, as well as other causes of a prolonged TCT that have already been discussed. The most frequent causes of acquired hypofibrinogenemia or dysfibrinogenemia include DIC and advanced liver disease or hepatocellular carcinoma, where hypersialylated forms of fibrinogen may produce a dysfunctional molecule. Rarely, a primary hyperfibrinogenolytic state may produce significant hypofibrinogenemia in the absence of other markers of DIC, such as thrombocytopenia or reduction of circulating antithrombin levels. Certain drugs, such as asparaginase, may also lead to hypofibrinogenemia.

Treatment

The mainstays of treatment or prophylaxis for bleeding in the fibrinogen defects are cryoprecipitate and antifibrinolytic agents. In some countries, virally inactivated plasma-derived

fibrinogen concentrates are available.^{6,7} The target plasma level for fibrinogen should be > 100 mg/dL until hemostasis is achieved, then 50 mg/dL until wound healing is complete. In an average-sized adult, one bag of cryoprecipitate, which contains about 250 mg of fibrinogen, is expected to raise the fibrinogen level by 6–8 mg/dL, with a half-life of 2–4 days in the absence of accelerated consumption. In the case of a dysfibrinogenemia associated with excessive bleeding, one strategy is to raise the fibrinogen level by at least 100 mg/dL over baseline.⁸ Longer-term prophylaxis may be reasonable in certain situations, for example in a patient who has suffered an intracranial hemorrhage, targeting a fibrinogen level > 50 mg/dL. Similarly, in a pregnant woman with afibrinogenemia who has suffered multiple miscarriages, maintenance of a trough fibrinogen level > 50 mg/dL throughout pregnancy, increasing to > 100 mg/dL at the time of delivery, may improve the outcome.

Antifibrinolytic agents are a logical adjunct for bleeding associated with hypofibrinogenemic states, but are probably best avoided in dysfibrinogenemias associated with thrombosis. Fibrin glues may be useful for control of topical hemorrhage if a temporarily dry wound can be secured to allow their application.

Multiple congenital deficiency states

Apart from the chance occurrence of two inherited factor deficiency states that may occur sporadically, there are some disorders resulting from a single gene defect that may manifest as deficiency of more than one clotting factor. These include combined FV and FVIII deficiency, and deficiency of all the vitamin K-dependent factors.

Combined FV and FVIII deficiency

Structure and function

Combined FV and FVIII deficiency is a fascinating disorder for which the molecular basis has only been recently elucidated. Most affected subjects have a mutation in the gene for endoplasmic reticulum golgi intermediate compartment (ERGIC)-53, a protein that facilitates cellular export of certain glycosylated proteins (including FV and FVIII) from the endoplasmic reticulum during their synthesis. The gene for ERGIC-53 (also known as LMAN-1) is located on chromosome 18. A second defect accounts for about one-third of cases; here the defective protein is called MCFD2, the gene for which is on chromosome 2.

Inheritance and prevalence

This disorder is inherited in an autosomal recessive fashion, and is primarily found in Jews of Sephardic and Middle

Eastern origin in Israel and in other countries in which consanguinity is common. Approximately 150 cases are described in the literature.

Clinical and laboratory features

In 27 Iranian patients with combined FV and FVIII deficiency, epistaxis, menorrhagia and postsurgical bleeding were the most common manifestations, but occasional hemarthroses and muscle hematomas were described.²⁰ Typically, both PT and APTT are prolonged, and correct on mixing. Plasma levels of FV:C and FVIII:C are usually in the range 5–30%, with antigen levels equivalently reduced. Heterozygotes generally have normal, or very slightly reduced, plasma levels of FV:C and FVIII:C, and are asymptomatic.

Treatment

Although FVIII concentrates are widely available, there is no FV concentrate. Therefore, some combination of FFP and FVIII concentrate is probably the most logical approach to bleeding in these patients.

Combined deficiency of all vitamin K-dependent factors

Structure and function

Combined inherited deficiency of vitamin K-dependent FII, FVII, FIX, FX, protein C and protein S is a very rare bleeding disorder. Mutations in the γ -glutamyl carboxylase (γ -GC) enzyme lead to impaired posttranslational γ -carboxylation of glutamic acid residues in the Ca^{2+} -dependent membrane-binding (Gla) domain of these proteins. The gene encoding γ -GC is located on chromosome 2. Alternatively, combined deficiency of these zymogens may result from inherited deficiency of vitamin K epoxide reductase (VKOR), a microsomal enzyme responsible for recycling the oxidized form of the cofactor for γ -GC (vitamin K epoxide).

Not surprisingly, γ -GC^{-/-} mice do not survive, and manifest skeletal abnormalities, reflecting the fact that some bone proteins such as osteocalcin and matrix Gla-protein also depend on vitamin K-dependent posttranslational modification.

Inheritance and prevalence

This combined deficiency state is inherited in an autosomal recessive fashion. It is very rare, with less than 20 affected families described.

Clinical and laboratory features

The severity of the factor deficiencies in a given kindred is quite variable. Some homozygotes exhibit coagulation

factor activities of < 5%, whereas others range from 20 to 60%. Heterozygotes are generally asymptomatic. Umbilical cord hemorrhage and CNS bleeding may occur as the presenting features in severely deficient subjects. Mucocutaneous hemorrhage and hemarthroses are described. In some pedigrees with severe factor deficiencies there are associated skeletal deformities, including nasal hypoplasia and defective bone ossification. Laboratory studies reveal marked prolongation of PT, APTT, and RVVT with correction on mixing. One-stage clotting assays for all the vitamin K-dependent factors are low, with modest if any reduction of antigen levels. Since VKOR is one of the pharmacologic targets of coumarins, it is important to rule out intentional or unintentional poisoning by these agents, or severe vitamin K deficiency. Evaluation of the subject's parents may be useful in demonstrating partial (heterozygous) deficiency.

Treatment

In some families, high-dose oral vitamin K may partially or even completely correct coagulation factor levels in individuals with mild or moderate deficiencies. If this is the case, long-term use may be needed. In the absence of correction, FFP or PCC may be administered either on demand for bleeding, or prophylactically several times weekly.

Congenital deficiency states not associated with any abnormality in screening coagulation assays

Factor XIII deficiency

Structure and function

FXIII is a zymogen that is activated by thrombin in the presence of Ca^{2+} . FXIIIa is a transglutaminase that cross-links α - and γ -fibrin chains through γ -glutamyl- ϵ -lysine bonds. Cross-linked fibrin forms a more stable clot that is more resistant to fibrinolysis. By covalently attaching α_2 -plasmin inhibitor (also called α_2 -antiplasmin) to the fibrin clot, FXIIIa further enhances resistance to fibrinolysis.

FXIII is composed of two enzymatically active A subunits (encoded on chromosome 6) and two carrier B subunits (encoded on chromosome 1). The molecular mass of the heterotetrameric A_2B_2 entity is 320 kDa. FXIII-A is synthesized in megakaryocytes, monocytes, and macrophages, whereas FXIII-B is synthesized in hepatocytes. Activation of A chains by thrombin follows proteolytic cleavage of the Arg³⁷–Gly³⁸ bond.

FXIII-A^{-/-} mice are normal at birth and mature to adulthood, although there is gradual attrition due to death from hemoperitoneum, hemothorax, and massive subcutaneous hemorrhage. Pregnant females die in gestation due to massive uterine bleeding in mid-pregnancy.

Inheritance and prevalence

FXIII deficiency is inherited as an autosomal recessive disorder with a prevalence of less than 1 per 2 million of the population. Most patients are homozygous for FXIII-A deficiency, and always with a type 1 deficiency state, with concomitantly low FXIII:C and FXIII-A:Ag levels. Bleeding is unusual in individuals with FXIII:C > 5%.

Clinical and laboratory features

The diagnosis of FXIII deficiency is suggested by characteristic clinical features, especially umbilical cord bleeding, a family history of consanguinity, and normal screening coagulation studies, including PT, APTT, and TCT.

Umbilical cord bleeding occurring a few days after birth is a common mode of presentation (~ 80%), as is bleeding at circumcision. Ecchymoses occur in about 50% and CNS bleeding in 20–30%, frequently at a very early age. About 25% of patients with FXIII deficiency manifest defective wound healing. Affected women, like those with afibrinogenemia, experience menorrhagia, hemoperitoneum during ovulation, and recurrent pregnancy loss. Like individuals severely deficient in prothrombin and FX, FXIII-deficient patients may experience hemarthroses and muscle hematomas (~25%).

Screening for FXIII deficiency is usually performed using a qualitative assay of fibrin clot solubility in 5 mol/L urea or 1% monochloroacetic acid. This poorly standardized test is probably sensitive to FXIII levels < 3%. Diagnosis is confirmed usually by immunologic measurement of FXIII-A and FXIII-B subunit antigens; generally the former are very low, while the latter are only modestly reduced.

Treatment

Two plasma-derived FXIII concentrates are marketed, although one of these, manufactured by Bio Products Laboratory (UK), is available only in the UK. Fibrogammin P is available more widely, including in the USA on an Investigational New Drug (IND) license from the Food and Drug Administration.⁶ The recommended dose is 10–20 units/kg for prophylaxis and 50–75 units/kg for treatment of bleeding. Other potential sources of FXIII include FFP, cryoprecipitate and platelets.

Long-term prophylaxis is recommended for all patients with severe FXIII deficiency because of the high incidence of intracranial hemorrhage. Because FXIII has an extremely long half-life, administration of concentrate or plasma/cryoprecipitate is required infrequently, generally every 4–6 weeks. This should be adjusted to maintain trough FXIII levels at 3% or more. Prophylaxis can also facilitate a successful pregnancy outcome in FXIII-deficient women. Inhibitor alloantibodies to FXIII may occur rarely as a result of exposure to concentrates, necessitating immune suppression, plasmapheresis, and/or high-dose FXIII concentrate.

α_2 -plasmin inhibitor deficiency

Structure and function

α_2 -plasmin inhibitor (α_2 -PI) is a serine protease inhibitor (SERPIN) of about 70 kDa that is synthesized in the liver and probably the kidneys. Its function appears to be threefold: inhibition of plasmin enzymatic activity, competitive inhibition of plasmin(ogen) binding to fibrin, and FXIIIa-dependent covalent cross-linking to fibrin α -chains. The net effect is therefore antifibrinolytic. The gene for α_2 -PI is located on chromosome 17.

α_2 -PI^{-/-} mice are normally fertile and viable. They demonstrate a normal hemostatic response to tail transection, but by other *in vivo* thrombosis models can be shown to have modestly accelerated fibrinolysis of intravascular fibrin thrombi.

Inheritance and prevalence

α_2 -PI deficiency is transmitted in an autosomal recessive fashion. It appears to be extremely rare, with fewer than 20 reported cases. Both type 1 and type 2 deficiency states are described.

Clinical and laboratory features

In contrast to α_2 -PI^{-/-} mice, homozygous patients with this disorder have a severe bleeding disorder characterized by delayed-onset hemorrhage after vascular injury. Presentation is in childhood, sometimes with umbilical cord bleeding. Post-surgical and posttraumatic bleeding are common, as is deep tissue bleeding including muscle hematomas, hemarthrosis and, somewhat uniquely, intramedullary hematoma formation in the diaphyses of long bones. Heterozygous carriers probably have little, or at most a mild, bleeding tendency.²¹

Treatment

Antifibrinolytic agents are the mainstay of therapy for bleeding in α_2 -PI deficient individuals. Failing this, FFP may be used as a source of the SERPIN. Solvent-detergent treated plasma should not be used, as the process inhibits the functional activity of α_2 -PI. The half-life of α_2 -PI is about 2.5 days, but for infused concentrates is much shorter.

Plasminogen activator inhibitor-1 deficiency

Structure and Function

Plasminogen activator inhibitor (PAI)-1 is a 45-kDa SERPIN that rapidly inactivates tissue-type plasminogen activator (tPA) and urokinase-type plasminogen activator (u-PA). PAI-1 is found in a variety of cells, including platelets, vascular endothelial cells, and other vascular and nonvascular cells.

PAI-1^{-/-} mice manifest mild hyperfibrinolysis and enhanced resistance to venous thrombosis, but no abnormal bleeding or rebleeding after injury. Interestingly, α_2 -AP^{-/-}PAI-1^{-/-} mice do demonstrate prolonged immediate-onset bleeding after tail transection, as well as a more profound hyperfibrinolytic state than is seen with either variant alone.

Inheritance and prevalence

The prevalence of PAI-1 deficiency is unknown, and indeed there are less than 20 homozygous deficient individuals described in the literature. It is therefore presumed to be extremely rare.

Clinical and laboratory features

Unlike the murine model, homozygous PAI-1-deficient individuals do manifest delayed rebleeding, often severe, after surgery or trauma. Intracranial bleeding, hemarthrosis, and extensive ecchymoses may occur, but spontaneous hemorrhage (with the possible exception of menorrhagia in affected females) is unusual. Heterozygotes appear to be asymptomatic. It is recommended that PAI-1 antigen and activity be measured in both plasma and serum to include the PAI-1 contributed by platelets.

Treatment

The antifibrinolytic agents tranexamic acid and ϵ -aminocaproic acid are the mainstays of treatment. Theoretically, transfusion of FFP or platelets would be a reasonable alternative for refractory bleeding events.

Connective tissue disorders: Ehlers–Danlos syndrome

Inherited disorders of connective tissue are a consequence of defects in the quantity and/or structure of extracellular matrix proteins, including collagen, elastin, fibrillin, and non-collagenous extracellular matrix proteins such as basement membrane proteins and proteoglycans. Although bleeding complications have been associated with several connective tissue disorders, the most common condition associated with bleeding manifestations is Ehlers–Danlos syndrome (EDS).²²

EDS is a heterogeneous disorder caused by an inherited abnormality of collagen. It is characterized by varying degrees of skin elasticity, joint hypermobility and tissue fragility. At least 10 different variants of EDS have been described, and these were reclassified in 1997 into six major types based on symptoms, physical characteristics and certain molecular and/or histologic findings (Table 28.2).²³

The diagnosis of EDS is based primarily on clinical symptoms, physical examination (skin and musculoskeletal system), and family history. A scoring system focusing on joint

Table 28.2 Classification of Ehlers–Danlos syndrome (EDS).

New	Former	OMIM	Inheritance
Classical type	Gravis (EDS type I)	130000	AD
	Mitis (EDS type II)	130010	AD
Hypermobility type	Hypermobile (EDS type III)	130020	AD
Vascular type	Arterial-ecchymotic (EDS type IV)	130050	AD
		(225350) (225360)	
Kyphoscoliosis type	Ocular-scoliotic (EDS type VI)	225400 (229200)	AR
Arthrochalasia type	Arthrochalasia multiplex congenita (EDS types VIIA, VIIB)	130060	AD
Dermatosparaxis type	Human dermatosparaxis (EDS type VIIC)	225410	AR
Other forms	X-linked EDS (EDS type V)	305200	XL
	Periodontitis type (EDS type VIII)	130080	AD
	Fibronectin-deficient EDS (EDS type X)	225310	?
	Familial hypermobility syndrome (EDS type XI)	147900	AD
	Progeroid EDS	130070	?
	Unspecified forms	–	–

AD, autosomal dominant; AR, autosomal recessive; XL, X-linked.

Reproduced with permission from Ref. 23.

hypermobility, abnormal scar formation, and hemorrhagic symptoms has been successfully used to screen patients for EDS.²⁴ A skin biopsy is recommended to evaluate for molecular genetic and/or histologic abnormalities, and to rule out the vascular form of EDS. In many patients, particularly those with the hypermobility (the most common) variant, the biopsy is uninformative.

The presentation of EDS depends on the variant but typically includes musculoskeletal, skin, and cardiovascular manifestations, although other organ systems may also be affected (intestine, lung, uterus, eye, etc.). The most common symptoms (according to organ system) are as follows.

- Musculoskeletal: hypermobile joints, recurrent dislocation, ligament and tendon injury, early-onset degenerative joint disease, flat feet, club feet, scoliosis, temporomandibular joint disease, and early dental loss.
- Skin: velvety or doughy texture, fragility with tearing, poor wound healing, wide dystrophic scars, papyraceous-appearing scars, subcutaneous nodules on pressure points and wound dehiscence following surgery.
- Vascular: mitral valve prolapse, aortic root dilation, aneurysm of the aorta, rupture or dissection of mid-sized arteries, and early-onset varicose veins.
- Other: recurrent hernias, bladder diverticuli, intestinal rupture, recurrent pneumothorax, scoliosis, detached retina, scleral fragility, rectal prolapse, and uterine prolapse or rupture.

Described bleeding manifestations include easy bruising, soft-tissue hematomas, recurrent nosebleeds, intraoperative

or postoperative dental or surgical bleeding, gastrointestinal and pulmonary hemorrhage, menorrhagia, and bleeding with childbirth. Not uncommonly, children with EDS are suspected to be victims of child abuse because of prominent bruising.

The etiology of bleeding in these patients is probably multifactorial, and includes increased vascular fragility and poor wound healing. Abnormal subendothelial collagen that is less adhesive for platelets and/or associated platelet function abnormalities and other inherited factor (VIII, IX, XI and XIII) deficiency states may also contribute to the bleeding propensity.

Evaluation of a patient who has clinical evidence of a connective tissue disorder and bleeding symptoms should include PT, APTT, TCT, and von Willebrand studies. The bleeding time, although technically problematic, may be the only abnormal coagulation study in these patients. Further evaluation, including specific factor assays and more specific platelet function studies such as platelet aggregation, may be indicated based on bleeding symptoms and the results of preliminary screening studies.

Treatment should include the avoidance of aspirin, non-steroidal antiinflammatory drugs, and other medications that might increase the risk of bleeding. Attention should be paid to surgical technique, including choice of suture material, and postoperative care can be important in preventing surgical bleeding and wound dehiscence. If there is an associated inherited coagulation abnormality, this should be treated aggressively with appropriate replacement therapy.

Despite these general recommendations some patients with EDS have significant bleeding particularly related to surgery and trauma. Many have been treated with intravenous or intranasal desmopressin and/or oral or intravenous antifibrinolytic agents. With surgery or trauma where serious bleeding occurs that is not responsive to desmopressin, or where desmopressin is contraindicated, intermediate-purity FVIII concentrates such as Humate-P have been used successfully to control bleeding. Anecdotally, rFVIIa has also been used successfully in rare instances.

Fortunately, the majority of patients with EDS have minor bleeding issues. Consideration of EDS as a possible cause of postoperative or posttraumatic bleeding is often overlooked because the clinical manifestations of EDS are frequently not recognized. In addition there is a paucity of clinical studies examining treatment options for these patients. Therefore, most therapeutic regimens are based on limited and anecdotal experience.

Acquired disorders of hemostasis

Elizabeth A. Chalmers, Michael D. Williams and Angela Thomas

Developmental hemostasis during childhood

Many features of the hemostatic system appear to be age dependent. This is most apparent during the neonatal period, where differences can be observed in the levels of many hemostatic proteins compared with adult values.^{1,2} Considerable "maturation" of the hemostatic system occurs during the first 6 months of life even in preterm infants.¹⁻³ Despite this a number of differences persist throughout childhood and adolescence.⁴ The availability of normal reference ranges for children of different ages is therefore crucial for accurate diagnosis in this age group and is also important in the management of clinical problems, particularly where therapeutic agents interact with the hemostatic system.^{5,6}

The development of microtechniques during the early 1980s provided the first opportunity for the detailed study of the hemostatic system in neonates and young children. Using this technology, Andrew *et al.*⁴ performed a comprehensive analysis of coagulation and fibrinolytic parameters across three different age ranges in healthy children undergoing minor elective day surgery. Comparison of the results obtained demonstrated the presence of important differences in the mean levels of many procoagulant proteins, coagulation inhibitors and fibrinolytic proteins.

Based on these data mean plasma concentrations of vitamin K-dependent factors (II, VII, IX and X) and the contact factors XI, XII and V are all 15–20% lower in children than in adults (Table 29.1). In contrast, concentrations of fibrinogen, factor (F)VIII and von Willebrand factor (vWF) are similar to adult values throughout childhood. The inhibitor antithrombin is increased by approximately 10% while α_2 -macroglobulin is almost doubled and heparin cofactor II reduced by 10–20% (Table 29.2). Free protein S levels are similar to adult values, while mean protein C levels remain significantly reduced even in the 11–16 year age range (Table 29.2).⁴ Plasma concentrations of some fibrinolytic

proteins are also affected by age and while plasminogen and α_2 -antiplasmin levels are similar in adults and children, plasminogen activator inhibitor (PAI)-1 is increased and tissue plasminogen activator (tPA) decreased so that overall fibrinolytic capacity appears reduced during childhood (Table 29.3).

Despite reduced levels of several procoagulant proteins, routine coagulation screening tests such as prothrombin time (PT) and activated partial thromboplastin time (APTT) show relatively minor differences compared with adult values, which reflects the relative insensitivity of these tests to minor changes in procoagulant concentrations (Table 29.1).⁴

While the data published by Andrew *et al.* still provide extremely comprehensive information on the nature of the hemostatic system during childhood, they were generated in the 1980s and do not therefore reflect current technology. All reference ranges, regardless of patient characteristics, are both instrument and reagent dependent and it is generally recommended that all laboratories establish their own in-house reference ranges. Caution is therefore required when interpreting individual results in children against previously published ranges. This was highlighted recently by Monagle *et al.*⁷ who demonstrated the presence of significant differences in data derived in a group of children using currently available technology compared with data published previously by Andrew *et al.*

Normal ranges for the skin bleeding time have also been established using a number of different methods.⁸ The shortest bleeding times appear to occur in neonates and very young infants. In older children the data are conflicting, with bleeding times that are both longer and shorter than adult values having been reported (Table 29.1).^{5,8,9}

From a clinical point of view it has been of interest to try to assess the effects of these differences in the hemostatic system on overall thrombin regulation. Data from *in vitro* studies based on traditional models of thrombin generation have shown that thrombin generation is reduced by around 20%

Table 29.1 Reference values for coagulation tests in healthy children aged 1–16 years compared with adults.

	1–5 years	6–10 years	11–16 years	Adult
PT (s)	11 (10.6–11.4)	11.1 (10.1–12.1)	11.2 (10.2–12.0)	12 (11.0–14.0)

during childhood compared with adult values.¹⁰ Despite this, for any given hemostatic challenge there does not appear to be an increased risk of hemorrhagic problems during childhood. Conversely, the total capacity to inhibit thrombin,

as assessed *in vitro* using ¹²⁵I-labeled thrombin, is increased due to increased binding to α_2 -macroglobulin^{11,12} and may contribute to the relatively low incidence of thrombosis during childhood.^{13–16}

Table 29.3 Reference values for the fibrinolytic system in healthy children aged 1–16 years compared with adults.

	1–5 years	6–10 years	11–16 years	Adult
Plasminogen (units/mL)	0.98 (0.78–1.18)	0.92 (0.75–1.08)	0.86 (0.68–1.03)*	0.99 (0.77–1.22)
tPA (ng/mL)	2.15 (1.0–4.5)*	2.42 (1.0–5.0)*	2.16 (1.0–4.0)*	4.90 (1.40–8.40)

Evaluation of a bleeding child

When a child presents with bleeding or bruising, the main differential diagnoses are physiologic or accidental bleeding, nonaccidental injury or a bleeding diathesis. Clinical presentation and medical history, including response to any previous hemostatic challenges, are key to differentiating between these conditions. A history of any medications or other remedies taken should be included. In an ill child, bleeding is often acquired and due to more than one defect of the hemostatic mechanism. The underlying disorder such as renal failure, liver disease or sepsis may well be apparent. In a well child, bleeding, whether congenital or acquired, is more often due to a single defect such as thrombocytopenia or a coagulation factor deficiency. A family history of unusual bleeding in parents, siblings and other relatives or a family history of a specific diagnosis may be helpful in determining whether the child is likely to have an inherited disorder. X-linked disorders are usually but not exclusively seen in boys and age at presentation will influence the differential diagnosis and, in the case of congenital disorders, tends to be inversely associated with the severity of the disease.

The site and pattern of bleeding may indicate the most likely underlying hemostatic defect. Defects of platelets, both quantitative and qualitative, result predominantly in mucocutaneous bleeding. This can be manifest as petechial hemorrhages, ecchymoses, recurrent or prolonged epistaxis and menorrhagia in girls. Thrombocytopenia is commonly acquired and mucocutaneous bleeding in a well child, possibly following a viral infection, may indicate idiopathic thrombocytopenic purpura. In a sick child, the thrombocytopenia may be part of disseminated intravascular coagulation (DIC), with bleeding and oozing from multiple sites, or secondary to bone marrow failure or infiltration by malignant disease. Acquired coagulation protein defects are less common in well children but do occur in vitamin K deficiency, and occasionally hypoprothrombinemia resulting in bleeding can be seen with a lupus anticoagulant. Bleeding

from wounds or puncture sites and significant mucocutaneous bleeding are seen in sick children secondary to complex coagulopathies that occur with liver disease and DIC. Examination will indicate the general health and systemic well-being of the child and will confirm the pattern of bleeding. Stigmata of underlying disease or physical signs associated with specific congenital disorders may be evident.

Screening tests in a bleeding child should include a full blood count and blood film, PT, APTT and fibrinogen. In a sick child, liver and renal function may be evaluated and other markers of DIC such as D-dimers measured. In a well child with mucocutaneous bleeding, vWF antigen and activity may be informative, particularly if the screen is normal. Further investigations will depend on initial results in association with clinical and family history.

Disseminated intravascular coagulation

DIC is a common acquired coagulopathy which in children is usually an acute event and related to a systemic disorder. Definitions have sought to encompass the various aspects of this syndrome, including it being an acquired condition characterized by intravascular activation of coagulation including both procoagulant and fibrinolytic activation and causing thrombohemorrhagic effects that may result in end-organ damage.^{16,17} DIC remains a significant cause of morbidity and mortality in children and adults but progress in understanding the pathogenesis of this syndrome has provided novel approaches to diagnosis and treatment.¹⁸

Etiology

There are a number of disease processes that may result in DIC in children (Table 29.4). Infection remains the commonest cause of DIC. Bacterial infections predominate, with no difference being noted in the frequency of Gram-negative and Gram-positive organisms.¹⁹ meningococcal meningitis remains one of the most frequent causes of severe DIC in

Table 29.4 Causes of disseminated intravascular coagulation in children.

Infection
Malignancy, e.g., acute leukemia
Trauma, e.g., head injury, burns
Organ destruction, e.g., acute pancreatitis
Severe immune reaction, e.g., ABO-incompatible blood transfusion
Hepatic failure
Vascular abnormality, e.g., Kasabach–Merritt syndrome

children. Viruses (most commonly cytomegalovirus, varicella and hepatitis), protozoa and systemic fungi are also recognized triggers for this disorder. DIC in association with childhood malignancy is relatively uncommon except in acute promyelocytic leukemia and tumor lysis syndromes.²⁰ Chronic localized DIC is infrequent in children and almost exclusively occurs in association with giant hemangiomas. Kasabach–Merritt syndrome has its peak incidence in early infancy but may present later in childhood; although the diagnosis is usually obvious, occult hemangiomas can occur and should be excluded in the presence of a significant unexplained coagulopathy.²¹

Pathophysiology

These diverse disease conditions lead to the triggering of DIC through a number of mechanisms that occur simultaneously.^{17,18,22} Thrombin generation occurs via the tissue factor–FVIIa system^{23,24} and results in the deposition of fibrin: it seems likely that endogenous tissue factor pathway inhibitor cannot regulate this process once triggered.²⁵ The natural anticoagulant pathways such as the antithrombin and protein C systems are impaired, with reduced plasma levels of antithrombin and decreased activation of protein C being consistent features of DIC.^{26–28} Thrombin generation thereby increases, leading to excessive fibrin formation and consumption of coagulation factors and platelets. Circulating plasmin results in the generation of fibrin(ogen) degradation products that interfere with fibrin polymerization and platelet function, leading to additional hemorrhagic problems; however, fibrinolysis is largely suppressed due to a sustained increase in PAI-1.²⁹ Fibrin deposition leads to microvascular and, less frequently, large-vessel thrombosis with impaired perfusion and subsequent organ damage.

The interaction between the coagulation and inflammatory pathways has become increasingly recognized as an integral component in the pathogenesis of DIC. Cytokines and proinflammatory mediators can induce coagulation through tissue factor expression; activated coagulation proteases such as thrombin, fibrin and FXa bind with protease-activated receptors on cell surfaces to stimulate inflammation through the release of proinflammatory cytokines.^{30,31} In addition, impairment of the anticoagulant pathways diminishes the

regulatory effect that proteins such as activated protein C have on cytokine release, thereby adding to the inflammatory response.³² These processes have wide-ranging systemic consequences, including vasodilatation, capillary leak and shock.

Clinical features

The most obvious clinical manifestation of overt DIC remains hemorrhage. Spontaneous bruising, petechiae from localized pressure, oozing from venipuncture sites, and continued bleeding from sites of trauma or from surgical wounds are relatively common; internal hemorrhage can involve the gastrointestinal tract, central nervous system or other organs and be life-threatening in itself. Microvascular thrombosis is a common and underdiagnosed manifestation of DIC which although more difficult to recognize clinically may lead to irreversible end-organ damage.

Acute infectious purpura fulminans is an uncommon but severe form of DIC seen in children in which purpura is followed by the development of skin bullae and necrosis. These features are identical to those seen in homozygous protein C or protein S deficiency and are the result of acquired deficiencies of these natural anticoagulants. The condition is most often seen in children with meningococcal septicemia but is also associated with chickenpox and streptococcal infection.³³

The spectrum of DIC is wide: whereas overt DIC occurring in a patient with one of the associated conditions detailed in Table 29.4 can usually be recognized clinically, nonovert DIC is detected only by changes in laboratory parameters as it reflects hemostatic dysfunction rather than frank decompensation and is not accompanied by the clinical signs of hemorrhage or thrombosis.

Laboratory diagnosis

There is no one laboratory test that is diagnostic of DIC and the laboratory diagnosis is therefore based on the demonstration of activation of both the procoagulant and fibrinolytic systems accompanied by anticoagulant consumption. Serial testing is often necessary to establish the diagnosis of DIC; diagnosis can be made difficult by the reactive nature of such proteins as fibrinogen and FVIII, which are often elevated in ill patients; similarly, markers of fibrin(ogen) degradation are often elevated in trauma and after surgery.

In fulminant DIC the diagnosis is usually obvious, with prolongation of all coagulation screening tests together with thrombocytopenia, increased fibrin degradation and reduced plasma levels of anticoagulants, particularly antithrombin and protein C. In less severe forms of DIC, screening tests such as APTT and PT can be less reliable: thrombocytopenia is an important marker, particularly when there is a downward trend in the platelet count, as is evidence of increased fibrin degradation, with D-dimer tests being more specific for fibrin than tests for fibrinogen degradation products.

The limitations of routine laboratory tests in the diagnosis of DIC can be overcome by the use of more sensitive tests of thrombin and plasmin generation,¹⁷ including prothrombin activation fragment 1 and 2, fibrinopeptide A and thrombin–antithrombin (TAT) complexes which reflect thrombin activation, and plasmin–antiplasmin complexes which reflect fibrinolytic activity. However, the majority of these assays remain limited to research laboratories and are not available in most routine coagulation laboratories.

A new development in the diagnosis of DIC has been waveform analysis of the APTT performed using a specific coagulation analyzer, in which a specific waveform profile has been shown to correlate with overt and nonovert DIC.³⁴

Pragmatically, the laboratory diagnosis of DIC is therefore usually made using a combination of tests that are readily available in most hospitals and which can be performed quickly and serially as necessary. These include PT, APTT, fibrinogen, D-dimers and platelet count. A scoring system that incorporates these tests has been proposed for use in the diagnosis of overt and nonovert DIC.¹⁶

Management

The single most important aspect of the treatment of DIC remains treatment of the associated disease condition. Even with prompt and aggressive treatment, DIC may continue to evolve, with the affected child requiring intensive supportive therapy in order to reduce morbidity and mortality. Optimum supportive measures remain controversial, with recent treatment modalities incorporating the advances that have been made in understanding the pathophysiology of this condition.

Blood component replacement therapy continues to be the mainstay of most treatment strategies and should be used only in patients with either clinical bleeding or prior to invasive procedures, and not merely to correct clotting test abnormalities. The choice of product, timing of administration, and efficacy of treatment remain unclear. Fresh frozen plasma (FFP) is a source of procoagulant proteins and anticoagulants and is usually given in a dose of 10–15 mL/kg. Cryoprecipitate (10 mL/kg) provides higher concentrations of fibrinogen and FVIII and is useful when hypofibrinogenemia exists. In the absence of randomized clinical trials, it is generally accepted that platelet counts should be maintained $> 50 \times 10^9/L$ and plasma fibrinogen $> 1 \text{ g/L}$. If fluid volume is problematic, consideration should be given to the use of coagulation factor concentrates or exchange transfusion. There is no clinical or laboratory evidence to support the historical assertion that the use of blood component therapy worsens DIC by “adding fuel to the fire”.

Alternative or additional treatment strategies have centered on the use of anticoagulant therapy and more recently on the replacement of the natural anticoagulants protein C

and antithrombin. Heparin has not been shown in controlled clinical trials to have had a significant effect on the outcome in DIC,³⁵ although its use in specific circumstances has been advocated.¹⁷ The safety of heparin treatment in patients who are at risk of bleeding remains an obvious concern. Given the pathophysiology of DIC, an alternative target for anticoagulation has involved tissue factor activity; however, no survival benefit has been demonstrated in the single randomized clinical trial examining the use of recombinant tissue factor pathway inhibitor.³⁶

A number of small studies of the use of antithrombin concentrate in adults and children with DIC have previously shown improvement in laboratory and clinical parameters^{37–39} but use in patients with DIC associated with sepsis has been shown to have no significant effect on reduction in mortality.⁴⁰ Neither antithrombin concentrate nor heparin are therefore currently indicated in the routine management of children with DIC.

Protein C concentrate has been used with varying success in the treatment of purpura fulminans associated with meningococcal septicemia, a condition in which acquired protein C deficiency occurs.^{41,42} However, activation of protein C *in vivo* is dependent on functional endothelial cell surface receptors, which can be greatly reduced in sepsis.⁴³ It is therefore uncertain as to the role of the other treatment modalities that have been used in conjunction with protein C concentrate, including hemofiltration and heparin, and further randomized trials would be helpful in determining its effect.

Replacement therapy with recombinant activated protein C concentrate has been shown to have a positive effect in reducing mortality in adults with severe sepsis, reducing 28-day mortality from 31% to 25%,⁴⁴ improving clotting test abnormalities and being associated with less organ failure in treated patients.⁴⁵ Interaction with the inflammatory pathways (see section on pathophysiology) may well be a contributory factor in these trial results. However, both the recent antithrombin III and activated protein C trials have been criticized,⁴⁶ and there remains no clear indication for the use of these products in DIC. No such studies have been performed in children and efficacy and safety of these treatments in this age group are unknown.

Vitamin K deficiency

Vitamin K is a fat-soluble vitamin, first identified over 50 years ago by the Danish biochemist Hendrik Dam, who observed bleeding in chicks fed a cholesterol-free diet.⁴⁷ Vitamin K is critical for the posttranslational modification of a number of diverse proteins. In its reduced form, vitamin K is a cofactor for the activation of the microsomal enzyme γ -glutamyl carboxylase, promoting the conversion of protein-bound glutamate residues (Glu) to γ -carboxyglutamate

residues (Gla). The presence of Gla residues confers unique physiologic properties for calcium-mediated binding to negatively charged phospholipid surfaces, a requirement for effective hemostasis.⁴⁸ In the absence of vitamin K these precursor proteins are functionally inactive and circulate in their decarboxylated form (PIVKA, i.e., protein induced by vitamin K absence or antagonism).

Vitamin K-dependent proteins are present in a wide variety of tissues, including plasma (procoagulant factors II, VII, IX and X; anticoagulants protein C and protein S; protein Z), bone (osteocalcin or bone Gla-protein), kidney, lung, testes, spleen and placenta.^{49,50}

Vitamin K exists in two naturally occurring forms. Phylloquinone (vitamin K₁) is the main dietary source of vitamin K and is present predominantly in leafy green vegetables and a small number of vegetable oils.⁵¹ The menaquinones (vitamin K₂) exist in a number of molecular forms that are restricted in the diet and largely synthesized by intestinal bacteria.

Etiology

Vitamin K deficiency beyond infancy is relatively uncommon and is almost always a secondary event resulting from inadequate intake or absorption, poor utilization of vitamin K, or vitamin K antagonism. Because of the wide dietary distribution of phylloquinones, after infancy inadequate vitamin K intake is generally the result of unsupplemented total parenteral nutrition often combined with the prolonged administration of broad-spectrum antibiotics.⁵² Conditions associated with malabsorption are the commonest cause of vitamin K deficiency in the pediatric age group. Vitamin K deficiency secondary to malabsorption due to absence of bile salts, either from intrahepatic or extrahepatic biliary obstruction, responds to vitamin K replacement. In contrast, in primary hepatocellular disease, liver parenchymal cells may not be capable of utilizing vitamin K even when present in adequate amounts. However, inadequate bile salt secretion may be a contributing factor and partial correction may follow vitamin K administration.

The commonest cause of vitamin K antagonism is warfarin therapy, which inhibits vitamin K epoxide reductase, resulting in the accumulation of the epoxide metabolite. There is a hepatic NAD(P)H-dependent pathway for vitamin K reduction that is fairly insensitive to warfarin.⁵³ Thus, vitamin K can bypass the enzyme, epoxide reductase, in situations requiring reversal of the warfarin effect. Second- and third-generation cephalosporins can also produce hypoprothrombinemia by inhibiting vitamin K epoxide reductase,⁵⁴ but these antibiotics are relatively weak vitamin K antagonists and probably only pose a risk in the presence of coexisting predisposing factors such as malnourishment with compromised vitamin K status.^{55,56}

Clinical features

Although laboratory evidence of vitamin K deficiency is quite common in the predisposing conditions described above, clinical bleeding is relatively infrequent and when it occurs is usually mild to moderate and typified by bruising, oozing from venipuncture sites and, rarely, internal bleeding. The underlying cause can usually be identified from the history and physical examination. In patients with liver disease, impaired synthesis of coagulation factors may coexist with vitamin K deficiency, increasing the severity of the coagulopathy. At-risk children who require an invasive procedure such as liver or jejunal biopsies should have a coagulation screen prior to the procedure and should receive appropriate vitamin K replacement in the event of a correctable abnormality.

Laboratory diagnosis

FVII has a short half-life and is the first of the vitamin K-dependent procoagulants to become deficient, resulting in an isolated prolongation of the PT.⁵⁷ Levels of FII, FIX and FX then decline, prolonging the APTT. Both the PT and APTT are corrected by a 1 : 1 mix with normal plasma. These screening test abnormalities are not specific for vitamin K deficiency and confirmatory tests may be both necessary and helpful in some patients. Specific factor assays may help distinguish isolated vitamin K deficiency from congenital factor deficiency, liver disease or DIC. Measurement of decarboxyprothrombin (PIVKA II), which is increased in vitamin K deficiency, is a more specific test.^{58–60} It is extremely sensitive and able to detect the early subclinical deficiency state. PIVKA II has a long half-life and can be used to diagnose vitamin K deficiency even after vitamin K therapy has normalized the PT.

The diagnosis of isolated vitamin K deficiency can also be confirmed if administration of a therapeutic dose of vitamin K is followed by a fall in the PT, which can occur in as short a period as 30 min if the vitamin is given intravenously.^{61,62} The rapid correction of vitamin K deficiency following parenteral administration of vitamin K has led to the hypothesis that undercarboxylated prothrombin may be stored in vitamin K deficiency states, which can then be rapidly carboxylated and secreted following replacement therapy.⁶³

Treatment

Appropriate treatment of vitamin K deficiency is dictated by the urgency of the clinical situation. Where there is no or only minor bleeding and in the presence of normal absorption, oral vitamin K is effective but correction of the PT is slower than following parenteral administration. Parenteral vitamin K results in the most rapid correction of vitamin K deficiency

and may be administered by either the intravenous or subcutaneous route. Severe anaphylaxis can occur following intravenous vitamin K and it is important that the preparation is diluted appropriately and infused slowly. The intramuscular route may result in painful hematoma formation and should be avoided.

Patients who are bleeding secondary to vitamin K deficiency and who require rapid correction of their coagulopathy should receive parenteral vitamin K and should also be given factor replacement therapy. Options for replacement therapy include FFP, prothrombin complex concentrate (PCC) or a four-factor concentrate.⁶⁴ FFP in a dose of 10–15 mL/kg will raise the levels of vitamin K-dependent factors by 0.1–0.2 units/mL. Virally inactivated FFP should be used wherever possible. PCCs have the advantage of rapid administration in low volume but do not contain FVII and additional supplementation with either FFP or recombinant FVIIa may also be required. Four-factor concentrates containing all the vitamin K-dependent factors may ultimately offer the best therapeutic option; however, at present these products are not licensed for use in children and there is only limited clinical data available on their use in this area.

Prophylaxis

Vitamin K 1 µg/kg is considered an adequate daily requirement.⁶⁵ Consideration should be given to the use of vitamin K supplementation in children at high risk of developing deficiency.

There is a surprising paucity in the literature of evidence-based guidelines in this area. The best researched of the disorders predisposing to vitamin K deficiency is cystic fibrosis, but even here there is no clear consensus on the need for routine vitamin K supplementation.⁶⁶ Studies suggest that vitamin K deficiency is probably unusual in patients with cystic fibrosis not receiving vitamin K supplements, but a negative effect may be masked by the current common use of vitamin K supplements in this patient group.⁶⁶ A literature review identified the children at greatest risk as those with:

- severe noncholestatic or cholestatic liver disease;
- major small bowel resection for intestinal complications;
- pulmonary disease necessitating long-term use of antibiotics;
- pancreatic insufficiency.

This review suggested that these categories of patients receive vitamin K prophylaxis until evidence from future studies identifies risk factors.⁶⁶ The Consensus Conference of the Cystic Fibrosis Foundation on Nutritional Assessment and Management in Cystic Fibrosis (1990) made dosage recommendations but there are few data on the effectiveness of specific regimens.⁶⁷ Wilson *et al.*⁶⁸ demonstrated that an oral fat-soluble vitamin combination containing modest amounts of vitamin K failed to reduce PIVKA levels in all children with cystic fibrosis and pancreatic insufficiency,

and van Hoorn *et al.*⁶⁹ have suggested that doses in excess of 1 mg/day may be required to prevent potential vitamin K deficiency-related complications.

Hemostatic complications of liver disease

Hepatic failure

Given the importance of the liver in the synthesis and clearance of components of the coagulant and fibrinolytic systems, it is not surprising that liver disease is often accompanied by abnormal hemostasis that contributes to both hemorrhage and thrombosis in affected individuals. Although the disease processes vary in neonates, children and adults, the pathophysiology of abnormal hemostasis is similar in these age groups.

Pathophysiology

Liver disease affects the procoagulant and anticoagulant pathways and the fibrinolytic system, and contributes to thrombocytopenia and impaired platelet function.^{70,71} As the liver is the main or sole site of synthesis of procoagulant proteins, liver failure will cause a progressive reduction in synthesis of these proteins, with the exception of FVIII, which is also produced by endothelial cells.⁷² The liver is also the site for the postribosomal carboxylation of the vitamin K-dependent proteins, this process being impaired in liver failure and resulting in dysfunctional FII, FVII, FIX, FX and proteins C, S and Z.

Plasma fibrinogen levels fall in acute hepatic failure, with increased consumption and clearance also thought to contribute to impaired synthesis. Dysfibrinogenemia is a common feature of acute and chronic liver failure, resulting from an increased number of sialic acid residues in the fibrinogen molecule and leading to impaired fibrin polymerization.^{73,74} All proteins of the fibrinolytic system except tPA and PAI-1 are synthesized in the liver and their plasma levels fall in liver failure. However, plasma tPA levels are increased in liver failure, with PAI-1 levels increased in acute but not chronic liver failure.^{75,76} Acute liver failure is therefore associated with a hypofibrinolytic state and chronic liver failure with a hyperfibrinolytic state.

Failure of the hepatic reticuloendothelial system to clear activated coagulation factors together with localized activation due to hepatocellular damage may result in DIC and a further impairment of hemostasis, though the presence of DIC in liver disease remains controversial.⁷⁷ Impaired protein synthesis also results in reduced plasma levels of the natural anticoagulants, which may contribute to thrombotic events in children with liver failure.

Thrombocytopenia of varying degree is common in liver disease and is multifactorial, its causes including splenic

sequestration, consumption and reduced platelet production. Platelet function is abnormal and results from a number of mechanisms, including impaired platelet signal transduction,⁷⁸ increased production of platelet inhibitors,⁷⁹ and defective platelet–vessel wall interaction.⁸⁰

Clinical features

The overall result of the hemostatic changes is a tendency toward a hemorrhagic state in children with liver failure. Spontaneous hemorrhage is relatively uncommon but bruising and hemorrhage following invasive procedures is common. Epistaxis can occur, as can hemorrhage from the gastrointestinal tract. Coagulation abnormalities exacerbate bleeding from varices or ulcers, which may be life-threatening. Diagnostic procedures such as liver biopsy can result in significant hemorrhage in patients with a coagulopathy,⁸¹ laboratory coagulation results alone being a poor predictor of bleeding in individual patients.

The extent to which the hemostatic systems are disturbed is related to the severity of hepatocellular damage that has resulted in liver failure. The PT is a sensitive marker of liver dysfunction and is the first screening test to become abnormal, reflecting a fall in plasma FVII levels, and is followed by decreases in the other vitamin K-dependent factors. More extensive damage leads to a reduction in nonvitamin K-dependent factors and a prolongation of the APTT. At this time, fibrinogen levels are usually normal or increased due to the acute-phase response. Increasing liver failure will result in a further fall in all procoagulants and natural anticoagulants, an increasing PT and APTT, falling fibrinogen levels and evidence of dysfibrinogenemia. Markers of thrombin and plasmin generation appear, such as TAT complexes and D-dimers. Thrombocytopenia is a common feature of liver failure, platelet counts usually ranging between 50 and $150 \times 10^9/L$.

Management

Apart from local measures, treatment is largely supportive in order to allow the liver to recover from the underlying insult or to enable the patient to undergo liver transplantation. Vitamin K supplementation should be administered. Blood product support should not be given unless the child is bleeding or requires an invasive procedure: in these circumstances FFP and cryoprecipitate can be used and platelet counts maintained above $50 \times 10^9/L$. Platelet increment and platelet survival are often reduced because of splenic sequestration, leading to increased requirements for platelet transfusion.

PCCs should be avoided where possible due to the increased risk of activation and thrombosis. Desmopressin has been used in patients with liver failure and coagulopathies, although its efficacy remains to be confirmed.⁸²

Recombinant activated FVII (rFVIIa, NovoSeven) has recently been successfully used to correct the PT and

maintain hemostasis in patients undergoing liver biopsy and there are increasing numbers of anecdotal reports of its use as adjuvant therapy to correct bleeding in patients with liver failure.^{83,84}

Liver transplantation

Orthotopic liver transplantation is often the only effective treatment for children with acute or chronic end-stage liver failure. The procedure itself may add to existing hemostatic defects and can result in severe hemorrhage or, less commonly, arterial or venous thrombosis.^{85–87}

Whereas bleeding during the first (preanhepatic) stage of the transplant is likely to be of surgical origin, hemorrhage in the second (anhepatic) stage of the transplant is associated with increased fibrinolysis secondary to the impaired clearance of tPA. A second burst of fibrinolysis then follows in the final (postanhepatic) stage following graft reperfusion, caused by increased tPA release from the graft endothelial cells. PAI-1 levels fall in the anhepatic stage and begin to normalize during the postanhepatic stage. Other processes that contribute to the hemostatic impairment include DIC, thrombocytopenia and the release of heparin-like factors from the graft.^{85,88}

Preoperative coagulation tests are poor predictors of bleeding during liver transplantation and intraoperative monitoring of hemostasis has therefore been widely used to rationalize the use of appropriate blood components and drug therapy during surgery. As well as blood counts and coagulation screening tests, thromboelastography has been used as an overall measure of both coagulation and fibrinolysis, though doubts remain as to its value in the absence of severe bleeding. Indeed, there are no well-defined evidence-based guidelines for the use of blood component therapy during liver transplantation, and conflicting evidence exists as to the value of intraoperative coagulation testing.^{89,90}

Antifibrinolytic therapy with tranexamic acid and aprotinin has been successful in reducing blood product support during surgery,^{91–94} although the use of such drugs continues to vary between different liver transplant centers.

The introduction of rFVIIa has been reported to have reduced hemorrhage and blood product requirements in liver transplantation though further studies involving randomized trials are required to support these findings.^{87,95,96} A large randomized and controlled study has shown that the use of rFVIIa during major liver resections has not influenced red cell transfusion requirement.⁹⁷

Following liver transplantation there is an increased risk of hepatic artery thrombosis, which occurs in 2–20% of transplant patients with children having a higher incidence of this complication than adults.⁹⁸ Thrombosis usually occurs 4–10 days after transplant, the mechanism involving a relative delay in the recovery of the natural anticoagulants compared with procoagulant proteins, resulting in a transient

prothrombotic state.^{99,100} Fulminant graft necrosis often occurs, and this is also seen in the less frequent complication of portal vein thrombosis.

Hemostatic complications of renal disease

Renal disease can have a significant effect on hemostasis and result in hemorrhage or thrombosis, depending on the disease mechanism involved. In addition, treatments such as dialysis and renal transplantation can also be associated with particular hemostatic impairment.¹⁰¹

Nephrotic syndrome

Proteinuria, hypoalbuminemia and edema remain the characteristic features of this syndrome. The association between thromboembolic disease and nephrotic syndrome is well recognized both in children and in adults, occurring in up to 35% of patients.^{102,103} Heavy proteinuria, membranous glomerulopathy and uncontrolled or refractory disease are risk factors for thrombosis; deep vein thrombosis, renal vein thrombosis and pulmonary embolus are the most frequent sites for thrombosis. Arterial thrombosis can also occur, though less frequently than venous disease.

A number of hemostatic defects occur in nephrotic syndrome and the etiology of thrombosis is demonstrably multifactorial.¹⁰⁴ Platelet aggregation and adhesion are increased, hyperfibrinogenemia is a constant finding and plasma antithrombin levels are reduced, with high levels of protein C often reported.^{101,105} Effects on fibrinolysis remain unclear, both hypofibrinolysis and hyperfibrinolysis having been observed.^{106,107} In addition, the contributory role of such factors as low-density lipoproteins requires further study.¹⁰⁸

Coagulation tests are not predictive of the risk of thromboembolism in nephrotic syndrome.¹⁰⁹ Heparin and warfarin are effective treatments for established thrombosis, with thrombolytic therapy being used infrequently.¹⁰³ Prophylactic anticoagulation has been proposed for high-risk nephrotic syndrome,¹¹⁰ this being continued until the resolution of proteinuria.

Chronic renal failure

Bleeding is a well-known complication of chronic renal failure (CRF) that caused significant morbidity and mortality prior to the introduction of renal dialysis.¹¹¹ However, CRF should also be regarded as a prothrombotic state, and numerous studies have been undertaken to determine the pathogenesis of bleeding and thrombosis in this condition.

Bleeding is often mild and mucosal in origin, although surgery and invasive procedures can result in excessive hemorrhage. The bleeding diathesis is mainly due to defective platelet function and impaired platelet–vessel wall

interaction, partly caused by uremic toxins.¹¹² Various and sometimes conflicting defects of platelet aggregation, adhesion and secretion have been described,^{113–115} as has impaired interaction of vWF and platelet glycoprotein IIb–IIIa. Plasma vWF levels are increased in uremia, and this increase may compensate for any intrinsic platelet defect(s). Production of prostacyclin and nitric oxide by the vascular endothelium are increased in CRF, further contributing to impaired platelet aggregation and adhesion.^{116,117} Activation of coagulation and fibrinolysis may also result in platelet dysfunction.^{115,118}

In the absence of heparin the characteristic coagulation abnormalities in uremic children are a prolonged bleeding time with a normal or mildly reduced platelet count and normal coagulation screening tests. The hematocrit affects the bleeding time and an increase in hematocrit by red cell transfusion or erythropoietin therapy may result in a partial improvement in this parameter.^{119,120} Desmopressin infusion and cryoprecipitate can result in temporary improvement in the bleeding time in some but not all patients with CRF.^{121,122} The efficacy of platelet transfusions in uremic bleeding remains unproven.

Although children with CRF are at risk of bleeding, uremia can also be considered a prothrombotic state and thrombosis is a significant cause of morbidity and mortality in such patients. Again, the etiology of thrombosis is multifactorial, with hyperfibrinogenemia, high levels of vWF, increased thrombin generation and reduced plasma levels of natural anticoagulants identified as risk factors.¹⁰¹ Increased platelet activation is seen with hemodialysis and can be considered a further contributory thrombophilic factor.^{123–125} It is possible that the platelet dysfunction in uremia compensates for this prothrombotic state, and that the correction of platelet function may then increase the potential risk of thrombosis. Warfarin remains effective treatment for established thrombosis in CRF.

Hemolytic–uremic syndrome

Hemolytic–uremic syndrome (HUS) comprises microangiopathic hemolytic anemia, thrombocytopenia and acute renal dysfunction. The severity of the syndrome is variable but it remains the commonest cause of acute renal failure in children. The commonest, epidemic form of HUS (D+) follows infection with verotoxin-producing organisms, over 90% of cases being due to *Escherichia coli* and typically presenting with a prodromal illness of acute diarrhea or bloody diarrhea.¹²⁶ Sporadic (D–) HUS is not associated with preceding diarrhea and occurs much less commonly in children, with an incidence of about 1 per million children in the UK. Various causes of this atypical form have been described including drug exposure, other infective organisms and complement factor H deficiency.¹²⁷

The pathogenesis of HUS is complex and follows injury to the renal endothelial cell and to circulating platelets.

Intravascular activation of coagulation occurs leading to fibrin deposition in the glomerular capillaries.^{128,129} Fibrinolysis is also activated, though an overall decrease in plasma fibrinolytic potential secondary to high PAI-1 levels has been reported.^{128,130} Platelet adhesion and aggregation are increased, and an imbalance in thromboxane and prostaglandin has been described.¹³¹ Plasma levels of vWF antigen are increased and multimeric analysis may be normal or abnormal.^{132,133} In contrast to thrombotic thrombocytopenic purpura, ADAMTS-13 (von Willebrand cleaving protease) deficiency has not been demonstrated in D+ HUS,^{134,135} confirming different pathogenetic mechanisms in these two conditions.

Routine hematology investigations show a microangiopathic anemia, with thrombocytopenia a consistent finding. Severe thrombocytopenia is unusual and in D+ HUS both anemia and thrombocytopenia are of short duration; prolonged thrombocytopenia (>10 days) is an adverse prognostic factor, as is a raised neutrophil count on presentation. Coagulation tests are usually normal, with D-dimer levels either normal or only mildly increased.

Treatment for D+ HUS remains largely supportive with no evidence to show that FFP or plasma exchange improves outcome. Blood transfusion should be given on clinical indication and platelet transfusion avoided whenever possible. The management of D- HUS is more controversial, with plasma infusion and plasma exchange being used in selected patients.¹²⁷

Cardiovascular-related hemostatic problems

Congenital heart disease

Conflicting data exist regarding the presence, mechanism and severity of hemostatic defects in children with congenital heart disease (CHD). The majority have been described in children with cyanotic CHD in association with secondary polycythemia.^{136–146} In a study of 41 children, Henriksson *et al.*¹³⁸ concluded that hemostatic defects were common in the presence of cyanotic CHD and frequently involved deficiencies of FV and the vitamin K-dependent factors II, VII, IX and X. The mechanism was postulated to be reduced hepatic synthesis due to hypoxia, as a consequence of high blood viscosity, and there was no evidence of activation of the coagulation system. Other studies suggest that the coagulation system is activated and that low-grade DIC contributes to the observed abnormalities.^{139,146}

In contrast, other investigators have demonstrated normal coagulation parameters in cyanotic CHD and it has been suggested that some of the previously documented abnormalities may have been artifactual due to failure to correct *in vitro* for the presence of polycythemia.^{143,146} In support of this, a recent prospective study of 22 children with both cyanotic

and acyanotic CHD failed to demonstrate any difference in baseline preoperative concentrations of procoagulant proteins and inhibitors when compared with age-related normal ranges.¹⁴⁷ However, there was an increase in baseline TAT complex levels, which has been confirmed in other studies analyzing TAT together with other sensitive markers of coagulation activation.^{148,149} This suggests that thrombin generation is increased in at least a proportion of patients but not to such an extent as to result in significant consumption of coagulation proteins.

Mild-to-moderate thrombocytopenia and abnormalities of platelet function have also been recorded in cyanotic CHD but again the mechanisms are poorly understood.^{139,142,145,150,151} Coagulation and platelet abnormalities appear less common in acyanotic CHD; however, Gill *et al.*¹⁵² demonstrated loss of high-molecular-weight multimers of vWF in children with a number of noncyanotic defects (atrial septal defect, ventricular septal defect and aortic stenosis), which normalized after successful cardiac surgery. Again, the mechanism is unclear but may involve platelet or endothelial cell activation.

In long-term follow-up of children who have undergone Fontan-type operations, variable coagulation defects have been reported including reduced levels of procoagulant and anticoagulant proteins.¹⁵³ These abnormalities are thought to occur as a consequence of abnormal hemodynamics resulting in subclinical hepatic dysfunction.

Noonan syndrome is a rare inherited disorder characterized by dysmorphic facies, CHD, short stature and a bleeding tendency. Various coagulation defects have been described in this condition, the most common being FXI deficiency although von Willebrand disease and abnormalities of platelet function are also reported. As yet the mechanism underlying this association in Noonan syndrome is not defined but may relate to the underlying disorder rather than the congenital heart defect.^{154,155}

Although children with CHD rarely have hemorrhagic problems in day-to-day life, they may be at increased risk of bleeding during surgery, which highlights the need to correct potential underlying hemostatic defects preoperatively.

Cardiopulmonary bypass surgery

Hemorrhage remains an important problem both during and after cardiopulmonary bypass (CPB) surgery in children and the etiology is likely to be multifactorial in virtually all cases. Contributing factors include hemodilution of procoagulant proteins, thrombocytopenia and platelet dysfunction, activation of the coagulation and fibrinolytic systems with DIC, and iatrogenic anticoagulant effects (Table 29.5).¹⁵⁶ Whereas platelet dysfunction is thought to be the most important factor in adults, hemodilution of procoagulant proteins and problems relating to anticoagulant monitoring are probably more important in children.^{157,158}

In one study, 22 children with CHD undergoing CPB had

Table 29.5 Causes of bleeding associated with cardiopulmonary bypass.

Preoperative coagulation defects
Hemodilution
Consumption (disseminated intravascular coagulation)
Thrombocytopenia
Platelet dysfunction
Heparin effects

samples collected for analysis of hemostatic proteins at various time points before, during and after bypass.¹⁴⁷ Significant hemodilution was demonstrated following initiation of CPB, with a reduction in the concentration of all hemostatic proteins by an average of 56% (range 50–70%). In some cases this resulted in reduction in procoagulant proteins to a level below that generally considered necessary for normal hemostasis. Although there was little further fall in levels during surgery, following completion of bypass the concentrations of certain procoagulants (FII, FV, FVII, FIX, FXI and FXII) remained significantly reduced 24 hours after the procedure. Platelet counts were also significantly reduced after bypass (mean $117 \times 10^9/L$; range $65\text{--}172 \times 10^9/L$).

Evidence of increased thrombin generation and increased fibrinolysis are also apparent during CPB and DIC may therefore contribute to hemorrhagic problems.^{147,148,159} As well as thrombocytopenia, qualitative platelet defects develop during CPB, resulting in prolongation of the bleeding time independent of the actual platelet count. Platelet dysfunction is thought to be due to platelet contact with the synthetic surfaces of the bypass circuit and the effects of hypothermia. These functional abnormalities develop soon after commencement of bypass and are progressive, such that after 2 hours on bypass the bleeding time may exceed 30 min.¹⁶⁰ However, this effect is transient and normalization is reported after 2–4 hours in adult studies.¹⁶⁰ The nature of the platelet function defect remains controversial and results in keeping with platelet activation, as well as abnormalities of platelet membrane glycoproteins, have been described.^{160–163} It has also been suggested that the problem may relate to an *in vivo* shortage of platelet agonists rather than to an actual intrinsic platelet defect.¹⁶⁴

Anticoagulation with heparin is an important part of the CBP procedure. Current protocols utilize unfractionated heparin monitored with the activated clotting time (ACT), aiming to maintain the ACT above a predefined level (usually >400–450 s). At the end of the bypass procedure, heparin is reversed using protamine sulfate. It is clear, however, that the ACT correlates poorly with actual heparin levels as assessed by anti-FXa assays and this may result in sub-optimal anticoagulant control in a significant number of cases.^{147,165} The response to heparin may also be affected by the reduction in antithrombin levels that occur during the bypass procedure.¹⁶⁶

Another potential complication of heparin therapy in this setting is heparin-induced thrombocytopenia (HIT). Although HIT appears less common in children than in adults, the incidence of this complication may be underestimated.^{167–169} Although HIT typically develops five or more days after the initiation of heparin therapy, the onset can be more rapid where there has been prior heparin exposure.¹⁷⁰ This typically occurs in children who have undergone cardiac catheterization prior to surgery or in those undergoing a second surgical procedure involving CPB. Paradoxically, patients with HIT are at increased risk of thromboembolic complications, which can be arterial or venous and are often life-threatening. Patients with HIT who develop thrombotic complications and those with a prior history of HIT who require further anticoagulation have been treated with a variety of agents, including danaparoid, hirudin and argatroban.^{167,171,172}

Bleeding in the context of CPB is often a multifactorial process and strategies aimed at the prevention and management of excessive bleeding need to take account of all the potential mechanisms involved. Correction of hemostatic defects with FFP, cryoprecipitate and platelets remains an important aspect of management, although there is no evidence base on which to recommend an optimal approach to replacement therapy. Adequate reversal of heparin with protamine sulfate following completion of CPB is also important. In addition, a number of other pharmacologic agents have been, or are currently in the process of being, investigated in an attempt to reduce perioperative and postoperative blood loss in this patient group. Recent interest has centered on the use of two agents, aprotinin and rFVIIa.

Aprotinin is a serine protease inhibitor that nonspecifically inhibits coagulation, fibrinolysis and complement activation.^{173,174} A number of studies have now been completed in children and although early results were conflicting, more recent studies have generally shown a beneficial effect using various different end points.^{174–176} In a large study published by Chauhan *et al.*,¹⁷⁵ 300 children with CHD were prospectively randomized to receive aprotinin plus ϵ -aminocaproic acid, ϵ -aminocaproic acid alone, or no treatment. Their results showed that all parameters, including blood loss at 24 hours and both red cell and platelet requirements, were improved in the aprotinin plus ϵ -aminocaproic acid group.¹⁷⁵ Questions remain regarding the optimal dose regimen and whether there is a benefit to adding an antifibrinolytic agent and these issues are the subject of ongoing studies.

rFVIIa (NovoSeven) is a hemostatic agent that was first developed for the treatment of hemophilia patients with inhibitors.¹⁷⁷ Following intravenous injection, rFVIIa enhances hemostasis by increasing thrombin generation on activated platelets. Preliminary data in small numbers of children with excessive bleeding following cardiac surgery have demonstrated potential benefits.^{178,179} Further randomized studies are now required to define the place of this agent in

the prevention and management of bleeding in this setting and to establish optimal dosing strategies.

Extracorporeal membrane oxygenation

Hemorrhage, particularly intracranial hemorrhage (ICH), is also a significant complication of extracorporeal membrane oxygenation (ECMO) and is an important predictor of outcome in this procedure.¹⁸⁰ ECMO facilitates the transfer of oxygen into blood across a semipermeable membrane and is used in a variety of conditions complicated by severe cardiorespiratory failure.¹⁸¹ As with CPB, the etiology of bleeding is probably multifactorial, with thrombocytopenia, platelet dysfunction, coagulation abnormalities and problems relating to anticoagulant control all contributing. ICH is more frequent in the neonatal age group, which may reflect additional problems relating to immaturity of the hemostatic system as well as problems related to cerebral blood flow.¹⁸²

McManus *et al.*¹⁸³ examined coagulation factors prior to and following the initiation of ECMO in 19 children and demonstrated the presence of preexisting coagulation defects (defined as reduced levels of two or more coagulation factors) in 68% of cases prior to ECMO. In addition, despite the use of coagulation factors in the circuit prime, which would be expected to compensate at least to some extent for the effect of hemodilution, 53% of patients had similar coagulation abnormalities after the start of ECMO. Four patients (three neonates and one older child) developed ICH and in this subgroup deficiencies in more than five coagulation factors were noted. McManus *et al.* concluded that a high proportion of cases have significant preexisting coagulation defects that are inadequately corrected by the circuit prime fluid at the onset of ECMO. Evidence of coagulation activation has also been demonstrated in term infants undergoing ECMO, particularly during the first 24 hours of the procedure; as with CPB, the ACT shows a poor correlation with actual heparin levels, which may increase the risk of both hemorrhagic and thrombotic problems.^{184–186}

Hemostatic complications of metabolic disease

Gaucher disease

Gaucher disease is an inherited autosomal recessive condition caused by a deficiency of the enzyme glucocerebrosidase, which results in accumulation of glucocerebroside in cells of the monocytes/macrophage system. Bleeding manifestations are common in such patients and are partly caused by thrombocytopenia due to splenomegaly but platelet function abnormalities have also been described.¹⁸⁷ In addition, low levels of several coagulation factors, including FII, FV, FVII, FX, FIX, FXI and FXII, have been reported with

prolonged PT and APTT values in 38% and 42% of patients, respectively.^{188,189} However, FXI deficiency in some cases may be an independent abnormality as both inherited FXI deficiency and Gaucher disease are common in Ashkenazi Jews.¹⁹⁰

Bleeding is generally mild despite the apparent severity of the coagulation abnormalities and in most cases correlates best with the degree of thrombocytopenia. The pathophysiology of the coagulopathy remains poorly understood but does not appear to reflect impaired synthesis due to hepatic dysfunction. The effect of enzyme replacement therapy with aglucerase also appears variable, with partial correction of the coagulation disturbance recorded by Hollak *et al.*¹⁸⁸ while Billet *et al.*¹⁹¹ did not find any effect.

Acquired inhibitors of coagulation

Acquired inhibitors of coagulation can be divided into those which inhibit specific coagulation factors (e.g., FVIII and FIX) and those which are nonspecific and interfere with other aspects of the coagulation cascade (e.g., lupus anticoagulants). Inhibitors characteristically prolong one or more of the coagulation screening tests, which will shorten as the plasma is serially diluted, rather than lengthen as happens in deficiency states.

Inhibitors of specific coagulation proteins

Factor VIII and factor IX inhibitors

Specific inhibitors are a well-recognized complication of replacement therapy in the management of congenital factor deficiencies and are most frequently seen in hemophilia A. FVIII and FIX inhibitors in children without hemophilia are uncommon but have been reported in a few cases sometimes in association with malignancy or possibly recent use of high-dose penicillin.^{192–195} The pattern of bleeding is variable, with some cases being diagnosed incidentally or in association with only mild-to-moderate bleeding symptoms, while others present with severe life-threatening hemorrhage.

Management of bleeding in children with acquired antibodies to FVIII or FIX is similar to that used for children with hemophilia who develop inhibitors and may involve the administration of high-dose FVIII or FIX; alternative therapies include porcine FVIII, PCCs or rFVIIa.^{196,197} Treatment aimed at the eradication of these antibodies may not always be required as some seem to disappear spontaneously. In cases where there are significant hemorrhagic problems, early introduction of immunosuppressive therapy with intravenous immunoglobulin may be beneficial. Steroids and cytotoxic agents (e.g., cyclophosphamide) have also been used successfully in some children with persisting antibodies, but may be associated with significant side-effects.^{192,195}

von Willebrand factor inhibitors

Acquired inhibitors to vWF are again extremely rare in children but have been reported in association with other autoantibodies and in children with Wilm tumor.^{198,199} Recognition of von Willebrand disease in Wilm tumor is important as some treatment protocols utilize early surgery. These antibodies usually disappear spontaneously following successful treatment of the tumor; however, in the event of treatment being required, desmopressin or replacement therapy with factor concentrate containing high-molecular-weight vWF multimers may be indicated.²⁰⁰

Factor V inhibitors

Acquired FV inhibitors in children have been most commonly reported following surgery in which fibrin sealant containing bovine thrombin has been used to improve hemostasis.^{201,202} Only occasionally have they been reported in other situations, typically following major surgery. The development of a FV inhibitor is characterized by prolongation of both the PT and APTT on routine postoperative coagulation monitoring which may be associated with excess bleeding. While many of these antibodies appear to be transient, reexposure to the same fibrin sealant product can result in the reappearance of the antibody and lead to severe hemorrhagic problems.²⁰²

When treatment is required due to acute bleeding, FFP is the only available source of FV but may result in problems with fluid overload. Alternative strategies include the use of plasmapheresis, high-dose intravenous immunoglobulin and rFVIIa.^{202,203}

Other inhibitors

Antibodies with specificity against FX, FXI and other contact factors have also been reported and can result in hemorrhagic problems but appear to be extremely rare in the pediatric age group.^{204–206}

Antiphospholipid antibodies

Antiphospholipid antibodies comprise a family of antibodies reactive with epitopes on proteins that are complexed to negatively charged phospholipid. They can be detected *in vitro* in solid-phase immunoassays, where they are generally called anticardiolipin antibodies, or in phospholipid-dependent coagulation tests, where the term “lupus anticoagulant” is usually applied. Lupus anticoagulants prolong phospholipid-dependent clotting assays, usually the APTT, which does not correct on mixing. To confirm that there is a lupus anticoagulant present, guidelines recommend a test such as the dilute Russell’s viper venom time with a platelet neutralization procedure.²⁰⁷

Although antiphospholipid antibodies can be associated

with increased thrombotic risk, they are detected incidentally in a significant proportion of healthy subjects and particularly in children. The thrombotic risk associated with such incidental antiphospholipid antibodies is relatively low,²⁰⁸ the antibody often being secondary to a viral infection that resolves spontaneously.^{209,210} Systemic lupus erythematosus (SLE) is rare in children but where it is associated with antiphospholipid antibodies, the risk of thrombosis is significantly increased. A positive test for lupus anticoagulant is more predictive of thrombosis than a positive test for anticardiolipin antibodies, increasing the risk of thrombosis 16- to 25-fold.²¹¹

A number of studies have examined the prevalence of antiphospholipid antibodies in children presenting with thrombosis who do not have SLE. Manco Johnson and Nuss²¹² found antiphospholipid antibodies in 19 of 78 (24%) children who presented with thrombosis at a single institution over a 7-year period. Only five fulfilled the necessary criteria for a diagnosis of SLE, while the other 14 were classified as having the antiphospholipid syndrome. The association of childhood thrombosis with antiphospholipid antibodies in the absence of SLE has been recognized in a number of other small case series and, in particular, it has been suggested that there may be a significant association with childhood stroke.^{213–217} Children with the antiphospholipid syndrome may also exhibit some of the other clinical features defined in adults with this condition, including chorea, livedo reticularis and thrombocytopenia.²¹⁸

With regard to management, standard anticoagulant protocols should be employed in the initial treatment of acute thrombotic events in children with antiphospholipid antibodies. The subsequent duration and intensity of warfarin therapy and the role, if any, of steroids and immunosuppressive agents in such patients remain uncertain.

Another syndrome that is now fairly well recognized is the association of a lupus anticoagulant with acquired protein S deficiency, resulting in DIC and purpura fulminans following varicella infection.²¹⁹ Autoantibodies to protein S result in a transient free protein S deficiency, probably as a result of increased clearance of protein S from the circulation. Fragment 1 + 2 levels are increased in keeping with DIC. Although most cases involve microvascular thrombosis and purpura fulminans, large-vessel thrombosis including deep vein thrombosis and stroke has also been reported. This is a rare condition and the optimal management strategy is not yet defined. Anticoagulant therapy with heparin has been used successfully in some cases but the use of protein S replacement therapy with FFP requires further evaluation to establish a beneficial effect.

Although the vast majority of children with clinically symptomatic antiphospholipid antibodies have thrombotic events, hemorrhagic problems are occasionally seen in association with the presence of a concomitant autoimmune thrombocytopenia or coagulation factor deficiency. In the

latter situation, the so-called hemorrhagic lupus anticoagulant syndrome has most commonly been observed in association with acquired hypoprothrombinemia.^{220,221} Typical features of this syndrome include the sudden onset of bleeding symptoms of variable severity in a child with no past history of bleeding problems, who may have had a recent viral infection. Laboratory studies show a prolonged APTT with evidence of a lupus anticoagulant and reduced prothrombin levels. The syndrome usually resolves spontaneously within 3 months and does not generally require treatment, although steroids have been given in some cases. In the presence of significant bleeding, the use of PCCs should be considered.

Bleeding in the neonate

Elizabeth A. Chalmers

Neonatal hemostasis: developmental aspects

Normal hemostasis reflects a highly complex process that is dependent on a series of interactions between hemostatic proteins, endothelial cells and platelets. The hemostatic system is profoundly influenced by age, and this is particularly apparent in the newborn period, when significant differences are observed compared with older children and adults. While many of these differences are quantitative, qualitative changes are also present, particularly with regard to platelet function. Despite what is often regarded as the functional immaturity of the hemostatic system at birth, the healthy term infant experiences few hemostatic problems. This contrasts with the situation in the sick preterm infant, where additional acquired abnormalities may rapidly alter the hemostatic balance, contributing to both hemorrhagic and thrombotic problems.

Normal coagulation data for fetuses and newborns

The unique nature of the neonatal hemostatic system necessitates the use of specific normal ranges for this age group. In addition, the hemostatic system during fetal and neonatal life is constantly changing as it evolves toward what we regard as a fully mature system, and sequential reference ranges are therefore required to take account of both the gestational and postnatal age of the infant. Such reference ranges not only provide information regarding the physiology of the neonate but are absolutely crucial for diagnostic and monitoring purposes.

The International Society for Thrombosis and Haemostasis (ISTH) Scientific and Standardisation Subcommittee on Neonatal Haemostasis has previously published recommendations regarding the establishment of normal ranges for neonates, which deal with various issues including the

selection of subjects for investigation, sample type, collection and storage, laboratory methodology and data analysis.¹ Nevertheless, research in this area remains difficult and data are not infrequently published based on cord blood sampling, which may not always reflect the situation in the neonate.

Based on the work of several authors, reference ranges have been published previously for most of the components of the coagulation system in both term and preterm infants at sequential stages of postnatal development.^{2–5} These include ranges for screening tests, procoagulant proteins, inhibitors of coagulation and proteins involved in fibrinolysis (Tables 30.1 and 30.2; see also Tables 37.6, 37.7, 37.32 and 37.33).

Much of these data were derived by Andrew *et al.*, who used a standard protocol whereby venous blood samples were obtained from healthy term and preterm infants (30–36 weeks gestation), all of whom had received 1 mg of intramuscular vitamin K at least 12 hours before the first blood sample. Standardized procedures were then followed for the collection, storage and analysis of these samples, which were obtained sequentially, at predetermined time points over a 6-month period.^{2–4} Although this still represents the most comprehensive set of published data for this age group, much of this work was performed in the late 1980s and early 1990s and does not therefore reflect current technology. As all reference ranges are both instrument and reagent dependent, ideally laboratories processing neonatal samples should derive at least limited in-house reference ranges, which may then be used in conjunction with published values to interpret results.

It has not been possible to establish ranges from an adequate number of healthy premature infants born at < 30 weeks gestation, and information relating to this period currently relies on the availability of samples obtained by fetoscopy. Reverdiau-Moalic *et al.*⁶ published data on 285 healthy fetuses analyzed between 19 and 38 weeks gestation and compared their results with a cohort of normal full-term neonates and an adult control group (Table 30.3). Fetal samples were obtained by direct puncture of the umbilical vein under ultrasound guidance. It is of interest that in the 30–38-week

Table 30.1 Reference values for the components of the fibrinolytic system in healthy full-term infants during the first 6 months of life compared with adult values. All values are given as a mean followed by the lower and upper boundary encompassing 95% of the population (in brackets).

Fibrinolytic component	Day 1 mean (boundary)	Day 5 mean (boundary)	Day 30 mean (boundary)	Day 90 mean (boundary)	Day 180 mean (boundary)	Adult mean (boundary)

PAI (unit/mL)	5.4 (0.0–12.2)* [†]	2.5 (0.0–7.1)*	4.3 (0.0–10.9)*	4.8 (1.0–11.8)	4.9 (1.0–10.2)* [†]	3.6 (0.0–11.0)

For explanation of abbreviations see footnotes for Table 30.1.

* Denotes values that are indistinguishable from those of the adult.

† Denotes values that are different from those of the full-term infant.

Reproduced with permission from Ref. 6.

gestation cohort, lower values were observed for the majority of the procoagulant proteins compared with the levels recorded in the study by Andrew *et al.*³ of preterm infants of equivalent gestation. One possible explanation for this apparent discrepancy is that the birth process itself may affect the coagulation system.

Coagulation proteins

Procoagulants

Coagulation proteins do not cross the placental barrier but are synthesized in the fetus from around the 10th week of gestation onwards.⁷ Both the absolute and relative concentrations of coagulation proteins in the neonate differ from adult values and are dependent to a varying extent on both the gestational and postnatal age of the infant (see Tables 37.6 and 37.32).

The vitamin K-dependent factors (II, VII, IX and X) are the most extensively studied of all the procoagulant proteins.

Mean levels in the term infant are around 50% of normal adult values and are variably reduced further in the premature infant. The postnatal maturation pattern is nonuniform, with factor VII (FVII) levels reaching the adult range by 5 days, while the other factors increase gradually over the first 6 months of life. Although within the normal adult range, mean levels remain reduced throughout infancy.

The four contact factors, XI, XII, prekallikrein (PK) and high-molecular-weight kininogen (HMWK), are reduced to around 30–50% of normal at term. HMWK increases rapidly, whereas the other factors show a more gradual increase. Analogous to the vitamin K-dependent factors, all four are within the adult range at 6 months, but average levels remain lower than comparative adult values.

Factor VIII (FVIII) levels on day 1 are indistinguishable from normal adult values and remain so throughout the neonatal period. von Willebrand factor (vWF) levels are increased at birth and although they decline slightly, remain high compared with adult values until around 3 months of age. The persistent elevation of vWF beyond the immediate

Table 30.3 Reference values for coagulation screening tests and coagulation factors in fetuses (19–38 weeks gestation), neonates and adults.

	Fetuses (weeks gestation)			Newborns (n = 60)	Adults (n = 40)

postnatal period suggests that its level is more than just a reactive response to the birth process. In addition, vWF, which is made up of a series of multimeric forms of differing molecular weights, is characterized in the neonatal period by an excess of unusually large multimers, which are not seen in older children or adults with pathologic states.^{8,9} These multimers appear to be functionally more active, as indicated by increased platelet aggregation in response to ristocetin.¹⁰ vWF collagen binding activity has also been shown to be increased in early neonatal life.¹¹

Mean levels of factor V (FV) are within the normal adult range at birth and show a further minor increase by day 5. Fibrinogen levels are normal in both term and preterm neonates. A transient increase in fibrinogen is observed at day 5 but thereafter levels are stable throughout the neonatal period. Fetal fibrinogen is not identical to adult fibrinogen, having an increased content of sialic acid, similar to the situation seen in patients with chronic liver disease. The functional significance of fetal fibrinogen is unknown; however, the thrombin clotting time (TCT) is normal provided calcium is included in the buffering system.¹² FXIII is 70% of normal at birth and increases to adult levels by day 5.

Many of the coagulation factors are gestationally dependent and are further reduced in the preterm infant.^{3,4} There is, however, evidence of an accelerated maturation pattern in

these infants, and levels of coagulation proteins are usually similar by 6 months of age.

Of the commonly used screening tests the prothrombin time (PT) is only minimally prolonged in the normal term infant and shortens within the first month of life (see Tables 37.6 and 37.32). This contrasts with the activated partial thromboplastin time (APTT), which can be markedly prolonged, particularly in the preterm infant. This is largely due to the reduced levels of contact factors, which have a disproportionate effect on APTT compared with FVIII and FIX. The normal range for the APTT is also significantly influenced by the choice of activating reagent.^{2,3} The TCT, as mentioned above, is normal if calcium is added to the buffering system; otherwise it is prolonged, reflecting the effect of fetal fibrinogen.

Inhibitors

The direct inhibitors of thrombin are antithrombin III (ATIII), heparin cofactor II (HCII) and α_2 -macroglobulin (α_2 -M). ATIII and HCII are around 50% of normal at birth and gradually increase thereafter to reach adult levels by around 3 and 6 months, respectively (see Tables 37.7 and 37.33). In contrast, α_2 -M is increased at birth and continues to rise postnatally: levels at 6 months are approximately twice normal adult values.

The indirect inhibitors, protein C and protein S, which are vitamin K dependent, are both reduced to < 50% of normal at birth, which parallels the reduction in the vitamin K-dependent procoagulants (see Tables 37.7 and 37.33). Although the concentration of each protein increases postnatally, the mean protein C concentration remains significantly reduced during infancy, and adult concentrations are not reached until the early teenage years. Protein C, like fibrinogen, circulates in a fetal form that is characterized by a relative increase in the proportion of the single-chain form compared with the double-chain form.^{13,14} This does not, however, appear to affect the function of the molecule. Protein S in adult plasma is normally present in both free and bound forms, with only the free form being active. The inactive bound form is complexed to the C4b-binding protein. C4b-binding protein is virtually absent in neonatal plasma and protein S therefore circulates entirely in its active free form.^{15,16}

Tissue factor pathway inhibitor (TFPI) or extrinsic pathway inhibitor (EPI) has not been as comprehensively investigated as the other naturally occurring coagulation inhibitors. Nevertheless, available data indicate that levels in cord plasma are reduced at birth to around 65% of adult values.^{17–19}

Effects on thrombin regulation

The results of a number of *in vitro* studies looking at thrombin regulation in neonatal and cord plasma have indicated that the capacity of neonatal plasma to generate thrombin is reduced to around 50% of adult values, which is analogous to the situation seen in an adult on therapeutic anticoagulant therapy.²⁰ In addition, Patel *et al.*²¹ have demonstrated that even when fibrin is formed, the activity of clot-bound thrombin from cord plasma is reduced compared with that from adult plasma. Both of these effects appear to be related to reduced levels of prothrombin. To what extent these *in vitro* thrombin generation assays mirror the situation *in vivo* remains open to debate. Thrombin generation assays based on coagulation activation via the extrinsic pathway using small amounts of lipidated tissue factor have been developed and are postulated to be more physiologic than conventional assays.²² Using this type of assay, Cvirn *et al.* have assessed thrombin generation using low levels of TFPI and anti-thrombin, and have demonstrated both an increased rate of thrombin generation and an increase in the total amount of thrombin generated, which suggests that thrombin generation in newborn plasma may be less impaired than previously thought.²³ This is also supported by data showing an absence of any defects on thromboelastography in healthy neonates.²⁴ While these results require further evaluation they do offer an explanation for the apparent adequacy of hemostasis despite low levels of procoagulant proteins.

Thrombin inhibition mediated by the direct thrombin inhibitors (ATIII, HCII and α_2 -M) is slower in neonatal plasma, but the overall capacity is similar to that seen in adults.²⁵ This

occurs despite the reduced levels of ATIII, which appear to be offset by the increased concentration of α_2 -M and increased thrombin binding to HCII.^{26–29}

These *in vitro* studies, although providing information on the overall capacity of neonatal plasma either to generate or inhibit thrombin, do not assess the extent to which thrombin generation is actually occurring *in vivo*. This can be quantified *in vivo* by measuring activation peptides, such as prothrombin fragment 1+2 (F1+2), fibrinopeptide A and thrombin–antithrombin (TAT) complexes, which are released at different stages of the coagulation process. Using these activation peptides as markers, it has been possible to demonstrate that the coagulation system is activated in the period immediately following delivery.^{25,30}

Fibrinolysis

The fibrinolytic system in the neonate, as with the coagulation system, can be regarded as physiologically immature, with the levels of all major fibrinolytic proteins showing age-dependent variation. The generation of plasmin from plasminogen is the most important step in the fibrinolytic system and is analogous to the generation of thrombin from prothrombin in the coagulation system.

Plasminogen is converted to plasmin by several activators, including tissue plasminogen activator (tPA) and urokinase plasminogen activator (uPA). The inhibitors of the fibrinolytic system include the plasminogen activator inhibitors, of which PAI-1 is the best characterized, and α_2 -antiplasmin (α_2 -AP), which acts directly on plasmin. α_2 -M can also inhibit plasmin but is less important than α_2 -AP.

Normal ranges for the major proteins involved in fibrinolysis have been published for both term and preterm infants (Tables 30.1 and 30.2).^{2–4,31} At birth plasminogen levels are around 50% of adult values in the term infant and slightly lower than this in preterm infants. Plasminogen remains reduced throughout the neonatal period, increasing toward normal adult levels by 6 months. Mean α_2 -AP levels are around 80% of normal at birth but neonatal and adult ranges do overlap. The levels of both tPA and PAI-1 appear to be transiently increased on day 1 of life in both term and preterm infants. These levels are higher than those documented in cord plasma and it is presumed that both tPA and PAI-1 are released from endothelial cells at the time of delivery.³²

As well as being reduced at birth, plasminogen is present in a “fetal” form. Fetal plasminogen has an increased concentration of sialic acid, similar to that found in fetal fibrinogen, and has also been shown to contain increased amounts of mannose. The physiologic significance of these differences from adult plasminogen are unclear. Summaria³³ failed to document any significant difference in the rate of plasmin generation in fetal and adult plasminogen. However, Edelberg *et al.*³⁴ documented both reduced functional activity and decreased binding to cellular receptors.

Various studies have demonstrated that the fibrinolytic system, like the coagulation system, is transiently activated at birth.^{35–38} Although activated, the overall rate of plasmin generation in neonatal plasma is reduced compared with adult values.³² This is thought to relate mainly to the reduced concentration of plasminogen; however, a contribution from a dysfunctional plasminogen molecule, as discussed above, cannot be completely ruled out.

The reduced ability to generate plasmin, theoretically at least, suggests that the neonate may have an impaired ability to lyse thrombi. What part this plays in the overall pathogenesis of thrombotic problems in the neonate is unknown. There are, however, important implications for the use of thrombolytic agents in the neonatal period, and it is clear from *in vitro* studies using fibrin clots derived from cord plasma that there is an impaired response to thrombolysis, which again appears to relate to the reduced concentration of plasminogen.^{39–41}

Platelets

Fetal platelet production is first observed toward the end of the first trimester, and platelet levels are usually within the normal adult range by the middle of the second trimester.^{42–45} Thrombocytopenia in both the term and preterm infant is therefore defined as a platelet count of $<150 \times 10^9/L$. The mean platelet volume (MPV) is also within the normal adult range at birth, although in one study the MPV was reported to be lower in preterm infants compared with term infants.^{46–48}

Thrombopoietin (Tpo) is known to be the most important regulator of platelet production in humans. Tpo and its receptor c-mpl can be detected in the human fetus in the early stages of fetal development.⁴⁹ Tpo mRNA transcripts have been detected as early as 6 weeks gestation, with the highest concentrations detected in fetal liver tissue.⁵⁰ Tpo levels in healthy nonthrombocytopenic term infants are reported to be higher than in nonthrombocytopenic adults.^{49,51}

Studies on platelet production have been hampered by difficulties in obtaining bone marrow samples to assess megakaryocyte numbers and function. Murray *et al.* have developed a novel assay system to study megakaryocyte precursor development in neonatal peripheral blood, and have shown that circulating megakaryocyte (MK) precursors measured in this assay reflect the bone marrow MK population. Using this assay it has been possible to define reference ranges for circulating MK precursors in healthy term neonates and also to show that preterm babies have increased numbers of circulating MK precursors.⁵²

Platelet function

Until relatively recently the investigation of neonatal platelet function was limited by sampling issues, and much of the available data were inconsistent and derived from the

analysis of cord blood. The recent development of new investigational tools has facilitated the analysis of blood samples from both term and preterm neonates, and new data are beginning to define both the characteristics and mechanisms involved in neonatal platelet function.^{53–55}

Platelet aggregometry is a well-established and widely used technique for the assessment of platelet function in all age groups. Unfortunately, aggregometry requires relatively large sample volumes, and there have been limited studies, particularly in preterm and very-low-birthweight (VLBW) infants, and results have not always been consistent. Nevertheless, data derived largely from studies using cord blood or samples from term neonates demonstrate that neonatal platelets are hyporesponsive to a number of specific agonists including adenosine diphosphate (ADP), epinephrine (adrenaline), collagen and thrombin.^{53–55} By contrast, the response to ristocetin is enhanced compared with adult platelets.

A number of mechanisms have been proposed to account for these responses. The reduced response to epinephrine is likely to be the result of reduced numbers of α_2 -adrenoceptors on neonatal platelets, while the response to collagen is thought to reflect impaired calcium mobilization. The enhanced ristocetin-induced aggregation reflects the high levels and increased activity of vWF in neonates.

Although the bleeding time remains the gold standard for assessment of the platelet–vessel wall interaction, it is a technique with significant limitations. Special templates are available for use in neonates, and using this device the bleeding time in the neonate is reported to be shorter than in adults.⁵⁶ It has been postulated that the shortened bleeding time reflects increased levels of vWF antigen and activity together with the increased red cell size and increased hematocrit. Bleeding times in VLBW infants have been reported to be longer than those of healthy term babies, and correlate with the presence of a low hemacocrit.⁵⁷

The use of the bleeding time in neonates will, however, be subject to the same limitations as in older age groups, namely lack of standardization, etc., and has not been shown to date to correlate with a bleeding risk.^{57,58}

The Platelet Function Analyzer-100 (PFA-100) is an *in vitro* method for the assessment of primary hemostasis. This assay utilizes citrated whole blood and measures the time taken for a platelet plug to occlude a standard aperture under conditions of high shear stress. Closure times can be assessed using membranes coated with collagen/epinephrine or collagen/ADP. Cord blood samples from term neonates have shorter closure times than samples from older children and adults, and therefore appear to correlate with reported bleeding times.^{59,60} These shorter closure times have been shown to correlate with increased vWF activity.⁶¹

The analysis of platelet function using whole-blood flow cytometry has a number of advantages over other techniques, in particular that the analysis can be carried out on very small sample volumes and is therefore very applicable to the

study of neonates. In a study performed on peripheral blood samples from 30 healthy neonates using whole-blood flow cytometry to look at platelet activation markers, Rajasekhar *et al.*⁶² demonstrated reduced reactivity to the agonists thrombin and ADP/epinephrine in both term and preterm neonates compared with adult platelets.⁶³ The issue of when neonatal hyporeactivity resolves is not well defined, with some authors describing normal function by day 10 while others have indicated that hyporesponsiveness may continue beyond the neonatal period.^{64,65}

Neonatal bleeding problems

Clinical considerations

Bleeding problems are commonly observed in neonatal practice, particularly in the neonatal intensive care unit (NICU) setting. Although the pathophysiology of these problems is often complex, hemostatic failure, due to either platelet abnormalities or a coagulopathy, may be causal or contributory in at least a proportion of cases. Thrombocytopenia is probably the most commonly observed cause of bleeding in this age group but coagulation defects are also common, and the two problems frequently coexist. Although the vast majority of hemostatic problems are likely to reflect acquired disorders, a number of relatively uncommon inherited conditions can also present at this time. Appropriate diagnosis and management of these conditions is highly dependent on prompt recognition of clinically abnormal bleeding and the initiation of appropriate investigations.

A number of clinical considerations are important in the investigation of a neonate who is bleeding and has a suspected underlying hemostatic problem. Foremost of these is probably the clinical setting in which the bleeding occurs.

Bleeding in an otherwise well term neonate is suggestive of an immune-mediated thrombocytopenia or an inherited coagulation disorder, whereas in a sick preterm neonate a nonimmune thrombocytopenia or a consumptive coagulopathy with disseminated intravascular coagulation (DIC) is more likely. Obstetric complications, and perinatal problems associated with delivery can also affect the hemostatic system resulting in coagulation activation and DIC. The presence of a family history of a bleeding disorder or of a previously affected infant can be an important diagnostic pointer. Finally, both maternal and neonatal drugs, particularly with regard to vitamin K metabolism, may be highly relevant at this time.

Laboratory investigations

Initial screening investigations usually comprise a full blood count and a baseline coagulation screen (PT, APTT, TCT and fibrinogen). Based on the pattern of abnormalities observed the results of these initial screening tests can then be used to guide the direction of additional investigations (Table 30.4). Where further investigation is required this may include specific factor assays, which as discussed previously must be interpreted using appropriate age-adjusted reference ranges. In certain circumstances more specialized techniques may be required to investigate for less common defects including abnormalities of platelet function.

Sampling problems are common in the newborn period and it is particularly important that samples for coagulation testing avoid contamination or activation prior to analysis. As discussed previously, the levels of many hemostatic proteins are low during the neonatal period, which affects routine screening tests, and it is therefore very important that these results are interpreted in conjunction with age-adjusted normal ranges. In addition, the high neonatal hematocrit

Table 30.4 Laboratory investigation of neonatal coagulation disorders.

	PT	APTT	Fibrinogen	Platelets	Diagnostic tests/ other useful tests
<i>Inherited disorders</i>

results in a minor degree of spurious prolongation of coagulation times, which may be relevant in polycythemic infants.

Inherited disorders of coagulation

Hemophilia A and B

Hemophilias A and B are inherited bleeding disorders that result from deficiencies of the procoagulant proteins FVIII and FIX, respectively. They are inherited as X-linked recessive disorders and together with von Willebrand disease (vWD) account for > 95% of all inherited bleeding disorders.⁶⁶ Current estimates of incidence of these disorders indicate that 1 in 10 000 males are affected by severe hemophilia A, and 1 in 50 000 males by severe hemophilia B.⁶⁷ Both FVIII and FIX play a crucial role in the activation of the coagulation cascade and result in clinically indistinguishable bleeding disorders of variable severity.

Hemophilia can be classified as severe, moderate or mild, based either on clinical bleeding criteria or on laboratory measurement of FVIII and FIX levels. Laboratory criteria have varied in different classifications, and in an effort to standardize this the Scientific Subcommittee of the ISTH have recommended revised criteria for the classification of hemophilia based on biologic FVIII:C and FIX:C levels, as follows.⁶⁸

- Severe hemophilia: FVIII/FIX level < 0.01 IU/mL (< 1% of normal).
- Moderate hemophilia: FVIII/FIX level 0.01–0.05 IU/mL (2–5% of normal).
- Mild hemophilia: FVIII/FIX level 0.05–0.40 IU/mL (5–40% of normal).

For the majority of patients, this classification should provide a good indication of the likely frequency and severity of bleeding episodes. However, issues persist regarding the ability of laboratories to satisfactorily classify patients, which reflects ongoing problems with the precision and accuracy of routine FVIII and FIX assays.⁶⁹

Clinical features

Hemophilias A and B are the commonest inherited bleeding disorders to present during the neonatal period.⁷⁰ A number of cohort studies have focused on the initial presentation of children with hemophilia and include data on the incidence of bleeding during the first month of life.^{71–74} Older studies suggest that bleeding in the neonatal period is a relatively infrequent event. In a large historical study published in 1966, Baehner and Strauss reviewed clinical data on 192 infants with hemophilia registered at a single center.⁷¹ In this study less than 10% of severely affected neonates and less than 2.5% of those with mild or moderate disease had a clinical event resulting in a diagnosis being made within the first month of life. Subsequent cohort studies from Sweden, North America

Table 30.5 Percentage of newborn infants diagnosed or presenting with bleeding during the first month of life.

Reference	Years	Number	Diagnosis	Bleeding
Baehner and Strauss ⁷¹	1952–1966	192	< 10%	5%
Ljung <i>et al.</i> ⁷²	1960–1987	140	52%	20%
Conway and Hilgarter ⁷³	1974–1989	56	68%	33%
Chambost <i>et al.</i> ⁷⁴	1980–1994	599	58%	15%*

* *De novo* cases only.

and France have recorded different results, with over 50% of neonates being diagnosed during the neonatal period and a much higher percentage than previously recorded having clinically significant bleeding (Table 30.5).^{72–74}

In a cohort of Swedish hemophiliacs diagnosed between 1960 and 1987, 28/140 (20%) were recorded as having abnormal bleeding in the immediate neonatal period (i.e., within 7 days of birth).^{72,75} In a similar study from North America, 68.4% of severe hemophiliacs were diagnosed within the first month of life, and in almost half of these cases the diagnosis was made after the initiation of appropriate investigations for abnormal bleeding.⁷³ Similarly, in a more recent French cohort study, 58% of cases were diagnosed neonatally and 15% of *de novo* cases had abnormal bleeding.⁷⁴

The higher incidence of reported bleeding compared with historic studies presumably reflects, at least in part, a greater awareness of the condition and improved recognition of abnormal bleeding symptoms but also suggests that previous figures underestimate the risk of bleeding at this time. One possible explanation for the particularly high incidence of bleeding in the North American cohort is the relatively frequent documentation of bleeding following circumcision, which was commonly carried out during the first few weeks of life during the period of this study.

The pattern of bleeding in neonates with hemophilia is different to that typically observed in older children, in whom muscle and joint bleeds predominate. Many neonatal bleeds are iatrogenic in origin, and continued oozing or excessive hematoma formation following venipuncture, heel stab sampling or the administration of intramuscular vitamin K are characteristic.^{71–74}

In a large retrospective review of the published literature Kulkarni and Lusher examined bleeding episodes reported in 349 newborns from a total of 66 publications.⁷⁶ Puncture bleeds accounted for 16% of the total, whereas joint bleeds were rarely observed (1%). Postsurgical bleeding, particularly following circumcision, was also common, occurring in 30% of reported cases. Umbilical bleeding, typical of fibrinogen and FXIII deficiency, is relatively uncommon in neonates with hemophilia. Other less common sites of bleeding include gastrointestinal hemorrhage and intraabdominal bleeding.^{77,78}

Fig. 30.1 Cephalhematoma in a 2-day-old infant with severe hemophilia A.

Cranial bleeding, which includes both intracranial hemorrhage (ICH) and extracranial hemorrhage (ECH), is potentially the most serious bleeding manifestation observed in the neonatal period and accounted for 41% of all reported bleeding episodes in the literature review of Kulkarni and Lusher. Despite the apparently frequent reporting of this complication the actual incidence of cranial bleeding is not well defined. In a second literature review covering 1964–1996, Kulkarni and Lusher identified 102 neonates with cranial bleeds and hemophilia in a total of 33 publications.⁷⁹ From a subgroup of five larger studies these authors calculated a cumulative incidence of cranial hemorrhage of 3.58%. There was, however, considerable variation in the incidence of bleeding between these studies, which included both retrospective and clinical trial data, and were therefore potentially subject to bias. Definition of the true incidence of cranial bleeding will thus require further large prospective cohort studies.

In the survey by Kulkarni and Lusher, ICH was more common than ECH and subdural hemorrhage was the most frequently observed site.⁷⁹ The mean age at diagnosis was 4.5 days, and although the majority of reported cases were severe hemophiliacs, bleeding also occurred in moderate and mildly affected cases. While the presentation of cranial bleeding in this age group may be acute and dramatic, clinical features may equally be subtle and nonspecific. ICH may present with seizures and focal neurologic signs or simply with lethargy, poor feeding or vomiting. ECH due to subgaleal

bleeding or cephalhematoma formation (Fig. 30.1) can also be potentially life-threatening, usually due to massive blood loss although cerebral compression has also been reported.^{80–82}

The outcome of cranial bleeding is not always adequately recorded but it is clear that a significant proportion of cases go on to develop long-term sequelae with neurodevelopmental problems. In their literature review of cranial bleeding, Kulkarni and Lusher found that overall mortality was 7% with long-term morbidity of 38%, but outcome data were only recorded in 28 cases.⁷⁹ In a survey of 30 cases of ICH in children with hemophilia, which included 11 neonates, psychomotor retardation and cerebral palsy were reported in 59% and neonates appeared to show a poorer outcome than older children.⁸³ It has also been reported that some of these cases may be at risk of recurrent ICH.⁸⁰

Perinatal management

Current opinion on the management of a known or suspected carrier of hemophilia suggests that if the fetus is male, the initial approach to delivery should be governed by obstetric factors and that there is no contraindication to vaginal delivery.^{46,55,56,72,84} This is generally followed by advice regarding the avoidance of instrumental delivery (i.e., forceps, vacuum extraction and the use of scalp electrodes), and early recourse to cesarean delivery is recommended where there is a failure of labor to progress. A survey of obstetric practice in North America has indicated that these recommendations do largely reflect current practice, which is also likely to be the case in the UK.⁸⁵ It is also usually advised that a cord blood sample is obtained for diagnostic purposes and that intramuscular (i.m.) vitamin K prophylaxis is withheld until hemophilia is excluded.^{76,86} If a neonate is shown to have hemophilia vitamin K should be given via an oral regimen.

Diagnosis

On baseline coagulation screening both hemophilia A and B typically result in an isolated prolongation of the APTT, which in an otherwise healthy male infant is highly suggestive of the diagnosis (Table 30.4). Confirmation of the diagnosis requires measurement of FVIII and FIX levels respectively. As FVIII levels are within the normal adult range or mildly increased at birth it is usually possible to confirm a diagnosis of hemophilia A regardless of the severity of the condition or the gestational age of the infant. The only exception to this is mild hemophilia A, where an initial result at the lower end of normal may warrant repeat screening when the infant is older.

The same is not true of hemophilia B, where levels of FIX, as with all vitamin K-dependent factors, are reduced at birth and are further reduced in preterm infants. It is therefore possible to make a diagnosis of severe and moderate hemophilia B at birth but confirmation of mildly affected cases is

problematic due to overlap with the normal range, necessitating repeat testing at around 6 months of age or molecular analysis if the genetic defect in the family is known.

It is estimated that in up to one-third of newly diagnosed hemophiliacs a positive family history of hemophilia will be lacking.^{71,73} Many of these cases arise as a consequence of a new mutation affecting either the male propositus or more often a female carrier in whom there may be no personal history of bleeding problems. Even where there is a positive family history of hemophilia, published data suggest that women are not always aware of their carrier status, which may have an impact on both their management and the timing of investigations of a potentially affected child.^{73,87}

In the absence of a positive family history the diagnosis of hemophilia may go unsuspected in the neonatal period. It is therefore important that neonates presenting with signs of abnormal bleeding are appropriately investigated for the presence of inherited bleeding disorders including hemophilia, and that these investigations include not only baseline coagulation screening tests (PT, APTT), but also appropriate factor assays.

Published case reports both in the past and more recently suggest that there is often a failure to recognize abnormal bleeding and that appropriate investigations are often delayed or misinterpreted, which inevitably results in a failure to manage such cases appropriately.^{80,88} In a series of eight cases of intracranial hemorrhage published by Yoff and Buchanan in 1988, the diagnosis of hemophilia was delayed in six cases, sometimes for a period of several months.⁸⁰ Similarly, Myles *et al.* in 2001 reported two infants presenting with intracranial hemorrhage in whom neurosurgery was undertaken before a definitive diagnosis was reached.⁸⁸ Occasionally, the diagnosis can be further confused by the coexistence of an acquired coagulopathy, for example DIC or vitamin K deficiency.⁸⁹

Neonatal management

In the developed world recombinant FVIII and FIX products are now the treatment of choice for infants with hemophilia. Where recombinant products are not available a high-purity, plasma-derived product may be used instead. Recombinant FVIII concentrates can be subdivided into first-, second- and third-generation products, which differ in terms of the presence or absence of human and animal proteins in the manufacturing process and in the final product.⁹⁰ There remains only a single commercially available recombinant FIX concentrate, which contains no human or animal proteins in the final product. There are only limited data available on the pharmacokinetics of replacement therapy in neonates, which suggests that the half-life of FVIII may be less than in older children.⁹¹ Careful monitoring is therefore recommended where replacement therapy is required.

The use of cranial ultrasound scanning to detect early intracranial hemorrhage and the administration of short-term

primary prophylaxis to minimize bleeding related to birth trauma are two aspects of neonatal hemophilia management that remain controversial.⁹² Recent surveys in both the UK and North America have reported significant variations in practice in this area, which reflects the uncertainties and the lack of evidence-based guidelines.^{93,94}

von Willebrand disease

vWD is the commonest inherited bleeding disorder, with an estimated prevalence of 0.8–1.3%.^{95,96} vWD is caused by either a quantitative or qualitative deficiency of von Willebrand factor (vWF). In most families vWD is inherited as an autosomal dominant disorder and the bleeding tendency is usually mild. vWF is physiologically increased in the neonatal period and high-molecular-weight multimeric forms are also disproportionately increased at this time.⁸

Clinical features

Due to the protective effect of physiologically raised levels of vWF, bleeding in the neonatal period secondary to vWD is a relatively uncommon event. Nevertheless bleeding may occur, particularly in severe type III disease and in some cases of type II vWD. Bleeding in type II vWD may occur in association with thrombocytopenia in the type IIb subgroup.^{97,98} Both superficial bleeding problems and ICH have been reported in affected neonates.⁹⁹

Diagnosis

Type III vWD is confirmed by recording low or virtually absent levels of both FVIII and vWF antigen and activity. Some cases of type II vWD may also be diagnosed in the neonate where there is reduced vWF activity. Type IIb vWD can also be recognized at this time due to the presence of thrombocytopenia, and should be included in the differential diagnosis of congenital thrombocytopenia.^{97,98} Most other forms of vWD are masked by physiologically elevated levels of vWF and cannot be diagnosed neonatally other than by molecular analysis. In most cases where there is a family history of mild type IV vWD, screening can be delayed until around 6 months of age.⁸⁶

Management

Current guidelines on the treatment of bleeding in vWD recommend the use of a viridically treated FVIII concentrate that contains both FVIII and vWF.^{90,99,100} Recombinant vWF has been developed but clinical trials have not been completed.¹⁰¹ The use of desmopressin (DDAVP) should be avoided in the neonatal period due to the risk of hyponatremia.⁸⁶ Platelets may also be required in the management of bleeding in type IIb disease.

Rare inherited bleeding disorders

The rare inherited bleeding disorders comprise a group of recessively inherited conditions that include deficiencies of FI (fibrinogen), FII (prothrombin), FV, FVII, FX, FXI, FXIII and the combined deficiencies of FV/FVIII and of FII/FVII/FIX and FX. All of these disorders are extremely rare and the reported prevalence of homozygous defects ranges from around 1 in 500 000 for FVII deficiency to 1 in 2 million for FII (prothrombin) deficiency.¹⁰² The pattern of inheritance is autosomal recessive, and clinical manifestations are most severe in homozygous or compound heterozygous states. Due to the mode of inheritance these disorders are more frequently observed in countries where consanguineous marriage is common.

The rarity of these conditions has meant that information on the most common bleeding manifestations and on optimal management strategies has lagged behind that for the more common inherited bleeding disorders. In recent years data, mainly from Iran and Italy, have expanded our knowledge of these conditions, and more recently preliminary data have also been published from a North American Registry.^{102–104} In addition, significant advances have been made in our understanding of the genetic abnormalities that underlie these disorders.¹⁰⁵

Disorders of fibrinogen

Congenital abnormalities of fibrinogen reflect both quantitative and qualitative defects. These include afibrinogenemia, hypofibrinogenemia and the dysfibrinogenemias.¹⁰⁶ Both afibrinogenemia and hypofibrinogenemia are inherited as autosomal recessive disorders, and the estimated prevalence of afibrinogenemia is 1 in 1 million.¹⁰² Afibrinogenemia and the more severe forms of hypofibrinogenemia may present neonatally. Bleeding from the umbilical cord is the most frequently reported problem, but mucosal bleeding may also occur.^{104,107,108} ICH is described in afibrinogenemia, but the age of onset in these reports is unclear.^{107,108}

The dysfibrinogenemias are a heterogeneous group of disorders, which unlike most of the other rare disorders are inherited in an autosomal dominant manner. Clinically they may be asymptomatic or associated with either hemorrhagic or thrombotic problems, and are unlikely to present in the neonatal period although they may be diagnosed at this time due to the presence of a family history or following investigation of an abnormal coagulation result.

Diagnosis

Fibrinogen levels are within the normal adult range at birth.^{2,3} In afibrinogenemia the PT, APTT and TCT are

markedly prolonged and fibrinogen levels are undetectable using both functional (Claus) and antigenic assays.¹⁰⁹ In hypofibrinogenemia the PT, APTT and TCT are prolonged in proportion to the fibrinogen level, which is usually in the range 0.20–0.80 g/L. The TCT is the most sensitive screening test for dysfibrinogenemias and characteristically the fibrinogen level is higher using an antigenic assay.¹⁰⁹

Management

Fibrinogen concentrate is now generally recommended as the treatment of choice for the management of bleeding in afibrinogenemia and hypofibrinogenemia, and a number of viricidally inactivated concentrates are available.^{90,110} A fibrinogen level of 0.5 g/L is thought to represent the minimum level for hemostasis but it is usually suggested that fibrinogen levels are increased to 1 g/L in order to secure hemostasis in the bleeding patient.¹¹⁰ Fibrinogen has a half-life of 3–5 days, which facilitates relatively infrequent dosing. In the absence of fibrinogen concentrate, cryoprecipitate and fresh frozen plasma (FFP) provide alternative sources of fibrinogen. Fibrin glue and antifibrinolytic medication may also be helpful.

Primary prophylaxis in afibrinogenemia is not generally advised due to the paucity of data. In the event of severe bleeding (e.g., ICH), secondary prophylaxis with the aim of maintaining a fibrinogen level of above 0.5 g/L is thought to be appropriate.¹¹⁰

Deficiencies of FII, FV, FVII, FX, FXI and combined FV/FVIII deficiency

Bleeding manifestations have been recorded in the neonatal period in each of these disorders, both in individual case reports and in the larger case series reported from Iran and other groups.^{102–104} The pattern of bleeding observed includes umbilical hemorrhage, bleeding post-circumcision, soft-tissue hematomas, gastrointestinal bleeding and ICH.¹⁰² Umbilical bleeding, which is an uncommon manifestation in hemophilia, was documented in 0–28% of cases in the Iranian series and was most commonly seen in cases of FX deficiency (28%) and combined FV/FVIII deficiency (22%).

Severe bleeding manifestations, particularly ICH, appear most common in association with FVII and FX deficiency. In one series, 12/75 (9%) infants with FVII deficiency had ICH; however, this very high incidence has not been confirmed in other series.^{102,103,111,112} In the Iranian series, FX deficiency was associated with the most severe bleeding symptoms and the highest frequency of ICH.¹⁰² In FV deficiency, bleeding manifestations do not always correlate well with the plasma FV level and may depend more on platelet FV levels. Similarly a poor correlation between clinical bleeding and

plasma factor levels has also been recorded in FVII and FXI deficiency.

Diagnosis

Compared with adult values, plasma levels of factors II, VII, X and XI are all reduced at term and are further reduced in the preterm infant. Thus while it will be possible to diagnose the most severe deficiency states in the newborn period, infants with higher levels may require follow-up testing in order to clarify the diagnosis. Similarly it is not usually possible to diagnose heterozygous deficiencies in the newborn period. This contrasts with FV, which is within the normal adult range at birth, so it should be possible to diagnose both heterozygous and homozygous deficiencies at birth.

Management

Treatment of bleeding episodes should be with a specific factor concentrate if available (e.g., FVII and FXI), or with prothrombin complex concentrate (PCC) (e.g., FII and FX) or fresh frozen plasma (FFP).¹¹⁰ FXI concentrate and PCC should be used with care in the neonatal period because of the risk of coagulation activation with these products. Recombinant FVIIa has been used as an alternative to plasma-derived FVII for the treatment of inherited FVII deficiency.¹¹³ In the absence of factor concentrates or where their use is considered inappropriate, consideration should also be given to the use of viridically treated FFP if available.

Factor XIII deficiency

FXIII, or fibrin-stabilizing factor, is the final enzyme to be activated in the coagulation cascade and is responsible for cross-linking fibrin.¹¹⁴ Congenital deficiency of FXIII is a rare autosomal recessive disease. The homozygous form was initially described in 1960 and the estimated prevalence of this disorder is 1 in 1 000 000.¹⁰² The condition results in a moderate-to-severe bleeding disorder associated in some cases with defective wound healing.

Clinical features

Infants with severe homozygous FXIII deficiency in which the FXIII level is < 1 IU/dL, are at greatest risk of bleeding problems and classically present in the neonatal period with delayed bleeding from the umbilical cord, which is reported in up to 80% of cases.^{115,116} The time to presentation ranges from 1 to 19 days. Although characteristic, this pattern of bleeding is not pathognomonic, as around 50% of neonates with afibrinogenemia and other rare disorders also present in this way. Bleeding following circumcision and ICH has also

been recorded. The risk of ICH is lifelong and occurs in up to a third of untreated patients.

Diagnosis

FXIII deficiency does not prolong any of the routine screening tests and must be investigated specifically. The urea solubility test is a useful screening test for severe homozygous deficiency states but will not detect mild deficiencies or heterozygotes. The diagnosis is confirmed by measuring FXIII activity levels.

Management

Neonates diagnosed with FXIII deficiency with levels of < 3 IU/dL should be commenced on a prophylactic replacement regimen, preferably using a viridically treated FXIII concentrate. Initially a dose of 10 IU/kg every 4 weeks should be adequate, and subsequent monitoring should be performed in order to maintain a pretreatment trough level of > 3 IU/dL.^{110,117} If FXIII concentrate is not available, cryoprecipitate or FFP can also be used.

Combined deficiency of vitamin K-dependent coagulation factors

Hereditary combined deficiency of the vitamin K-dependent coagulation factors is an extremely rare autosomal recessive bleeding disorder, which has been described in < 20 kindreds worldwide. The condition is due to mutations affecting either the γ -glutamyl carboxylase enzyme or the vitamin K epoxide reductase enzyme complex (VKOR).^{118,119} These defects result in the secretion of inadequately carboxylated FII, FVII, FIX and FX, which as a consequence have poor hemostatic function. Failure of γ -carboxylation also affects a number of other proteins including protein C, protein S, protein Z, osteocalcin, the matrix Gla protein, and the growth arrest specific protein.

Clinically the condition is associated with a variable bleeding phenotype. In severely affected individuals the onset of bleeding may be in the neonatal period, and bleeding from the umbilical stump and ICH have both been reported.^{118,119} Skeletal abnormalities, similar to those reported in association with warfarin-induced embryopathy, are also reported.¹²⁰

In affected individuals both the PT and APTT are typically prolonged in association with a variable reduction in the activity levels of the vitamin K-dependent coagulation factors. The condition must be distinguished from acquired vitamin K deficiency, and measurement of fasting serum vitamin K may be helpful. Molecular studies may also be useful.

Some individuals will show partial or complete improvement in factor levels following the administration of vitamin K. Vitamin K is therefore indicated in all cases at diagnosis, and ongoing vitamin K prophylaxis may be required to prevent

bleeding.¹²¹ In those who are unresponsive to vitamin K or in the presence of bleeding, factor replacement may be required. Both FFP and factor concentrates have been used in the management of such cases. As before, the use of viridically inactivated products is usually advised.

Acquired disorders of coagulation

Disseminated intravascular coagulation

The term “disseminated intravascular coagulation” is used to describe an acquired disorder that involves abnormal thrombin generation and always occurs as a secondary event to another disease entity. DIC is common during the neonatal period, particularly in preterm and VLBW infants.¹²² DIC in the neonatal period may occur as a consequence of both fetal and neonatal disorders and is also seen in association with certain obstetric complications (Table 30.6). As in older children and adults, DIC is often associated with increased mortality.

Pathophysiology

Although DIC is often seen as a hemostatic disorder, activation of coagulation with increased and abnormal thrombin generation is only part of a complex process that involves inflammatory pathways as well as endothelial cell activation and dysfunction.¹²³ Failure to regulate this process results in massive uncontrolled thrombin generation, with widespread fibrin deposition and consumption of coagulation proteins and platelets. This is discussed in more detail in Chapter 29.

Table 30.6 Conditions associated with neonatal disseminated intravascular coagulation.

Fetal/Neonatal disorders

Hypoxia–acidosis: birth asphyxia, respiratory distress syndrome
Infection
Meconium aspiration
Aspiration of amniotic fluid
Necrotizing enterocolitis
Brain injury
Hypothermia
Hemolysis
Giant hemangioma (Kasabach–Merritt syndrome)
Homozygous protein C/S deficiency
Malignancy

Maternal/obstetric disorders

Severe preeclampsia
Placental abruption
Intrauterine death

Clinical features

The clinical spectrum of neonatal DIC varies greatly from low-grade subclinical DIC to fulminant DIC with bleeding and thrombosis. Superficial bruising, purpura and iatrogenic bleeding from venipuncture and central line insertion sites are relatively common. More serious hemorrhagic problems can also occur, and both pulmonary and intraventricular hemorrhage in preterm infants may be exacerbated by the presence of thrombocytopenia and an uncompensated coagulopathy. Where there is extensive large vessel and microvascular thrombosis this may contribute to end-organ damage and multiorgan failure.

Diagnosis

The diagnosis of fulminant neonatal DIC is usually fairly straightforward and is characterized by prolongation of routine coagulation screening tests (PT, APTT and TCT), combined with thrombocytopenia and evidence of increased fibrin(ogen) degradation products (FDPs) (Table 30.4). Examination of a peripheral blood film may also reveal the presence of red cell fragmentation.

A normal coagulation screen does not, however, exclude the presence of a consumptive coagulopathy. This reflects the wide clinical spectrum of DIC, and early nonovert DIC may be more difficult to diagnose, particularly in the neonatal period.¹²⁴ With the development of new therapeutic modalities early diagnosis of DIC may become increasingly important, and in adult practice this has led to the development of diagnostic algorithms for the detection of early nonovert DIC.¹²⁵

The platelet count is almost universally reduced in DIC and has been found to be a useful predictor of a coagulopathy in high-risk neonates.¹²⁶ Thrombocytopenia is, however, extremely common in neonatal practice and is often due to failure of production rather than consumption. The PT and APTT are less predictive and can be normal in early DIC.¹²⁴ Prolongation of the TCT, which reflects both reduced fibrinogen and the effect of increased FDPs, is again often absent in the early stages.

Evidence of increased fibrin degradation is an important component of the diagnosis of DIC. The D-dimer assay, which measures fragments generated following digestion of fibrin, is now used routinely in many laboratories as a measure of FDPs.¹²⁷ D-dimer levels should, however, be interpreted with caution in the neonatal period because raised levels have been found in both term and preterm infants and may initially reflect a degree of coagulation activation at birth.¹²⁸

Although not routinely performed for diagnostic purposes, reduced levels of procoagulant proteins and inhibitors, especially ATIII and protein C, can be observed in high-risk

infants, a proportion of which will go on to develop overt DIC.^{129,130} El Beshlawy *et al.* demonstrated reduced levels of AT, protein C and protein S in 100% of neonates with hypoxic-ischemic damage, 50% of whom went on to develop overt DIC.¹²⁹

Management

DIC is a secondary phenomenon and it therefore follows that an important aspect of management is reversal of the underlying disease process. In the critically ill preterm infant this may be difficult to achieve; however, failure to remove the underlying procoagulant stimulus will result in ongoing uncontrolled thrombin generation. Beyond this, evidence-based guidelines for other specific treatment modalities are currently lacking and reflect the difficulty of conducting randomized controlled trials in this area.

Currently there is considerable interest in the use of activated protein C for the management of DIC associated with severe sepsis. Recombinant activated protein C (drotrecogin alfa [activated]) has already been shown to be beneficial in the management of severe sepsis in adults.¹³¹ Activated protein C limits thrombin generation via degradation of the coagulation cofactors FVa and FVIIIa and also has profibrinolytic and antiinflammatory effects. Data on the use of this agent in pediatric practice are currently limited to case reports and a single phase 3 study, which included only five children under one year of age.^{132,133} The latter study did, however, provide preliminary data on safety and pharmacokinetics and was able to demonstrate a reduction in the level of D-dimers and an increase in both AT and protein C following treatment.¹³³ Further placebo-controlled trials addressing the efficacy of this novel agent in children are currently ongoing.

Supportive therapy with FFP, cryoprecipitate and platelets to maintain adequate hemostasis remains an important aspect of the management of this condition. Although the use of blood products and the thresholds set for transfusion are largely empirical, it would appear reasonable to institute replacement therapy, particularly where there is an increased risk of bleeding. Guidelines for the transfusion of platelets suggest that the platelet count should be maintained above $50 \times 10^9/L$ by the transfusion of platelet concentrates (10–15 mL/kg).¹³⁴ FFP (10–15 mL/kg) can be used to replace hemostatic proteins, including the coagulation inhibitors ATIII, protein C and protein S.⁸⁶ Cryoprecipitate (5–10 mL/kg) is a better source of fibrinogen, which should be maintained above 1 g/L. PCCs, although used in the past, are not currently indicated due to the risks of further coagulation activation and thrombosis. Red cell concentrates are also frequently required, and exchange transfusion may be indicated to avoid problems from volume overload.

Studies looking at the efficacy of blood product replacement

therapy in neonatal DIC have yielded conflicting results.^{135–138} In one small controlled study 33 neonates with DIC were randomized to receive either exchange transfusion, FFP and platelets, or no therapy directed specifically at the coagulopathy, but the results failed to demonstrate any difference in either the resolution of DIC or in survival.¹³⁸ Other studies have shown improvement in coagulation profiles and variable improvement in clinical outcome.^{135–137} In a recent study Hyttianen¹³⁹ demonstrated reduced thrombin generation in a group of neonates following the administration of FFP but the effect on clinical outcome was not reported.

Experimental data from animal studies support the use of both heparin and ATIII concentrates in the treatment of DIC.^{140,141} There are, however, only limited data on the use of heparin in neonates with DIC.¹⁴² Gobel *et al.* reported a reduction in the duration of ventilation in a group of neonates with DIC and respiratory distress syndrome treated with heparin compared with placebo but the results were not statistically significant and there was no difference in mortality.¹⁴² ATIII levels are reduced in the neonatal period and are further reduced in the presence of DIC. Because the effectiveness of heparin depends on adequate levels of ATIII it has been postulated that the administration of heparin plus ATIII might be more efficacious than heparin alone. Again, there are few published data on the use of ATIII with heparin in the pediatric age group, with only one small nonrandomized study dealing exclusively with neonates, which failed to document any major benefit. Therefore, neither heparin nor ATIII, alone or in combination, are currently recommended for the routine treatment of neonatal DIC.¹⁴³

Vitamin K deficiency bleeding

The clinical features of hemorrhagic disease of the newborn (HDN) were first described by Townsend in 1894,¹⁴⁴ but it was only some years later that the link with vitamin K deficiency was established. The term HDN has now been replaced by vitamin K deficiency bleeding (VKDB), which highlights the fact that bleeding in the newborn may be due to causes other than vitamin K deficiency and that VKDB may occur beyond the neonatal period.¹⁴⁵ For further information on vitamin K see Chapter 29.

Pathophysiology of VKDB

Levels of the vitamin K-dependent coagulation proteins are physiologically reduced at birth and are functionally inactive in the presence of vitamin K deficiency.² In the absence of vitamin K prophylaxis, prothrombin activity has been shown to decrease on days 2–4 of life.¹⁴⁶ The tendency of the neonate to become vitamin K deficient is in part due to the limited stores available at birth. The neonate has a very small hepatic reserve of vitamin K, stored almost exclusively as vitamin K₁.

Circulating vitamin K levels are low or undetectable at birth, with maternal:cord vitamin K ratios of between 20 : 1 and 40 : 1.¹⁴⁷ These findings reflect the limited passage of vitamin K across the placental barrier. The reasons for the apparent protection of the neonate from high levels of vitamin K are not well understood because there is no immediately clear biologic advantage.¹⁴⁸

The situation is further aggravated by the variable but limited content of vitamin K in breast milk, the small volume intake during the first few days of life, and perhaps also by the presence initially of a sterile gut. Vitamin K requirements in the neonate are estimated to be around 1 µg/kg/day; however, breast milk often contains levels as low as 1–2 µg/L, with even lower levels in colostrum.^{149,150} This is not the situation in formula-fed infants, who achieve significantly higher concentrations of vitamin K by 3–4 days of age and are therefore relatively protected and rarely develop VKDB in the absence of other factors.¹⁵¹

Clinical features

VKDB is generally divided into three forms: early, classical and late. This classification reflects differences not only in the clinical presentation but also in the associated risk factors and prophylactic strategies.^{152,153}

Early VKDB

This is the least common form of the disorder, with the onset of bleeding occurring within the first 24 hours of life. The bleeding pattern is variable but can be serious and ICH does occur. This form of VKDB is typically, but not exclusively, associated with the ingestion during pregnancy of drugs that can cross the placenta and interfere with vitamin K metabolism. Warfarin, anticonvulsants and the antituberculous drugs rifampicin and isoniazid have all been implicated.¹⁵⁴

Warfarin is the classic drug that can enter the fetal circulation and cause hemorrhagic problems via reduced carboxylation of vitamin K-dependent proteins. In addition to hemorrhagic problems, warfarin is teratogenic following exposure in early pregnancy.¹⁵⁵ With the increasing use of low-molecular-weight heparin, warfarin is less frequently prescribed during pregnancy but is still used in some countries for the management of women with artificial heart valves. Where warfarin is prescribed during pregnancy it is generally advised that it is avoided between weeks 6 and 12 of gestation due to the risk of teratogenicity and close to term due to the risk of neonatal bleeding.¹⁵⁶

The risk of VKDB following ingestion of anticonvulsant drugs, particularly phenytoin, phenobarbitone and carbamazepine, is poorly defined. Using PIVKA (protein induced by vitamin K absence or antagonism)-II to assess vitamin K deficiency, Cornelissen *et al.* demonstrated detectable PIVKA II (i.e., vitamin K deficiency) in cord blood from 54% of neonates on anticonvulsant therapy compared with 20% in

the control group.¹⁵⁷ The mechanism whereby anticonvulsant drugs cause this problem is not well understood, but is thought to involve the induction of hepatic microsomal oxidase enzymes, which result in increased degradation of vitamin K.

Classical VKDB

Estimates of the frequency of classical VKDB in the absence of vitamin K prophylaxis vary considerably (0.25–1.7%) and depend particularly on the method of feeding employed in the study population.^{158–162} The condition typically presents between days 2 and 5 with bruising, purpura and gastrointestinal hemorrhage in infants who appear otherwise well. They are almost exclusively breast-fed but may have had problems feeding. Bleeding from the umbilicus and mucous membranes is also common, but ICH appears to be relatively infrequent.

Late VKDB

Although classical VKDB had been recognized for many years, the first reports of late VKDB were not published until 1967.^{163,164} The onset of bleeding occurs after the first week of life, with a peak incidence between 2 and 8 weeks. It has been proposed that the upper age limit should be extended from 3 to 6 months following the recognition of cases occurring after 15 weeks of age.¹⁶⁵ Unlike classical VKDB, in late VKDB ICH is seen in around 50% of cases and is associated with significant morbidity and mortality.

Breast-feeding and failure to receive vitamin K at birth are frequently documented risk factors. Late VKDB is also seen in association with underlying conditions that result in malabsorption, and it can be the presenting feature of cystic fibrosis, celiac disease, α_1 -antitrypsin deficiency and biliary atresia. In other cases it is thought that transient, mild abnormalities of liver function may contribute to cholestasis and temporarily reduced vitamin K absorption.^{166,167}

Again, it is difficult to estimate the frequency of late VKDB in unprotected populations but figures ranging from 4.4 per 100 000 births in the UK to 72 per 100 000 in Japan have been published.¹⁶⁸ Recently a study from Vietnam reported an unexpectedly high incidence of late VKDB of 116 per 100 000 births, which highlights the fact that VKDB remains a very significant problem in the developing world.¹⁶⁹

Laboratory diagnosis

Vitamin K deficiency results in prolongation initially of the PT and subsequently the APTT as well (Table 30.4). The diagnosis is confirmed by finding reduced levels of the vitamin K-dependent factors FII, FVII, FXI and FX.

Vitamin K prophylaxis

Prophylactic strategies differ depending on the type of

VKDB. In an attempt to reduce *early VKDB*, guidelines have been published previously for the management of pregnant women with epilepsy. In addition to advice regarding the choice of anticonvulsant medication, these suggest the need for both the immediate administration of parenteral vitamin K (1 mg) to the neonate and the use of oral vitamin K (20 mg/day) during the last 4 weeks of pregnancy.¹⁷⁰ The latter recommendation is based on the finding of absent PIVKA II in the cord blood of women who received antenatal oral prophylaxis.^{170,171} This advice has, however, more recently been challenged by new data from both the UK and North America where there did not appear to be an increased incidence of bleeding in infants where maternal antenatal vitamin K administration had been omitted.^{172,173}

Classical VKDB can be effectively prevented by the post-natal administration of a single dose of vitamin K. Various studies have shown that a single oral dose is as effective as parenteral administration.

The prevention of *late VKDB* is less straightforward and has been a major source of controversy over the last 20 years or so. It was apparent by the early 1980s that, while a single oral dose of vitamin K provided adequate protection against classical VKDB, it did not prevent late VKDB.¹⁷⁴ In a study by McNinch and Tripp in 1991, 27 cases of VKDB were identified, of whom 20 had received no vitamin K prophylaxis and 7 oral prophylaxis.¹⁷⁵ The latter presented significantly later (median 38 days) than those who had not had any prophylaxis (median 13.5 days). The solution appeared to be the use of a single dose of i.m. vitamin K at birth for all newborn infants.

In 1992 the safety of this form of prophylaxis was called into question by the case-control study of Golding *et al.*, who reported an increased incidence of childhood leukemia and cancer following intramuscular vitamin K at birth.¹⁷⁶ Although subsequently a number of well-designed studies have failed to support Golding's original findings, concerns over the potential risks of intramuscular vitamin K have been associated with significant variations in practice in different parts of the world.^{177–181}

Following Golding's original study, the American Academy of Pediatrics recommended the continued use of intramuscular vitamin K, whereas the British Paediatric Association recommended that oral vitamin K supplements should be given to newborn infants, with repeated doses for breast-fed infants.^{182,183} There followed a general trend in the UK and other parts of Europe toward oral vitamin K prophylaxis, but compliance with the triple dose regimen was initially variable, and in 1994 Croucher and Azzopardi reported that > 10% of breast-fed infants did not receive a second dose of vitamin K and < 40% received a third dose.¹⁶²

Although oral vitamin K prophylaxis continues to be widely practiced, especially in Europe, the optimal formulation and dosing regimen remains to be defined.¹⁸⁴ It does, however, appear that regimens consisting of multiple doses

are more effective, particularly for breast-fed infants.^{185,186} With regard to vitamin K formulations, in 1998 guidelines in the UK recommended the use of the Konakion mixed micellar preparation for oral prophylaxis. However, subsequent data published in 2003 failed to show that this formulation was superior to older vitamin K preparations for the prevention of late VKDB.^{187,188}

Treatment

Once VKDB has been confirmed, intravenous vitamin K should be administered to correct the deficiency. In suspected cases a therapeutic trial of vitamin K may be given while factor assays are pending. Vitamin K should be administered by slow intravenous or subcutaneous injection but not by the intramuscular route in the presence of a coagulopathy. Following parenteral administration of 1 mg of vitamin K₁, the vitamin K-dependent proteins start to increase after 20–30 minutes and should normalize over a few hours.¹⁸⁹

In the presence of significant bleeding, factor replacement therapy may also be required with either viridically inactivated FFP, PCC (FII, FIX, FX) or a four-factor concentrate containing all the vitamin K-dependent factors.⁸⁶

Liver disease

Although some degree of hepatic impairment is not uncommon in the neonatal period, fulminant hepatic failure is a relatively rare event. Recognized causes of neonatal hepatic failure include viral infections, metabolic disorders, mitochondrial cytopathies, storage disorders and shock.¹⁹⁰ The usual division into acute and chronic liver failure is somewhat arbitrary in the neonate; however, it is recognized that the onset of hepatic dysfunction may occur *in utero* or develop in the perinatal period. Lesser degrees of hepatic impairment may occur in conjunction with sepsis, hypoxia and the use of total parenteral nutrition.

Pathophysiology

The pathophysiology of the coagulopathy in neonatal liver disease is multifactorial but is not significantly different from that seen in older children and adults. Reduced synthesis of procoagulant proteins plays an important role and is further aggravated in the neonatal period by the immaturity of the liver and the physiologically reduced levels of many coagulation proteins. Reduced clearance of activated coagulation factors by the hepatic reticuloendothelial system, activation of fibrinolysis, impaired utilization of vitamin K and thrombocytopenia also contribute.^{191–194}

Clinical and laboratory features

The pattern of bleeding is variable and reflects the severity of

the coagulopathy. Laboratory features include prolongation of both the PT and APTT, and in fulminant hepatic failure the TCT also becomes prolonged in association with reduced levels of fibrinogen (see Table 37.32). The main differential diagnosis is vitamin K deficiency and DIC, and specific factor assays and analysis of fibrinogen/fibrin degradation products may be helpful.

Management

Management of the coagulopathy in liver disease is purely supportive. As mentioned above, neonatal liver failure is a relatively infrequent event and there are few published data on the efficacy of blood product support. In the presence of clinical bleeding, replacement therapy with FFP, cryoprecipitate and platelet concentrates may restore normal hemostasis, at least temporarily. Occasionally, exchange transfusion may be required if there are problems with fluid overload. As in DIC, PCCs should be avoided due to the risks of thrombosis. If there is evidence of cholestasis, the administration of vitamin K supplements may also be helpful.

Cardiopulmonary bypass

Neonates with congenital heart disease (CHD) who require early corrective surgery involving cardiopulmonary bypass (CPB) are at increased risk of both hemorrhagic and thrombotic complications.^{195–198} Excessive bleeding may occur both perioperatively and postoperatively and is correlated with the duration of the bypass procedure. The actual incidence of major nonsurgical bleeding is difficult to define and is dependent on the criteria used but is likely to be higher in neonates than in older children.

The pathophysiology of nonsurgical post-CPB hemorrhage is complex and several contributing mechanisms are recognized (see also Chapter 29).^{195,196} Although the mechanisms involved are similar in neonates and older children, the relative importance of each is influenced by age, particularly during the neonatal period, when the hemostatic system is physiologically immature.

The presence of a preoperative coagulation defect would be expected to increase the risk of bleeding associated with surgery. There are conflicting reports in the literature regarding the presence of underlying coagulation defects in CHD in older children.^{197,198} In cyanotic CHD, some of the previously noted abnormalities may have been artefactual, secondary to polycythemia; however, it is likely that a low-grade consumptive coagulopathy exists in some cases. Abnormalities in acyanotic CHD have also been documented and include the loss of high-molecular-weight vWF multimers, which return to normal after surgery.¹⁹⁹ Chan *et al.* documented normal procoagulant and inhibitor levels in a group of 22 children (1–15 years) prior to CPB.²⁰⁰ This contrasts with data from a neonatal study in 1992, in which 53% of infants,

aged between 1 and 30 days, had reduced procoagulant levels preoperatively compared with age-matched controls.²⁰¹ It was postulated that these abnormalities were due to impaired hepatic maturation secondary to poor organ perfusion or severe cyanosis. It was not, however, possible in this study to predict which neonates were more likely to have a preoperative coagulopathy.

Following the onset of CPB there is a very predictable decrease in the levels of virtually all hemostatic proteins, which occurs secondary to hemodilution. Mean plasma concentrations of procoagulant proteins and inhibitors are reduced by around 50% of pre-CPB values.^{200,201} There is a similar reduction in the fibrinolytic proteins plasminogen and α_2 -AP. These changes have a significant effect on the regulation of thrombin, and *in vitro* studies have demonstrated that the capacity to generate thrombin is reduced by 50%. This contrasts with the *in vitro* plasma thrombin inhibitory capacity, which, despite the reduced inhibitor levels, is relatively spared.²⁰² It has been suggested that this may be one reason why the risk of hemorrhagic complications post-CPB is relatively greater than the risk of thrombosis.

Compared with data from adult studies, the effect of hemodilution in neonates is profound. This reflects the greater degree of dilution in the neonate's circulating blood volume, which is estimated to be 5–10 times greater than that seen in an adult. The resulting global reduction in procoagulant proteins combined with the physiologic immaturity of the coagulation system may result in concentrations lower than those generally considered necessary for adequate hemostasis. The situation is further aggravated in the presence of reduced preoperative levels.

In addition to the effects of hemodilution, there is also evidence that both the coagulation and fibrinolytic systems are activated during CPB, which may result in a low-grade consumptive coagulopathy. Using prothrombin F1+2 and TAT as markers of thrombin generation, studies in both neonates and older children have shown that levels increase during CPB despite the use of heparin.^{200,203} Inadequate anticoagulation and tissue damage during surgery are thought to contribute. In support of the latter it has recently been suggested that it is predominantly the extrinsic pathway rather than the contact system that triggers coagulation activation during CPB.²⁰⁴ tPA and D-dimers are also increased during bypass indicating activation of the fibrinolytic system. In most studies levels fall again postoperatively in keeping with "fibrinolytic shutdown."^{200,205}

Optimal anticoagulation during CPB is crucial to the successful outcome of the procedure. Current protocols use standard heparin, monitored intraoperatively using the activated clotting time (ACT) and reversed by protamine sulfate at the end of the procedure. Inadequate heparinization may cause excess fibrin deposition and consumption of coagulation factors whereas overanticoagulation increases the risk of bleeding. Despite the importance of anticoagulation, there

are few or no data relating to the use of heparin in neonates undergoing CPB and current regimens are based on data from adult studies.

Current evidence suggests that neonates clear standard heparin faster than adults.²⁰⁶ In addition, physiologically reduced concentrations of ATIII, which decrease further during bypass due to hemodilution, are likely to impair heparin activity. The use of increased doses of heparin with or without the addition of ATIII supplements might therefore be expected to improve anticoagulation and reduce thrombin generation.²⁰⁷ It is also clear that use of the ACT to monitor heparin therapy during CPB is unsatisfactory because it is significantly influenced by other factors, particularly hemodilution, and correlates poorly with plasma heparin levels as measured by either antithrombin or anti-FXa assays.^{208,209}

Thrombocytopenia develops at the onset of bypass, again largely due to the effect of hemodilution. Platelet function defects also occur and lead to prolongation of the bleeding time independent of the platelet count. Although contributing to bleeding problems, platelet dysfunction, particularly in neonates, is probably less important than the changes in the coagulation system. This contrasts with the situation in adults, where acquired platelet dysfunction is usually the main cause of hemorrhage. The pathophysiology of platelet dysfunction in CBP remains controversial. Partial platelet degranulation and defects of platelet membrane glycoproteins have all been described, and it has been suggested that the problem is "extrinsic" and due to inadequate availability of platelet agonists.^{196,210}

Thrombocytopenia following CPB surgery may also be due to the development of heparin-induced thrombocytopenia, which is probably underdiagnosed in pediatric practice.^{211,212} It is not, however, clear to what extent this immune-mediated complication affects infants during the first month of life.

Management of bleeding after CPB is complex and requires careful assessment of the likely causes. Replacement therapy with FFP, cryoprecipitate and platelets may be required to correct hemostatic defects. Adequate reversal of heparin with protamine sulfate is also important. Various measures can also be undertaken in an attempt to prevent excessive blood loss. These include the use of fibrin sealants, which can improve local hemostasis during surgery, and the serine protease inhibitor aprotinin.^{213–216} A literature review on the use of aprotinin following cardiac surgery concluded that a number of beneficial effects had been observed in neonates following high-dose aprotinin, including attenuation of the inflammatory response, a reduction in postoperative blood loss and a reduction in overall hospital stay.²¹⁶

Recombinant factor VIIa (rFVIIa) (NovoSeven) is a hemostatic agent that was first developed for the treatment of hemophilia patients with inhibitors.²¹⁷ Following intravenous injection rFVIIa enhances hemostasis by increasing thrombin generation on activated platelets. There has been

considerable interest in the use of rFVIIa in patients with a variety of acute hemorrhagic problems and there have been a small number of reports of its use in neonatal practice.²¹⁸ Preliminary data on the management of bleeding in children undergoing cardiac surgery have demonstrated potential benefits, and further randomized studies are ongoing at the present time.²¹⁹

Neonatal thrombocytopenia

Incidence

Data from fetal blood sampling indicate that the fetal platelet count is within the normal adult range from as early as 15–18 weeks gestation and neonatal thrombocytopenia is therefore defined as a platelet count of $< 150 \times 10^9/L$.^{42,44} The incidence of neonatal thrombocytopenia is highly dependent on the population studied. In large population-based studies of unselected term neonates the reported incidence of thrombocytopenia is 1–5%.^{44,220–223}

Severe thrombocytopenia (platelets $< 50 \times 10^9/L$) is less common. In a large prospective study, where platelet counts were determined from $> 15\,000$ cord blood samples, only 19 cases (0.12%) were $< 50 \times 10^9/L$.²²⁰ Six infants in this study had a platelet count of $< 20 \times 10^9/L$, all of whom had an underlying diagnosis of neonatal alloimmune thrombocytopenia (NAIT).

The situation in sick neonates is somewhat different and in this context thrombocytopenia is relatively common. In a 1-year prospective study of 807 infants admitted to a regional neonatal intensive care unit (NICU), Castle *et al.* documented thrombocytopenia in 22% of cases.²²⁴ A similar incidence was recently recorded in a similar study from Pakistan, where 24% of all NICU admissions were thrombocytopenic.²²⁵

Etiology and mechanisms of thrombocytopenia

As with thrombocytopenia in other age groups, neonatal thrombocytopenia may relate to inadequate platelet production or a shortened platelet lifespan, often due to increased peripheral destruction or sequestration. Although it has been recognized for many years that a large number of maternal, perinatal and neonatal problems may be associated with the presence of neonatal thrombocytopenia, until recently relatively little was understood about the actual mechanisms involved.²²⁴ This particularly applies to nonimmune thrombocytopenias, where the presence of a low platelet count is often attributed to the presence of a low-grade consumptive coagulopathy with DIC.

Studies focusing on the natural history of neonatal thrombocytopenia have highlighted specific patterns of thrombocytopenia and, in conjunction with data on megakaryocyte numbers and thrombopoietin (Tpo) levels, have helped to

define the pathophysiology of this problem.^{226,227} Revised classifications of neonatal thrombocytopenia have therefore been proposed, which define thrombocytopenia in terms of the time of onset, which is likely to relate to specific underlying mechanisms and disorders (Table 30.7).

In the majority of thrombocytopenic neonates the platelet count is low at birth or falls within the first 72 hours of life. Although a small proportion will be due to immunologic causes or other specific problems, the majority are the result of impaired platelet production, which is reflected in reduced numbers of megakaryocytes and increased levels of Tpo. The natural history of this type of thrombocytopenia is for the

platelet count to fall to a nadir at around day 5 and then increase spontaneously thereafter.^{226,227} Thrombocytopenia that develops after the first 72 hours of life is frequently associated with sepsis and necrotizing enterocolitis. This type of thrombocytopenia is often severe and persistent and is due to a combination of impaired production and increased consumption.^{226,227}

Clinical features

The most serious potential risk associated with neonatal thrombocytopenia is ICH/IVH, and a number of studies have shown an association between thrombocytopenia, IVH and other adverse outcomes.^{228,229} Such infants are often extremely sick, and whether such adverse outcomes are directly related to the presence of thrombocytopenia or can be improved by platelet transfusion remains controversial.

Platelet transfusion therapy

Outside of specific immune-mediated forms of neonatal thrombocytopenia (see below), platelet transfusion remains the most important therapeutic option for the management of neonatal thrombocytopenia. Despite this there is evidence of considerable variation in clinical practice and an absence of controlled trial data on which to base guidelines.^{230,231} At present there are no data to suggest that platelet transfusion reduces the risk of neonatal bleeding, especially IVH.²³² Currently therefore a threshold for transfusion of 20–30 × 10⁹/L is suggested for nonbleeding term and preterm neonates, with higher thresholds for VLBW infants and those who are bleeding²²⁶ (Table 30.8).

Other potential therapeutic options: hematopoietic growth factors

There is considerable interest in the possibility of using hematopoietic growth factors as a method of either preventing or treating neonatal thrombocytopenia. Tpo and interleukin-11 (IL-11) are the two factors that have been investigated as potential therapeutic candidates.²³³ Tpo is the major regulator of platelet production but, to date, information about the clinical use of recombinant Tpo remains limited. Although recombinant Tpo is a potent stimulator of megakaryocyte precursors there is a delay of 5–7 days before the platelet count increases, which may limit its clinical usefulness.²³⁴ In addition, Tpo has been associated with the development of anti-Tpo antibodies, and recent attention has therefore been focused on the development of Tpo-mimetic peptides, which are small molecules with thrombopoietic activity but that do not share sequence homology with endogenous Tpo.²³⁵

IL-11 is able to exert an effect on platelet production and may also have a beneficial effect in sepsis, but again there

Table 30.7 Classification of fetal and neonatal thrombocytopenias.

Fetal	Alloimmune Congenital infection (e.g., CMV, <i>Toxoplasma</i> , rubella, HIV) Aneuploidy (e.g., trisomies 18, 13, 21 or triploidy) Autoimmune (e.g., ITP, SLE) Severe Rhesus disease Congenital/inherited (e.g., Wiskott–Aldrich syndrome)
Early-onset neonatal (<72 hours)	Placental insufficiency (e.g., PET, IUGR, diabetes) Perinatal asphyxia Perinatal infection (e.g., <i>Escherichia coli</i> , GBS, <i>Haemophilus influenzae</i>) Disseminated intravascular coagulation Alloimmune Autoimmune (e.g., ITP, SLE) Congenital infection (e.g., CMV, <i>Toxoplasma</i> , rubella, HIV) Thrombosis (e.g., aortic, renal vein) Bone marrow replacement (e.g., congenital leukemia) Kasabach–Merritt syndrome Metabolic disease (e.g., propionic and methylmalonic acidemia) Congenital/inherited (e.g., TAR, CAMT)
Late-onset neonatal (>72 hours)	Late-onset sepsis Necrotizing enterocolitis Congenital infection (e.g., CMV, <i>Toxoplasma</i> , rubella, HIV) Autoimmune Kasabach–Merritt syndrome Metabolic disease (e.g., propionic and methylmalonic acidemia) Congenital/inherited (e.g., TAR, CAMT)

CAMT, congenital amegakaryocytic thrombocytopenia;
CMV, cytomegalovirus; GBS, group B *Streptococcus*; HIV, human immunodeficiency virus; ITP, idiopathic thrombocytopenic purpura; IUGR, intrauterine growth restriction; PET, preeclampsia; SLE, systemic lupus erythematosus; TAR, thrombocytopenia with absent radii. Most frequently occurring conditions are emboldened.

are currently no clinical data available to support its use in clinical practice.²³³

Specific types of thrombocytopenia

Neonatal alloimmune thrombocytopenia

NAIT occurs as a result of transplacental passage of maternally derived IgG antibodies directed against paternal antigens on fetal platelets. These antibodies result in immune-mediated platelet destruction leading to fetal thrombocytopenia, which may develop *in utero* as early as 20 weeks gestation. The pathophysiology of the condition is therefore analogous to hemolytic disease of the newborn.

In addition to ABO and human leukocyte antigen (HLA) class I antigens, platelets express specific human platelet antigens (HPA, groups 1–5), which represent antigens associated with platelet membrane glycoproteins. In Caucasian populations, HPA-1a (PLA-1) is the commonest human platelet antigen (expressed by almost 98% of the population) and is responsible for the majority of cases of NAIT.²³⁶ HPA-5b (Br) and HPA-3a (Bak) are less frequently involved, while in other ethnic groups antigens such as HPA-4 (Yuk/Pen) are more frequently implicated.²³⁷

In a recent study from North America HPA alloantibody specificity was reported from 1162 cases of NAIT investigated at a reference center over a 12-year period.²³⁸ In this study HPA-1a accounted for 79% of cases, while HPA-5b, HPA-3a and HPA-1b were reported in 9%, 2% and 4% of cases, respectively. Interestingly a number of cases with multiple HPA-specific alloantibodies were also identified.²³⁸

NAIT has very rarely been reported in association with other platelet alloantibodies including anti-Nak(a) and anti-Duv(a+) and also in association with HLA alloantibodies.^{239–243}

Recent estimates from screening studies in predominantly white populations suggest that the prevalence of clinically significant NAIT is around 1 in 2000 live births.^{236,244} Thus, although around 2.5% of Caucasian women are HPA-1a negative and are therefore potentially at risk, platelet antigen incompatibility does not invariably result in alloimmunization, and alloimmunization, in turn, does not always result in clinically apparent disease.²⁴⁵ The immune response in this condition is in part related to the maternal HLA phenotype, with HLA-Dw52a associated with an increased risk of sensitization.²⁴⁶

In contrast to the situation in Rhesus hemolytic disease, first pregnancies are affected in around 50% of cases.^{236,247} The risk of recurrence in future pregnancies is almost 100% where the father is homozygous for the HPA-1a antigen and 50% in the heterozygous state.²⁴⁷ Maternal antibodies can cross the placenta from 14 weeks gestation, and fetal thrombocytopenia has been documented as early as 20 weeks gestation.

In the neonatal period the typical feature of NAIT is moderate-to-severe thrombocytopenia in an otherwise well infant in the absence of any history of maternal thrombocytopenia. The severity of the thrombocytopenia is variable and although the reasons for this are incompletely understood the platelet antigen specificity and antiplatelet antibody titer are probably important factors.^{248,249}

The most serious complication is ICH, which occurs in up to 20% of all cases, with around 10% occurring *in utero*.^{250,251} ICH can be clinically silent and it is important that any infant suspected of having NAIT should have a cranial ultrasound

scan performed. In addition to ICH, superficial hemorrhage, anemia and gastrointestinal bleeding are also relatively frequent. The risk of bleeding in NAIT is further aggravated by impaired platelet function, which occurs as a consequence of antibody blocking the glycoprotein IIb–IIIa complex.²⁵²

The degree of thrombocytopenia is typically most marked on the first day of life and is followed by a gradual return to normal over a period of around 2–4 weeks. Mortality associated with NAIT is estimated at 10–15%, with the majority of deaths occurring as a consequence of ICH. In addition, neurodevelopmental sequelae in survivors of ICH are frequent and often severe, and include cerebral palsy, seizures, hydrocephalus and mental retardation.^{253,254}

Laboratory confirmation of NAIT is based on the demonstration of maternal antibody with specificity for paternal antigens. In populations of European origin, rapid typing of maternal platelets for the HPA-1a antigen and screening of maternal serum for evidence of anti-HPA-1a alloantibodies should be undertaken first and will provide confirmation in the majority of cases of NAIT. If these results are negative, platelet phenotyping of both parents and screening of maternal serum for alloantibodies against other platelet-specific antigens as well as HLA and ABO antigens should also be performed. Paternal zygosity studies are important for the prediction of recurrent NAIT in future pregnancies. Although the estimated prevalence of this condition is in the order of 1 in 2000 live births, recent data from both the UK and Ireland based on confirmed clinical cases of NAIT suggest that the condition remains underdiagnosed.^{255,256}

NAIT is a self-limiting condition; however, until the platelet count recovers, the affected neonate is at significant risk of life-threatening hemorrhage. Once the diagnosis has been confirmed, the most important aspect of management is the rapid administration of compatible, antigen-negative platelets, which, in the majority of cases, result in an increase in the platelet count.²⁵⁷ Transfusion of compatible platelets may have to be repeated until the infant's own platelet count recovers.

Platelets may be obtained from either accredited HPA-typed donors or alternatively the infant's mother is a potential source of compatible platelets because, by definition, she will be negative for the causative antigen.^{257,258} In suspected NAIT where the diagnosis has yet to be confirmed donor platelets that are HPA-1a and HPA-5b negative should be used until the results of serologic investigations are complete. In the event that maternal platelets are required these may be prepared from either a whole blood donation or by platelet pheresis. Regardless of the method of collection, maternal platelets should be plasma depleted (by washing or centrifugation) prior to administration to remove platelet alloantibodies and should also be irradiated to reduce the risk of engraftment of maternal lymphocytes and subsequent graft-versus-host disease.^{259,260} It is also recommended that, unless there is extreme clinical urgency, these platelets undergo standard virologic screening prior to use.

Where NAIT is anticipated, which usually occurs following a previously affected pregnancy, antigen-negative platelets should be prepared in advance of delivery either from the mother or from a specifically identified antigen-negative donor. As discussed above, the commonest causative antigen in NAIT is HPA-1a, and many larger donor centers now have a registry of known HPA-1a negative donors who can undergo platelet pheresis if required. Very occasionally it may be necessary to use frozen platelets.^{261,262} The only indication for the use of random donor platelets in this condition is life-threatening hemorrhage while awaiting antigen-negative platelets.

While high-dose intravenous immunoglobulin (IVIG) therapy has been shown to be of benefit in increasing the platelet count in NAIT, its effect is usually delayed and is less predictable than that of antigen-negative platelets and should only be used in addition to compatible platelet transfusion.^{263,264} IVIG also has the disadvantage of exposing the infant to a pooled blood product, and this should be taken into consideration when planning therapy. While IVIG may have a part to play in management, there is no evidence to support the use of corticosteroids.

NAIT, although rare, is potentially life-threatening, and prevention is therefore an important aspect of the overall management of the condition. Screening for HPA-1a phenotypes during pregnancy, which can facilitate the identification of unsuspected cases in a first pregnancy, remains controversial and is not routine practice. Currently, preventive strategies are therefore aimed at reducing the risk of recurrence in future pregnancies following identification of an affected fetus/neonate.^{265–268} There is, however, no consensus on the optimal management strategy. One option is regular maternal IVIG (1 g/kg per week), with or without additional corticosteroids, commenced following documentation of fetal thrombocytopenia with subsequent monitoring of the fetal platelet count by percutaneous umbilical blood sampling a few weeks later. Results achieved with this form of therapy are conflicting and it is likely that a significant percentage of cases will not respond adequately.^{269–272} The major alternative strategy is cordocentesis with regular platelet transfusion, which effectively increases the fetal platelet count but carries a significant risk of procedural complications.²⁷³ To minimize the risks from regular cordocentesis it has been suggested that regular platelet transfusions should be reserved for cases in which medical management with IVIG has demonstrably failed. Avoidance of trauma at the time of delivery is an important aspect of management, and early elective delivery by cesarean section is generally advocated.

Neonatal autoimmune thrombocytopenia

In the presence of maternal autoimmune thrombocytopenia Idiopathic thrombocytopenic purpura (ITP or other autoimmune conditions), placental transfer of idiopathic thrombo-

cytopenic purpura IgG antibodies may result in neonatal thrombocytopenia. The antibodies in this context are directed against antigens common to both maternal and neonatal platelets.

The prevalence of maternal ITP is estimated at between 1 and 5 per 10 000 pregnancies; however, clinically significant neonatal thrombocytopenia is relatively uncommon. Data from three published series that looked at chronic maternal thrombocytopenia recorded significant neonatal thrombocytopenia (platelets $< 50 \times 10^9/L$) in 25 of 182 cases (14%) and only 2 (1%) documented cases of ICH.²⁷⁴ Two other recent studies have confirmed that the risk of life-threatening hemorrhage remains low and is typically less than 1%.^{275,276}

Unlike NAIT the platelet nadir usually occurs a few days post-delivery and bleeding problems *in utero* or at delivery are rare. It should be noted that the count can be normal at birth and fall subsequently, necessitating serial platelet counts. The condition is self-limiting and the count has usually normalized by 2–3 months of age. Where the platelet count is $< 50 \times 10^9/L$, treatment options include IVIG and corticosteroids. IVIG 1 g/kg per day for 2 days is effective in the majority of cases and produces a relatively rapid response.^{277,278} The response to platelet transfusion is generally poor and this should only be used in infants with life-threatening hemorrhagic problems.²⁵⁹

Management of the fetus in the presence of maternal ITP remains controversial and there is no evidence that any maternal therapy increases the fetal platelet count. There is no correlation between maternal and neonatal platelet counts, and the severity of thrombocytopenia in a previous infant is the best predictor of the likelihood of thrombocytopenia in a subsequent pregnancy.²⁷⁹

Current management strategies for maternal ITP are mostly conservative, and attempts to assess the platelet count by fetal scalp sampling or fetal blood sampling have been abandoned in most centers due to the procedural risks associated with these techniques.^{280,281} Routine cesarean section for maternal ITP has not been shown to improve fetal outcome and, as the risk of neonatal hemorrhage is low, the route of delivery can be determined primarily by obstetric factors.^{275,279,282}

Maternal systemic lupus erythematosus (SLE) may be associated with transplacental passage of other antibodies, including anti-SSA/Ro-SSB/La antibodies, and infants are therefore at risk of other complications in addition to thrombocytopenia.²⁸³ Neonatal lupus erythematosus comprises a number of clinical manifestations including skin rashes, complete heart block, thrombocytopenia, hepatomegaly and abnormal liver function.^{283,284} Bleeding due to severe thrombocytopenia has been treated successfully with IVIG.²⁸⁴

Inherited thrombocytopenia

The inherited thrombocytopenias represent a heterogeneous group of disorders, most of which are very rare.²⁸⁵ Neverthe-

Table 30.9 Inherited thrombocytopenia classified by platelet size.

<i>Small platelets</i>
Wiskott–Aldrich syndrome
X-linked thrombocytopenia

Velocardiofacial syndrome
Gray platelet syndrome
Paris–Trousseau thrombocytopenia
Jacobsen syndrome

less, these disorders can present with bleeding early in life but are often overlooked, at least during initial investigations. In addition to thrombocytopenia these conditions can also be associated with defects in platelet function or with other somatic abnormalities.²⁸⁶ The genetic defects responsible for many of these conditions have recently been defined, and this has also resulted in the description of new disorders.^{287,288} Various systems have been proposed for the classification of inherited thrombocytopenias, the most useful of which are based on inheritance pattern, platelet size or the presence of other associated features²⁸⁵ (Table 30.9). The Italian Gruppo di Studio delle Piastrine has proposed a series of diagnostic algorithms for the investigation of inherited thrombocytopenia based on readily accessible clinical and laboratory parameters.²⁸⁹ The application of this type of approach may aid in the diagnosis of these conditions although it is likely that a proportion of cases may still not fulfil the criteria for any known condition.

Other nonimmune thrombocytopenias

Fetal congenital infection is frequently associated with thrombocytopenia. In addition to increased destruction, reduced platelet production and splenic pooling all contribute to the thrombocytopenia in this situation. In a study looking at the platelet counts of fetuses with known congenital infections, thrombocytopenia was documented in congenital rubella in 20%, toxoplasmosis in 26% and cytomegalovirus (CMV) in 36% of cases.⁴⁴ Thrombocytopenia in this study was most marked in cases of CMV infection. In general, however, congenital infections are an uncommon cause of severe ($< 20 \times 10^9/L$) thrombocytopenia. HIV infection can also lead to thrombocytopenia but this is an uncommon presentation in the neonatal period.²⁹⁰

Chromosomal abnormalities are another well-recognized but relatively uncommon cause of neonatal thrombocytopenia.²⁴⁵ The platelet count is usually only mildly reduced and clinical bleeding is uncommon. The diagnosis is almost always obvious due to the presence of characteristic associated abnormalities. In one study of fetal thrombocytopenia, 43 of 247 cases were due to chromosomal abnormalities.⁴⁴ These cases included trisomy 13, 18 and 21, Turner syndrome and triploidy, of which trisomy 18 was the commonest cause with 26 of 30 (87%) cases affected. In only one infant (triploidy) was a platelet count of $< 50 \times 10^9/L$ recorded. The mechanism of thrombocytopenia is incompletely understood but is thought to involve defects in megakaryocyte maturation.

Fanconi anemia is also recessively inherited and typically presents with marrow hypoplasia in association with a variable pattern of coexisting congenital abnormalities. There is increased sensitivity to DNA damage by alkylating agents and ionizing radiation and the diagnosis can be confirmed by performing chromosome breakage studies. Although thrombocytopenia is often an early hematologic finding, it only rarely manifests during the neonatal period.²⁹¹

Rarer causes of thrombocytopenia include giant hemangiomas (Kasabach–Merritt syndrome) and extensive thrombosis, both of which result in platelet consumption. Very rarely, congenital leukemia, neuroblastoma and histiocytosis may present with thrombocytopenia in the neonatal period as a consequence of marrow infiltration.

Thromboembolic complications in children

Mary Bauman and M. Patricia Massicotte

Introduction

Normal infants and children have a number of physiologic hemostatic differences compared with adults, including unique protective mechanisms resulting in an overall decreased incidence of thrombosis. However, children who are now being cured of their primary illnesses (congenital heart disease, prematurity, cancer) are increasingly developing thromboembolic complications as sequelae to new surgical techniques and medical therapies that are facilitating these cures. Unfortunately, systemic venous and arterial thromboembolic complications have associated mortality and morbidity.

Systemic venous thromboembolic events (SVTE) in children most often occur due to interaction of multiple risk factors, with the presence of a central venous line (CVL) appearing to be one of the strongest risk factors. Systemic arterial thromboembolic events (SATE) in children most often occur as a result of the placement of an arterial line. Both SVTE and SATE require rapid diagnosis and institution of therapy to prevent thrombus extension or embolism, which could result in mortality or morbidity. There are few well-designed clinical studies providing sensitive and specific diagnostic regimens and safe efficacious therapeutic regimens that should be instituted (in the absence of contraindications) once thrombosis is confirmed.

This chapter discusses the hemostatic differences between children and adults (developmental hemostasis), and the epidemiology, clinical presentation, and evidence-based approaches to diagnosis and therapy (treatment and prevention) of SVTE and SATE in children. Diagnostic recommendations are based on the sensitivity and specificity of the chosen diagnostic method. Therapeutic recommendations for thrombosis are based on the strength of the published evidence supporting the recommendation. Therapeutic recommendations for thrombosis are graded according to the

strength of the evidence supporting the recommendation. The grading system used is that described by the American College of Chest Physicians for antithrombotic guidelines.¹ Grade 1 recommendations have demonstrated a clear benefit for the intervention in the patient population; grade 2 recommendations are far less certain. The recommendations (grade 1, 2) are additionally supported by the level of evidence, where A represents multiple randomized trials with clear treatment effect or a metaanalysis, B represents single randomized trials, and C represents observational studies.

Developmental hemostasis

The hemostatic system in neonates and children has a number of differences compared with that of adults. Normal levels for age of the components of hemostasis have been determined and published.²⁻⁴ The levels of the hemostatic factors approach adult levels by the time of puberty. The main differences are:

- decreased levels of contact factors (FXII and FXI);
- decreased levels of vitamin K-dependent factors (FII, FVII, FIX and FX);
- decreased thrombin generation;
- downregulated fibrinolytic system (decreased plasminogen);
- altered levels of inhibitor proteins of coagulation;
- decreased protein C, protein S and antithrombin;
- increased α_2 -macroglobulin;
- decreased levels of inhibitors of fibrinolysis (plasminogen activator inhibitor, PAI).

Children are relatively protected from the development of thrombosis as a result of several unique mechanisms including:

- reduced capacity to generate thrombin;^{5,6}
- increased capacity of α_2 -macroglobulin to inhibit thrombin;⁷
- enhanced antithrombotic potential by the vessel wall.^{8,9}

Systemic venous thromboembolism

(Table 31.1)

Epidemiology

The epidemiology of SVTE has been studied in three international registries (UK, Netherlands and Canada).^{10–12} The

largest pediatric age groups for developing thrombosis are children of < 3 months and teenagers.

Etiology

The most common causative factors of SVTE are the presence of a CVL and the presence of serious diseases such as cancer, trauma/surgery, congenital heart disease and systemic lupus

Table 31.1 Venous thromboembolism: incidence, diagnosis and therapeutic considerations.

Thromboembolic event (TE)	Incidence	Diagnosis	Pretherapy considerations	Therapy
Systemic venous TE (SVTE): symptomatic and asymptomatic	General population: 0.07 per 10 000 in adults ^{2,4–7}	<i>Clinical symptoms:</i> Pain, redness, swelling of limb <i>Diagnostic:</i> US (albeit poor sensitivity). If US negative and clinical suspicion high proceed to venography or MRV. Neck vessels are sensitive to US	INR, PTT, hemoglobin, platelets, urea, creatinine <i>Rule out:</i> Current or potential for bleeding, hemorrhagic stroke, and recent surgery resulting in increased bleeding risk Head US in infants < 3 months to rule out intracranial hemorrhage	<i>Treatment recommendations:</i> LMWH/UFH therapy of 3 months' duration <i>Neonates:</i> follow with radiographic testing to ensure no extension of thrombus; if extension, treatment recommended Warfarin is not recommended in children < 12 months of age, except for mechanical heart valves Thrombolytic therapy (tPA, rUK) is recommended for therapy only where there is potential for loss of life, organ or limb
Pulmonary embolism (PE)	1.7–32%	<i>Clinical symptoms:</i> Chest pain, shortness of breath, hypoxia, atrial fibrillation, cardiovascular collapse <i>Diagnostic:</i> V/Q scan, MRI/MRV, spiral CT, angiogram	As above. NB: if cardiovascular collapse, proceed to urgent therapy	As above for SVTE Consider thrombolytic therapy or thrombectomy if cardiorespiratory compromise
Central venous line-related venous TE	Infants < 1 year of age: 0–30% ~35% in children; ALL, TPN, NS	As above for SVTE	As above for SVTE	As above for SVTE
Right atrial TE	No data	<i>Clinical symptoms:</i> Asymptomatic but may result in PE/cardiac failure <i>Diagnostic:</i> Cardiac echocardiogram, CC clinical diagnosis: currently no validated outcome measure	As above for SVTE	As above for SVTE Consider thrombectomy or thrombolytic therapy if cardiorespiratory compromise
Postthrombotic syndrome	12–62%	<i>Clinical diagnosis:</i> Currently no validated outcome measure		No effective treatment (custom-measured compression stockings may provide symptomatic relief)

ALL, acute lymphoblastic leukemia; CC, cardiac catheterization; CT, computed tomography; INR, international normalized ratio; LMWH, low-molecular-weight heparin; MRI, magnetic resonance imaging; MRV, magnetic resonance venography; NS, nephrotic syndrome; PTT, partial thromboplastin time; rUK, recombinant urokinase; tPA, tissue plasminogen activator; TPN, total parenteral nutrition; UFH, unfractionated heparin; US, ultrasound; V/Q, ventilation/perfusion scan.

erythematosus (SLE).^{4,13–15} The role of congenital prothrombotic states in SVTE remains controversial. Idiopathic SVTE is rare in infants, children and teenagers.

Incidence

The incidence of SVTE in children is decreased compared with that in adults (2.5–5%).^{12–21} The true incidence of pulmonary embolism (PE) among infants and children is unknown, and current studies probably underestimate the reported incidence.^{14,22–25} There are two cross-sectional studies using ventilation/perfusion (V/Q) scans to detect PE, reporting incidences of 12% and 28% in children requiring home total parenteral nutrition (TPN) and children with nephrotic syndrome, respectively.^{23,24} Right atrial thrombosis has been described usually in the presence of a CVL. The incidence is unknown.^{26,27} Clinically overt symptoms include cardiac failure, PE, loss of CVL patency, and persistent sepsis. Over 50% of thromboses occur in the upper venous system secondary to the use of CVLs.^{28,29}

Clinical symptoms

Acute symptoms

The acute symptoms of SVTE are:

- mortality, usually due to PE, estimated at 2%;¹²
- morbidity;
- loss of CVL patency;
- swelling, pain and discoloration of the related limb;
- swelling of the face and head with superior vena cava syndrome;
- respiratory compromise with PE and right atrial thrombosis.

Long-term outcomes

Various features can develop in the longer term as a result of SVTE, including the following.

- 1 Prominent collateral circulation in the skin:
 - (a) face, back, chest and neck as sequelae of upper VTE;
 - (b) abdomen, pelvis, groin and legs as sequelae of lower VTE.
- 2 Repeated loss of CVL patency:
 - (a) repeated requirement for CVL replacement;
 - (b) eventual loss of venous access.
- 3 CVL-related sepsis, chylothorax, chylopericardium, recurrent VTE (estimated to occur in 6% of children with SVTE³⁰) necessitating long-term anticoagulation and associated bleeding risk.

Postthrombotic syndrome

Postthrombotic syndrome (PTS) is a serious long-term outcome of SVTE consisting of pain, swelling, limb discoloration and ulceration resulting from damage to venous valves

in deep vessels. PTS that is clinically significant occurs in approximately 10–20% of children.³¹ There is no properly validated outcome measure for PTS in children.

SVTE related to a CVL

CVLs are used in short-term intensive care, in hemodialysis or for long-term supportive care for children requiring TPN or therapy for cancer.

Etiology

Several mechanisms may play a role in the development of CVL-related VTE, including damage to the vessel wall by the CVL or by substances infused through the CVL (TPN, chemotherapy),^{32,33} disrupted blood flow, and thrombogenic catheter materials.³⁴

Types of CVL-related SVTE (Fig. 31.1)

Three types of CVL-related VTE are described in the literature.

- 1 A clot at the tip of a CVL, which impairs infusion or withdrawal of blood.
- 2 Fibrin sleeves that are not adherent to vessel walls but may occlude CVLs.³⁵
- 3 CVL-related venous thromboembolic events that adhere to vessel walls, with partial or complete obstruction of vessels in which the CVL is located.³⁵

Fig. 31.1 Central venous line-related systemic venous thromboembolism.

Incidence

A CVL-related SVTE may be symptomatic or asymptomatic.

Symptomatic CVL-related SVTE

The incidence of symptomatic CVL-related SVTE has been recorded as 11% in a heterogeneous group (cardiac, cancer, other) of children.³⁶ Asymptomatic CVL-related SVTE occurred in 37% of children with acute lymphoblastic leukemia (upper limb CVL),³⁷ and an incidence of 45% was reported in children in intensive care with a lower limb CVL.²⁷ The incidence in other pediatric patient populations is not accurately known.

Asymptomatic CVL-related SVTE

Asymptomatic SVTE are clinically important in children and require therapy. Many are diagnosed on routine radiographic studies, with most children remaining asymptomatic.

Increasing evidence demonstrates that CVL-related venous thromboembolic events are associated with CVL-related sepsis. In a metaanalysis, prophylactic unfractionated heparin (UFH) reduced CVL-related SVTE (RR 0.43, 95% confidence interval (CI) 0.23–0.78), decreased bacterial colonization (RR 0.18, 95% CI 0.06–0.60) and likely CVL-related bacteremia (RR 0.26, 95% CI 0.07–1.03).¹⁴ In addition, CVL-related VTE is the most common source for PE in children,¹⁵ which may be fatal.¹⁴ In children, PE is frequently not diagnosed during life due to the subtlety of symptoms in the presence of primary illnesses that can cause sudden cardiorespiratory compromise.

Finally, long-term sequelae of CVL-related VTE occur in 10–20% of children,^{12,14} destroying the underlying venous system and potentially limiting life-saving therapy because of the absence of venous access. Case reports have documented sudden death resulting from rupture of an intrathoracic vessel, considered to be due to a previous CVL placement.³⁸

Diagnosis of SVTE (including right atrial thrombosis and pulmonary embolus)

(Fig. 31.2 and Table 31.1)

There is no evidence to support screening for SVTE in any high-risk groups.³⁹ Diagnosis entails the following steps.

1 Clinical assessment of symptoms:

- (a) pain, swelling or discoloration of an arm or leg;
- (b) altered patency of CVL.

2 Chest radiography if CVL in place to determine if the CVL is in a good position and not fractured.

3 Ultrasound scan of the neck and intrathoracic vessels should be obtained. If the ultrasound is negative, and the clinical suspicion is high for VTE, the child should have a venogram.

4 Venogram: magnetic resonance imaging (MRI)/magnetic resonance venography (MRV) of the intrathoracic vessels to rule out VTE.

Sensitivity of imaging studies for diagnosis of SVTE

There are currently no studies evaluating the sensitivity of MRI/MRV for venous thrombosis. With asymptomatic SVTE, ultrasound was demonstrated to have a sensitivity of only 20% for intrathoracic thrombosis, yet it diagnosed jugular thrombi that were missed on venography.³⁷ No studies have yet determined the sensitivity and specificity of any form of testing used to diagnose pulmonary embolus.

Right atrial thrombosis is diagnosed on transthoracic echocardiography, although this is not as sensitive as transesophageal echocardiography in teens or children with large chest dimensions (obesity, pectus).

Treatment recommendations for SVTE

(Fig. 31.2 and Table 31.1)

Anticoagulation should be instituted in the absence of contraindications (active bleeding, very high risk of bleeding) if a symptomatic proximal SVTE, pulmonary embolism or right atrial thrombosis is clinically suspected and until diagnosis can be confirmed. In addition anticoagulation therapy should be considered if an asymptomatic proximal SVTE is diagnosed during radiographic imaging performed for other reasons (i.e., diagnosis of malignancy, echocardiography to determine cardiac anatomy, cardiac catheterization).

Thrombolysis should be strongly considered in the case of PE or massive SVTE where risk of loss of life, organ or limb is diagnosed.

First-event SVTE

“Heparin therapy” should be used as initial treatment. Intravenous unfractionated heparin should be infused and the dose titrated to achieve therapeutic levels (see monitoring). (Grade 1C recommendation; see above). Initial treatment with heparin should continue for 5–10 days (Grade 1C) prior to proceeding with warfarin or longer-term LMWH. Duration of anticoagulant therapy is extrapolated from adults, and 3 months of therapy is recommended (Grade 2C).

SVTE secondary to risk factor(s)

If risk factors persist, such as the presence of a CVL, L-asparaginase therapy, lupus anticoagulant or nephritic syndrome, continue anticoagulant therapy in prophylactic or therapeutic doses until the risk factor is resolved (Grade 2C).

Caution: Do not use thrombolytic therapy routinely for SVTE due to the risk of major bleeds associated with its use (Grade 2C).

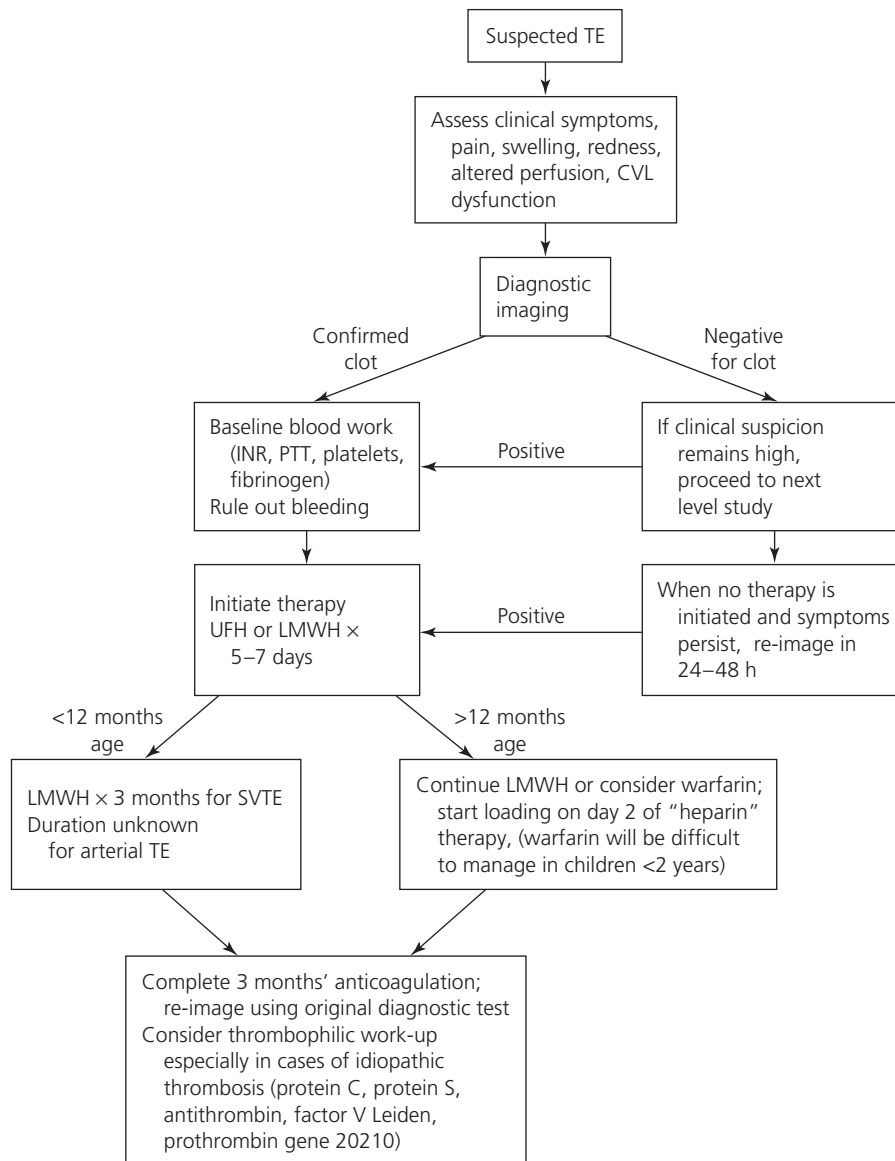

Fig. 31.2 Diagnostic and therapeutic protocol for systemic venous thromboembolism (SVTE). CVL, central venous line; INR, international normalized ratio; LMWH, low-molecular-weight heparin; PTT, partial thromboplastin time; TE, thromboembolism; UFH, unfractionated heparin.

Recurrent SVTE secondary to risk factor(s) while on anticoagulant therapy

Continue anticoagulation for an additional 3 months from the diagnosis of recurrent thrombosis or until removal of the precipitating risk factor.

CVL-related SVTE

If the CVL is not required or is nonfunctioning, remove the catheter following a minimum of 3–5 days of anticoagulant therapy (Grade 2C) to reduce the risk of embolism. Treat with heparin therapy as per first-event SVTE (see above). Treat with anticoagulant therapy for 3 months. If the CVL is functioning and is still required, it may be left in place (Grade 2C).

Idiopathic SVTE

Treat with heparin therapy as per first-event SVTE (see above). Treat with anticoagulant therapy for a minimum of 6 months (Grade 2C).

Recurrent SVTE

Treat with heparin therapy as per first-event SVTE (see above). Treat with anticoagulant therapy for an indefinite duration (Grade 2C).

Treatment of SVTE in neonates

Administer heparin therapy or follow with radiographic monitoring to ensure no extension of thrombus. If the

thrombus extends, treat with heparin therapy using UFH or LMWH for 10 days to 3 months (Grade 2C).

CVL prophylaxis

Primary prophylaxis is not recommended (Grade 1B) in any clinical situation at present.

Systemic arterial thromboembolic events

(Table 31.2)

Epidemiology

The epidemiology of SATE has not been well studied.

Etiology

The most common etiology is the presence of an arterial line.³⁹ Arterial lines placed in the femoral artery or peripheral arteries often result in SATE.

- Arterial lines placed in the umbilical artery may result in aortic thrombosis.
- Femoral arterial catheters are placed in infants and children for therapeutic or diagnostic cardiac catheterization and often result in femoral arterial thrombosis.
- Peripheral arterial catheterization is carried out in critically ill infants and children for blood pressure monitoring and can result in vessel thrombosis.
- Occlusion of the radial artery rarely results in loss of the hand if the ulnar artery is patent.

Clinical symptoms

Differential diagnoses within 24 hours of arterial catheter placement are vascular spasm or SATE. Symptoms of vascular spasm or SATE include decreased or absent pulses, pale or mottled limb and decreased capillary refill. Vascular spasm usually resolves within a few hours with no therapy. SATE only resolves with anticoagulation therapy, and should be confirmed by ultrasound.

Outcomes

SATE is associated with mortality or morbidity in children. Short-term morbidity may include tissue ischemia followed by tissue necrosis and nonviability of the affected organ or limb. If vascular occlusion persists, loss of limb function, and occasionally surgical limb amputation, organ and tissue damage, are reported. Additionally, symptoms of SATE may occur at remote sites due to embolic events.

Long-term morbidities include leg length discrepancy, muscle wasting, claudication and loss of arterial access. Loss of access will present significant morbidity for children who require multiple interventional cardiac catheterizations.^{40,41}

Classification

SATE unrelated to catheter use

Arterial thrombotic events are reported in the presence of congenital familial hyperlipidemia. Acquired conditions that are risk factors for development of SATE include Takayasu

Table 31.2 Arterial thromboembolism: incidence, diagnosis and therapeutic considerations.

Arterial thromboembolic event (TE)	Incidence	Diagnosis	Pretherapy considerations	Therapy
Femoral artery TE secondary to CC	Femoral artery 40% with no prophylaxis post-CC, 5% with prophylaxis	<i>Clinical:</i> Pain, swelling, pale, cool pulseless leg. Handheld Doppler may be used to assess pulses. Black leg may indicate irreversible tissue ischemia <i>Diagnostic:</i> US (albeit poor sensitivity). If US negative and clinical suspicion high proceed to MRA or angiogram	As for SVTE in Table 31.1	As for SVTE in Table 31.1 Duration of therapy unknown
Peripheral artery TE	Unknown	As above with arterial TE secondary to CC	As for SVTE in Table 31.1	As for SVTE in Table 31.1 Duration of therapy unknown
Umbilical artery (UA) TE secondary to UA catheter	1% symptomatic 3–59% on autopsy 10–90% incidental finding on ultrasound	<i>Clinical:</i> Pale, cool, pulseless lower limb(s) Renal dysfunction	As for SVTE in Table 31.1	As for SVTE in Table 31.1 Duration of therapy unknown

CC, cardiac catheterization; MRA, magnetic resonance angiography; US, ultrasound.

arteritis, Kawasaki disease, congenital heart disease and arterial thrombosis in transplanted organs.⁴²

SATE secondary to arterial catheters

Umbilical artery catheters

Umbilical artery catheters (UACs) are used in critically ill neonates for supportive care and hemodynamic monitoring. Vascular complications include local thrombosis of the aorta. The use of UACs with end holes results in less aortic thrombosis compared with catheters with side holes.⁴³ Thromboembolism to organs or limbs may result causing compromise or nonviability of the limb, and necrotizing enterocolitis.

There is no evidence that catheter tip location influences the incidence of thromboembolic events.^{44–49} Peripheral arterial lines may result in local thrombosis (see Peripheral artery catheterization, below).

Prophylaxis

- Low-dose heparin infusion (1–5 units/h) through the UAC should be used to improve patency^{50–53} and UAC-related SATE (Grade 2A recommendation; see above).
- Intermittent flushes with heparin are ineffective in preventing UAC occlusion.⁵⁴

Cardiac catheterization

Cardiac catheterization (CC) is used in children with congenital and acquired heart disease for diagnostic or therapeutic purposes. Most often, the superficial femoral artery is cannulated. In rare situations, the brachial artery is accessed.⁵⁵ The incidence of local thrombosis secondary to CC, without periprocedural heparin prophylaxis (after removal of the arterial sheath), is 40%, and with heparin prophylaxis is 5%.⁵⁶ There are a number of risk factors affecting the incidence of SATE, including:

- age (infants have a higher risk);
- duration of procedure;
- catheter to vessel proportion;
- larger sheath size than recommended for a given weight and body surface area;
- use of balloon dilatation;
- repeated catheter manipulations;
- increased hematocrit.^{56–61}

Recommendations for prophylaxis

If CC is performed using arterial access, the following guidelines are recommended.

- Intravenous UFH therapy (Grade 1A) as a bolus of 100–150 units/kg during CC (Grade 2B).⁵⁶
- Acetylsalicylic acid (ASA) alone for thromboprophylaxis for CC should not be used (Grade 1B).⁶²

Peripheral artery catheterization

Peripheral artery catheterization (PAC) is used in children

in an intensive care setting for monitoring as well as blood sampling.³⁰ Complications include thrombotic occlusion of the vessel and loss of patency of the arterial catheter,⁶³ with clinical symptoms as follows:

- decreased temperature;
- pale color;
- increased capillary refill time;
- blood pressure differential > 10 mmHg between limbs.

Prophylaxis

- Infuse continuous heparin 1 unit/mL through the peripheral arterial catheter to improve catheter patency (Grade 1A).^{61,64–67}
- There are no studies establishing the safety and efficacy of any agent (including low-dose heparin infusion) for the prevention of SATE due to PAC.

Diagnosis (Fig. 31.2)

The gold standard test to diagnose SATE is angiography, but this is difficult to perform in children with existing critical illness.^{68,69} The newer contrast agents are less hypertonic than those used previously allowing safer use in younger children. Other objective tests have not been tested in children for sensitivity and specificity: Doppler ultrasound and hand-held Doppler at the bedside may be useful to determine absent pulses. Blood pressure differential between two limbs of at least 10 mmHg⁶⁸ may also indicate SATE.

Treatment recommendations (Fig. 31.2 and Table 31.2)

Acute SATE secondary to catheter placement (UAC, CC or PAC)

Remove the arterial catheter from any anatomic location immediately if arterial occlusion is suspected (pale or cyanosed skin, decreased or absent pulses, increased capillary time). Treatment options include anticoagulation, thrombolysis or thrombectomy.

- Therapeutic doses of intravenous heparin are effective in 70% of cases of SATE,⁷⁰ and should be administered in the absence of contraindications (Grade 1C) (see Unfractionated heparin therapy, below).
- If life, organ or limb is threatened due to arterial thrombosis, in the absence of contraindications, thrombolysis therapy should be considered (Grade 1C) (see Thrombolytic therapy, below).
- In selected cases of femoral artery thrombosis, surgical intervention should be carried out (e.g., in cases where there is a contraindication to thrombolytic therapy or where organ or limb loss is imminent) (Grade 2C).
- Thrombolytic therapies that have been used successfully after CC include streptokinase,^{70–74} urokinase,⁷⁰ and tissue

Table 31.3 Thrombolytic dosing.

Agent	Load	Maintenance	Monitoring
Urokinase	4400 units/kg	4400 units/kg/h for 6–12 h	Fibrinogen, TCT, PT, APTT
Tissue plasminogen activator	None	0.1–0.6 mg/kg/h for 6 h	Same

APTT, activated partial thromboplastin time; PT, prothrombin time; TCT, thrombin clotting time.

plasminogen activator (tPA).^{75–77} The incidence of major bleeding has been reported to be as high as 30% (Table 31.3).⁷⁸

- The risk of bleeding may be reduced by pretreating children about to receive tPA with 10 mL/kg fresh frozen plasma (FFP), and limiting the tPA infusion (0.5 mg/kg/h) to 6 hours maximum.
- If thrombectomy is used in small children, there is high risk of arterial reperfusion injury.
- If arterial occlusion persists despite UFH therapy, thrombolytic therapy should be started if no contraindications are present (active bleeding, disseminated intravascular coagulation, central nervous system bleed). UFH therapy should be initiated postembolectomy to prevent vascular reocclusion (Grade 1C).

Surgical management for long-term outcomes of SATE

Reconstructive surgery should be considered if there is clinically significant claudication accompanied by muscle wasting and/or shortening of the limb. Options for reconstructive surgery include thrombectomy with autogenous saphenous vein patch angioplasty, direct angioplasty, segmental resection with end-to-end anastomosis, and interposition bypass grafting.⁷⁹

Before reconstructive surgery, the vascular anatomy of the affected leg should be established using Doppler ultrasound and possibly angiography via the contralateral femoral artery.

Medical treatment: anticoagulant agents

Practical tips for managing anticoagulation in children

Before initiating anticoagulation therapy, obtain the patient's weight (kg) and take a sample of blood for hemoglobin, platelets, international normalized ratio (INR), APTT, urea and creatinine. Note that "heparin" is a descriptive term referring to all heparins, including UFH and LMWH.

Certain precautions must be taken when dealing with an anticoagulated child.

- Avoid intramuscular injections and arterial punctures if possible. If necessary, use extended periods (minimum 5 min, firm pressure) of external pressure to decrease bleeding.

- If analgesia is required, avoid antiplatelet agents (e.g., ibuprofen). Acetaminophen (paracetamol) is acceptable.
- If long-term warfarin is to be used (>12 months) (e.g., in case of mechanical heart valves), bone densitometry studies at baseline and then every 12 months should be considered to assess for possible osteoporosis.⁸⁰ There are no data in humans on the effect of LMWH therapy on bone mineral density.^{81–83}
- Age-appropriate education should be given to the child regarding anticoagulation risk, benefit and monitoring, and this will decrease complications associated with therapy.^{84–88}

Anticoagulant agents

Unfractionated heparin

The advantage of using UFH in children is its short half-life (4 hours), which permits rapid cessation of anticoagulation by simply discontinuing the infusion, and gives the ability to rapidly reverse anticoagulant effects by using protamine sulfate when immediate reversal is necessary.

Caution: UFH is supplied in multidose vials in increasing concentrations with similar packaging. Extreme caution should be used when dispensing heparin doses to ensure the correct concentration is being used to avoid administering an overdose.

Mode of action and guidelines for administration

The anticoagulant activities of heparin are mediated by catalysis of antithrombin. In children, antithrombin (AT) levels may be low, reflecting physiologic, congenital and/or acquired etiologies. To achieve a heparin effect, the addition of AT may be necessary, as either FFP (1 unit/mL) or AT concentrate. Heparin dosing and monitoring guidelines are adapted from adults. Dosing of heparin in children will probably differ from adults, but further studies are needed to delineate this.^{6,89}

It is important to note the following.

- Monitor hemoglobin and platelets daily due to the risk of developing heparin-induced thrombocytopenia.
- A dedicated intravenous line is necessary for UFH infusions; this intravenous line must not be stopped for other medications, in order to maintain constant heparin levels.

Table 31.4 Heparin dosing nomogram.^{39,153}

APTT (s)	Anti-factor Xa (units/mL)	Heparin hold (min)	Heparin rate change	After 4h repeat APTT
<50	<0.1	0	Increase 20%	4 h
50–59	0.1–0.34	0	Increase 10%	4 h
60–85	0.35–0.70	0	0	24 h
86–95	0.71–0.89	0	Decrease 10%	4 h
96–120	0.90–1.20	30 min	Decrease 10%	4 h
>120	>1.20	60 min	Decrease 15%	4 h

APTT, activated partial thromboplastin time.

Intravenous dosing (Table 31.4)

1 In cases of acute PE or acute SVTE, a bolus of UFH should be administered by using 75 units/kg over 10 min followed by an age-appropriate infusion.

2 Maintenance heparin doses are age dependent:

(a) infants (28 weeks' gestational age to 12 months of age), 28 units/kg/h;

(b) children > 12 months of age, 20 units/kg/h.⁹⁰

Subcutaneous dosing

- Therapeutic UFH may be administered subcutaneously.⁹¹
- The daily dose (units/kg/h) is divided into two doses and is given subcutaneously every 12 hours.
- Dosing is calculated using the formula below:

Dose = patient weight × age-dependent dose of heparin (i.e., 20 units/kg/hr for children > 12 months of age or 28 units/kg/hr for children < 12 months of age) × the number of hours to be covered (maximum = 12 hours)

UFH as a "bridge" anticoagulant

Reversal of anticoagulant therapy for invasive procedures^{92,93} can be carried out using UFH as a "bridge" anticoagulant in children who are receiving LMWH or warfarin and who are at high risk for thromboembolic disease.

Monitoring

If possible, an anti-FXa and an APTT should be drawn within 24 hours of initiating therapy to ensure that the APTT is accurately reflecting the UFH concentration. Therapeutic levels need to be achieved and maintained for effective anticoagulant therapy. It has been shown that APTT (s) and anti-FXa levels (units/mL) correspond in 70% of children but rarely in children < 12 months of age.⁹⁴ Among infants and children, if the APTT and anti-FXa levels do not correspond, then UFH therapy should be monitored using anti-FXa levels.

- APTT or anti-FXa level (venous sample not from arterial or central venous line) should be drawn 4–6 hours after initiation of therapy. Once in the therapeutic range, monitor APTT or anti-FXa at least every 24 hours as the bioavailability of UFH is poor.
- Adjust the UFH infusion to maintain anti-FXa at 0.35–

Table 31.5 Reversal of heparin therapy.

Time since end of infusion, or last heparin dose	Protamine per 100 units unfractionated heparin dosed (maximum 50 mg/dose)
<30 min	1 mg
30–60 min	0.5–0.75 mg
61–120 min	0.375–0.5 mg
>120 min	0.25–0.375 mg

Reproduced with permission from Ref. 1.

0.7 units/mL or an APTT that corresponds to the therapeutic anti-FXa range in the treating institution.^{90,91}

- Subcutaneous UFH is monitored using either the APTT or anti-FXa level measured at 6 hours after the subcutaneous dose and adjusted according to the nomogram shown in Table 31.4.

Table 31.4 is an example of a heparin-dosing nomogram where the therapeutic APTT is 60–85 s.

Reversal and antidote for UFH (Table 31.5)

If anticoagulation with UFH needs to be discontinued for clinical reasons, termination of the UFH infusion will usually suffice because of the rapid clearance of UFH. If an immediate effect is required, consider administering protamine sulfate. Intravenous protamine sulfate neutralizes heparin activity by virtue of its positive charge within 5 minutes of administration. The dose of protamine sulfate required to neutralize UFH is based on the dose of UFH received in the previous 2 hours as shown in Table 31.5.

Caution: the maximum dose of protamine sulfate, regardless of the amount of UFH received, is 50 mg.

- Administration should not exceed a rate of 5 mg/min of a 10 mg/mL concentrated solution.
- Hypersensitivity reactions may occur in children with known hypersensitivity reactions to fish, and those who have received protamine-containing insulin or previous protamine therapy.
- Perform an APTT 15 min after administration to determine the effect of administration.¹

Table 31.6 Enoxaparin dosing nomogram: initial dose.^{105,106}

	Age ≤2 months	Age ≥2 months to 18 years
Initial prophylactic dose	0.75 mg/kg/dose s.c. every 12 h or 1.5 mg/kg/dose s.c. once daily	0.5 mg/kg/dose s.c. every 12 h or 1 mg/kg/dose s.c. once daily
Initial treatment dose	1.5 mg/kg/dose s.c. every 12 h	1 mg/kg/dose s.c. every 12 h
Maximum suggested dose	3 mg/kg/dose s.c. every 12 h	2 mg/kg/dose s.c. every 12 h

The therapeutic level of anti-factor Xa for Enoxaparin treatments is 0.5–1 units/mL.^{91,153}

Heparin-induced thrombocytopenia

There are case reports of heparin-induced thrombocytopenia (HIT) in children from ages 3 months to 15 years.^{95–101} Many infants and children in neonatal or pediatric intensive care units who are exposed to heparin have multiple reasons for thrombocytopenia and/or thrombosis, thus a high index of suspicion is required to diagnose HIT. During heparin therapy, the platelet count should be measured daily. If platelet counts decrease by more than 50% from baseline and clinical suspicion for HIT is high, then *all* sources of heparin should be discontinued and a HIT screen should be sent.

Danaparoid, hirudin and argatroban may be used as alternatives to heparin in children with HIT, although there is a paucity of dosing data.^{81,97,99,102,103}

Low-molecular-weight heparin

The use of LMWH should be considered in most children requiring anticoagulation. The potential advantages of LMWH for children include:

- minimal monitoring required due to good bioavailability (important in pediatric patients with poor or nonexistent venous access);
- lack of interference by other drugs or diet, unlike warfarin;
- reduced risk of HIT;
- probable reduced risk of osteoporosis with long-term use compared with heparin.

Dosing guidelines

The following are guidelines for initiating and monitoring enoxaparin therapy; modifications for individual clinical circumstances may be necessary. The dosage guidelines given in Table 31.6 apply to enoxaparin only and cannot be directly extrapolated to other LMWH products. The following precautions must be taken.

- LMWH is cleared renally. The blood creatinine level should be measured prior to initiating LMWH therapy. If renal compromise/failure is present, LMWH may be used cautiously.^{104–108}
- Side-effects associated with subcutaneous administration of LMWH are bleeding and bruising and hematoma formation at the administration site. Firm pressure for 3–5 min at the administration site will minimize these side-effects. Do not massage the site after administration.

Monitoring

Therapeutic range doses of LMWH are extrapolated from adults and are based on anti-FXa levels. The guidelines for therapeutic LMWH suggest maintaining an anti-FXa level of 0.5–1.0 units/mL in a sample taken 4–6 hours following a subcutaneous injection. Anti-FXa levels reflect the pharmacodynamic activity of the LMWH but do not accurately reflect its antithrombotic activity.¹⁰⁶ Table 31.7 provides guidelines for dose adjustment of enoxaparin.

Table 31.7 Enoxaparin dosing nomogram: dose adjustment.^{105,153}

Anti-FXa level	Hold next dose?	Change dose?	Next anti-FXa level?
<0.35 units/mL	No	Increase by 25% (round up to whole number*)	4 hours after next morning dose
0.35–0.49 units/mL	No	Increase by 10% (round up to whole number*)	4 hours after next morning dose
0.5–1 units/mL	No	0	Once a week at 4 hours after morning dose
<1.2 units/mL	No	Decrease by 20% (round down to whole number*)	4 hours after next morning dose Hold dose. Do a trough level. If trough < 0.5 units at 10 h post-dose, administer scheduled dose at 20% of previous dose

Note: the above nomogram assumes that there is no bleeding or renal compromise.

* When adjusting doses of enoxaparin, dose adjustments can be ordered in 1.0-mg increments (if monitoring results are available on a daily basis) to achieve targeted anti-FXa level.

Fig. 31.3 Insuflon catheter *in situ* demonstrating administration of low-molecular-weight heparin with an insulin syringe.

Monitor anti-FXa levels monthly and adjust dose accordingly. This is necessary in the pediatric population as children gain weight and outgrow current doses; also it avoids drug accumulation over time in renal compromise.¹⁰⁹

Practical tips for administration of LMWH therapy in infants and children

- Administration of enoxaparin using an insulin syringe with a short ultrafine (⁵/₁₆ inch, 8 mm) needle is easy for parents/guardians as well as health professionals; 1 mg of drug corresponds to 1 unit on the syringe. This may assist in reducing measuring error and side-effects such as bleeding, bruising and hematoma formation at the administration site. Similarly, an insulin syringe may be used for all LMWH with accurate calculations for dose measurement. The calculation for conversion is 0.01 ml = 1 unit on an insulin syringe.
- An Insuflon catheter (Fig. 31.3) may be used for subcutaneous therapy. This device is an indwelling subcutaneous vinyl catheter that is inserted into the subcutaneous tissue and which may remain in place for 3–7 days.
- Firm pressure should be applied to the heparin administration site for a minimum of 5 min following each dose.
- The Insuflon port site must be monitored closely for any bleeding, bruising, leakage or subcutaneous hematoma formation. If any of these are present, the Insuflon must be changed before administering the next dose. The use of an insulin syringe allows easier administration of drug through the port.
- The goal is to assist the parent or guardian to become independent in the safe administration of their child's heparin therapy and facilitate early discharge from hospital.

Reversal and antidote of LMWH

Unless immediate reversal is necessary, withholding two doses will suffice to reverse the anticoagulant affect. If

immediate reversal of effect is required, protamine sulfate reverses 80% of the anti-FXa activity of LMWHs.¹¹⁰

Warfarin

The INR ranges for children are extrapolated from the recommendations for adult patients, which is not appropriate due to the differences in the coagulation cascade between children and adults. However, there are no clinical trials that have assessed the optimal INR ranges for children based upon clinical outcomes. The recommended target INR for treatment of VTE is 2.5 (range 2.0–3.0), and 3.0 (range 2.5–3.5) for most children with mechanical heart valves.¹¹¹

Monitoring

Frequent monitoring of oral anticoagulant therapy in children is required due to a number of factors affecting warfarin metabolism, including diet, medications and primary medical problems. Warfarin administration in children requires close supervision, with frequent dose adjustments by experts in anticoagulation.^{112,113} Breast-fed infants are very sensitive to oral anticoagulants due to the low concentrations of vitamin K in breast milk.^{114–117} It is recommended that these children receive daily vitamin K supplements in the form of 50 mL of commercial formula. In addition, variations in daily intake for infants and young children increase the challenge of managing warfarin in this population. As an alternative, LMWH therapy may be considered. Some children are resistant to oral anticoagulants due to impaired absorption. Similarly, infants and children who are receiving infant or pediatric nutritional formulas will be resistant to oral anticoagulants as these preparations are routinely enhanced with Vitamin K. These challenges that are associated with managing warfarin therapy have resulted in the recommendation that warfarin should not be used in children under 12 months of age, except in infants with mechanical heart valves.

Initial warfarin loading dose (Table 31.8)

The child should be tolerating a full diet prior to initiating warfarin therapy. Most children will overshoot the target INR if full feeds are not tolerated. In children who are not tolerating full feeds, LMWH may be used until dietary toler-

Table 31.8 Warfarin dosing nomogram: loading phase.¹⁰³

INR	Action
<i>Following the initial loading dose, if the resultant INR is:</i>	
1.1–1.4	Repeat initial dose
1.5–2.9	50% of initial dose
>3.0	Hold until INR < 2.5 then restart at 50% less than the previous dose

Note: these dose reductions are critical to avoid “overshooting” the target range. INR, international normalized ratio.

Table 31.9 Warfarin dosing nomogram: maintenance phase for target international normalized ratio (INR) of 2.5¹⁵⁴

INR	Action
1.1–1.4	Check for compliance; if compliant increase dose by 20%
1.5–1.9	Dose increase by 10%
2.0–3.0	No change
3.1–3.5	Dose decrease by 10%
>3.5–4.0	Administer one dose at 50% less than maintenance dose. Then restart at 20% less than the maintenance dose
4.1–5.0	Hold $\times 1$ dose then restart at 20% less than maintenance dose
>5.0	Consider reversal with vitamin K

Note: in the case of mechanical heart valves where the target INR is 3.0, the above nomogram may be used by adjusting the INR range up by 0.5. For example, the INR range of 1.1–1.4 would correspond to 1.6–1.9 with a dose adjustment increase of 20%.

ance is achieved. This practice will result in accomplishing the warfarin maintenance phase safely and efficiently.

- In most children, the loading dose is 0.2 mg/kg p.o. as a single daily dose, with a maximum of 5 mg.¹⁰³
- In children with liver dysfunction or post-Fontan procedure, the loading dose should be reduced to 0.1 mg/kg p.o. as a single daily dose.

Practical tips for managing warfarin therapy in children

- If the INR is > 3.0 after the first or second loading dose, withhold warfarin, repeat the INR, then restart at 50% of the previous dose, providing the child is tolerating feeds.
- If the INR is not greater than 1.5 after two loading doses, increase the dose by 50% and follow the nomogram given in Table 31.8.

Long-term warfarin: maintenance dosing guidelines

The dosing guidelines for long-term maintenance of warfarin are given in Table 31.9. These apply primarily to medically stable patients already established on long-term maintenance therapy. Medically unstable patients or those completing the loading protocol may respond differently. Close monitoring with individualized dose adjustment of such patients is essential until they are clearly established on maintenance therapy.

Point-of-care testing using INR monitors

Whole-blood monitors provide an effective means of monitoring INRs in children on long-term oral anticoagulant therapy when there is a needle phobia or poor venous access. The INR is measured using a capillary blood sample. Point-of-care INR monitors have been evaluated in children and were shown to be acceptable and reliable for use in the outpatient laboratory and at-home settings.^{82,83,106}

The amounts of capillary blood required for INR testing in

**Fig. 31.4** Coaguchek (Roche Diagnostics) monitor for measuring INR using capillary whole blood samples.**Fig. 31.5** PROTIME Monitor (ITC) used to check INR using capillary whole blood samples.

the Coaguchek monitor (Fig. 31.4) and the PROTIME monitor (Fig. 31.5) are 10 μ L and 27 μ L, respectively.

Warfarin reversal for outpatients with INR > 6.0

It is helpful to discharge the child with a prescription for vitamin K to treat elevated INRs at home. A vitamin K elixir is available in some centers, although an ampoule of vitamin K 10 mg for intravenous use may be given orally. Oral administration of vitamin K is found to be most effective¹¹⁸ The nomogram given in Table 31.10 is based on adult recommendations. Repeat the INR within 24 hours.¹¹⁹

Reversal and antidote of warfarin

- For nonurgent reversal of warfarin withhold three doses (for children with mechanical valves consider subcutaneous unfractionated heparin 60 hours after the first dose is withheld).
- When urgent reversal is needed (e.g., in case of major bleeding or interventional procedure), administer FVIIa 50 units/kg i.v. (there are no safety or efficacy data) or FFP 20 mL/kg i.v.
- In case of nonurgent reversal, give vitamin K₁ 0.5–2 mg orally, depending upon the patient's size. The administra-

Table 31.10 Vitamin K dosing nomogram.

Child's weight	INR	Vitamin K dose
≤20 kg	6–10	0.5 mg orally
≤20 kg	>10	1.0 mg orally
>20 kg	6–10	1.0 mg orally
>20 kg	>10	2.0 mg orally

Note: dosing recommendations assume no active bleeding. If there is active bleeding, increase dose by 100% and consider fresh frozen plasma. Doses greater than those noted in the table should be used with caution in children with mechanical heart valves.

tion of vitamin K intravenously or intramuscularly has been shown to be less efficacious than oral administration unless gut absorption is severely compromised.

Thrombolytic therapy

Systemic thrombolytic therapy is indicated for clinical situations where there is potential loss of life, organ or limb, such as arterial occlusions, massive PE, or PE not responding to heparin therapy.¹²⁰ It may also be indicated for acute extensive SVTE.¹²⁰ The contraindications to thrombolytic therapy must be considered; however, in some patients the need for thrombolytic therapy may necessitate treatment in spite of contraindications. If possible, before the use of thrombolytic therapy, discuss with the family the high incidence of major bleeding (30%).

Contraindications

Thrombolytic therapy has various contraindications.

- Active bleeding.
- Significant potential for local bleeding (e.g., tumor surrounding vessel with clot), general surgery within the previous 10 days, neurosurgery within the previous 3 weeks.
- Hypertension.
- Arteriovenous (AV) malformations.
- Recent severe trauma.

Caution: streptokinase is not recommended in children due to potential anaphylactic reactions. Urokinase has recently been released in recombinant form.

Prior to commencing thrombolytic therapy

A range of measures must be taken before embarking on thrombolytic therapy.

- Complete blood count, platelet count, APTT, fibrinogen, cross-match and type for 1 unit of packed red blood cells (PRBC).
- Children have less plasminogen compared with adults. Before thrombolytic therapy, ensure plasminogen levels are adequate to achieve the desired lytic effect by administering FFP at 10–20 mL/kg.

- Admit to the pediatric intensive care unit or a designated floor identified for thrombolytic therapy.
- Consider sedation depending on the child and clinical circumstances.
- Place a sign at the head of the bed indicating that the patient is receiving thrombolytic therapy.
- Notify the blood bank to ensure cryoprecipitate is available.
- Ensure good venous access for drug administration and for monitoring purposes.

Thrombolytic dosing and therapy guidelines

During thrombolytic infusion, UFH 10–20 units/kg/h should be administered concurrently with either the tpa or urokinase (lytic drug of choice) infusion. If the patient is not already on heparin, start heparin infusion but do not give a bolus dose (Table 31.3). If catheter-directed local thrombolytic therapy is used, it is suggested that the dose is decreased by 50%. In children, there is no evidence for increased efficacy or safety with local dosing.

The following therapeutic guidelines should be observed.

- No intramuscular injections during therapy.
- Minimal manipulation of the patient, e.g., no bathing or physiotherapy.
- Avoid concurrent use of warfarin or antiplatelet agents (e.g., aspirin, dipyridamole, clopidogrel).
- No urinary catheterization, rectal temperature measurements, or arterial punctures.
- Take blood samples from a superficial vein or indwelling catheter. If blood sampling is difficult, insert an indwelling catheter for blood samples prior to thrombolytic therapy.
- Reevaluate radiographically following 6 hours of infusion (for arterial thrombi use the return of pulses and blood pressure to preinvestigation values).
- Monitor the response to thrombolytic therapy by the PT/INR, APTT and fibrinogen level if bleeding and every 6–8 hours after the start of infusion.
- Expect the fibrinogen concentration to decrease by at least 20–50%; maintain the fibrinogen concentration at approximately 1 g/L by infusions of cryoprecipitate (1 unit/5 kg bodyweight).
- If there is no change in the fibrinogen concentration, check D-dimers to ensure that a thrombolytic state has been established.
- Maintain the platelet count > 50–100 × 10⁹/L.

Prothrombotic disorders

Congenital prothrombotic disorders

The need to screen for prothrombotic disorders in children with major illnesses, who are undergoing an invasive procedure or who have confirmed thrombosis, especially in the

presence of clinical risk factors, remains uncertain. In general, homozygous deficiency of antithrombin, protein C and protein S will present in the neonatal period. Large family studies in patients with protein C, protein S, antithrombin, FV Leiden and prothrombin gene 20210 defects found negligible rates of SVTE in children <15 years of age.¹²¹ However, cross-sectional disease-oriented studies estimate the prevalence of congenital prothrombotic disorders in children with secondary SVTE to be 13–78%, depending on the population of children studied.¹²² FV Leiden homozygosity may be associated with SVTE in children.^{123–129} Venous and arterial thrombotic events are reported more in the presence of congenital familial hyperhomocysteinemia.

- Most children with prothrombin gene mutation 20210 do not develop thrombosis until adult life.¹²¹
- Excessive plasma levels of homocysteine due to homozygous deficiencies of enzymes such as cystathionine β -synthase or methylenetetrahydrofolate reductase may be associated with severe SVTE in children.^{130,131}
- Increased plasma levels of lipoprotein(a) in children have been reported in cohorts of children with SVTE.¹³²

Acquired prothrombotic disorders

Prothrombotic states can arise as the result of other conditions or therapies.

- The incidence of SVTE in children with nephrotic syndrome is at least 10% when using objective radiographic methods.¹³³
- There is an association between antiphospholipid antibodies and SVTE in children.
- The use of L-asparaginase and steroids in acute lymphoblastic leukemia therapy has been associated with VTE, possibly due to decreased antithrombin levels.

Heart disease in children and thrombosis

A number of different cardiac surgical procedures are used to palliate congenital heart disease. The shunts that are placed during these procedures vary in diameter, flow characteristics and composition, and are associated with the development of thrombosis. These include the following.

- Norwood procedure (Blalock–Taussig shunt, right ventricle–pulmonary artery conduit): Blalock–Taussig shunts are often as small as 2.5–3.0 mm, which results in abnormal blood flow.
- Glenn procedure (bicaval pulmonary): gortex is often used as the synthetic material for the extracardiac shunts.
- Sanno procedure (extracardiac right ventricle–pulmonary artery conduit).
- Fontan procedure (extracardiac shunt either fenestrated (right-to-left dynamic cardiac connection)) or nonfenestrated (no right-to-left dynamic cardiac connection). Blood flow is often very slow in the shunts placed during the Fontan procedure. A review of the literature revealed up to 20% incidence of

thromboembolic complications (shunt thrombosis, stroke and pulmonary embolism) in children following the Fontan procedure.

Primary prophylaxis in children with cardiac shunts

Norwood procedure

For children undergoing this procedure the recommended prophylactic regimen is intraoperative heparin followed by either aspirin (5 mg/kg/day) or no further anticoagulant therapy (Grade 2C). The duration of therapy, and the need for ongoing aspirin therapy are unknown.³⁹

Glenn procedure

Current clinical practices vary, and include both no anticoagulation and heparin followed by aspirin. There is no evidence to support a preference for either of these approaches at this time.

Fontan procedure

The results of a multicenter randomized controlled trial comparing ASA (5 mg/kg daily) and heparin followed by warfarin (target INR 2.5) in children post-Fontan procedure are being analyzed.^{39,134,135} The recommendation is aspirin (5 mg/kg daily) or therapeutic heparin followed by vitamin K antagonists to achieve a target INR of 2.5 (range 2–3) (Grade 2C).

Mechanical prosthetic heart valves in children

Cardiac valvular disease occurs as an isolated congenital event, as part of complex coronary heart disease, or as a result of treatments for an underlying cardiac disorder. Thrombosis of the valve or embolization to the central nervous system are both serious complications of mechanical prosthetic heart valves.^{136–143} Currently, mechanical prosthetic heart valves are usually used in the mitral and aortic position while biologic prosthetic heart valves are used for tricuspid or pulmonary valve replacements in children.

Randomized controlled trials in adults with mechanical prosthetic heart valves have clearly delineated the need for oral anticoagulants with an INR of 2.5–3.5.^{144–146} Antiplatelet agents have a role if there is more than one valve or a thromboembolism has occurred with a therapeutic INR.¹⁴⁷ There are no randomized controlled trials in children, only case series. In the absence of oral anticoagulants, and in the presence of no therapy or antiplatelet therapy alone, the incidence of thromboembolism is unacceptably increased in some studies.^{148,149} Only oral anticoagulants consistently maintained the incidence of thromboembolism at <5% per patient year, which is similar to that for adults.^{148,150–152}

With the use of oral vitamin K antagonists, major bleeding was <3.5% per patient year. Aspirin in combination with oral anticoagulants may be helpful in high-risk patients such as those with prior thromboembolism, atrial fibrillation, a large left atrium and/or multiple mechanical prosthetic heart valves.

Treatment recommendation

The following regimen is recommended for children with mechanical prosthetic heart valves.

- Oral anticoagulation to maintain a target INR of 2.5 (Grade 1C+).
- In children where additional antithrombotic therapy is required due to failure of vitamin K antagonists or there is a contraindication to full-dose vitamin K antagonists, use aspirin (6–20 mg/kg daily) (Grade 2 C).

Conclusions

Venous and arterial thrombosis is being increasingly diagnosed in children. The serious sequelae, including mortality and morbidity, result in the recommendation of therapy in children with thrombosis. However, the anticoagulant and thrombolytic agents used in children have had few properly designed studies to determine their age-related pharmacokinetics and provide estimates of safety and efficacy. The recommendations for the use of these agents – dosing, monitoring, duration and intensity – are based on results from adult studies. This extrapolation is inappropriate and may be exposing children to improper intensity and duration of antithrombotic agents. The difficulty in performing pediatric clinical trials should not preclude properly designed clinical studies in cohorts of children at risk for thrombosis or with thrombosis, to determine the safety and efficacy of prophylaxis and therapy.

Blood components and fractionated plasma products: preparation, indications and administration

Nancy Robitaille and Heather A. Hume

Blood component transfusion is an integral part of the treatment plan of many of the children and adolescents cared for by the pediatrician or the pediatric hematologist/oncologist. Physicians responsible for the transfusion of blood components should have a basic understanding of the components they prescribe, including the method of preparation, contents, the correct storage conditions, indications and contraindications for use, and procedures for administration. Physicians prescribing blood components should also be knowledgeable about the potential adverse effects of these products including requirements for further modifications of certain components, such as gamma-irradiation or the provision of components at low risk for cytomegalovirus (CMV) transmission, to meet special patient needs. These aspects of blood transfusion therapy are addressed in Chapter 33.

Blood component preparation

Blood components are prepared from blood collected by whole blood (WB) or apheresis donations. WB donations are separated into red blood cell (RBC), plasma (including cryoprecipitate) and platelet components. Automated apheresis procedures may be used to collect platelets, granulocytes or plasma, and more recently RBCs. Plasma protein products, such as albumin, immunoglobulins for intramuscular or intravenous injection and concentrated coagulation factors are prepared by more extensive processing of large pools of donor plasma obtained from WB or plasmapheresis donations. In many countries, the use of human-derived coagulation factor concentrates has been partially or totally replaced by recombinant products.

Preparation of components from whole blood donations

WB is collected into sterile blood bags that contain a premeasured amount of anticoagulant/preservative (AP) solution.

Standard blood bags contain enough AP solution to collect and store 450–500 mL ($\pm 10\%$) of WB. If smaller amounts of WB are to be collected, for example in pediatric autologous blood donations, the amount of AP solution must be adjusted appropriately. Because RBCs, platelets and plasma have different specific gravities they can be separated from each other by differential centrifugation. Generally WB is collected into a primary bag with one, two or three satellite bags depending on the components to be prepared. The satellite bags are attached to the primary bag with integral tubing so that components can be prepared in a closed system that maintains sterility. Two different production methods are regularly used to prepare platelets from whole blood donations: the buffy coat (BC) and the platelet-rich plasma (PRP) methods. The BC method has been used predominantly in Europe while the PRP method is used in North America. Platelets prepared by the BC method are pooled by the blood supplier, using platelets from four to six WB donations to make one pooled BC unit. Platelets prepared by the PRP are usually supplied to hospitals as single units.

Anticoagulant/preservative solutions

Two types of anticoagulant/preservative solutions, namely additive or nonadditive, may be used for blood component collection and storage. Using nonadditive solutions, the entire amount of the AP solution is present in the primary collection bag, whereas the use of additive solutions consists of collecting WB into the primary bag containing an anticoagulant solution and adding the constituents necessary for RBC preservation to the RBCs following separation of the RBCs from the plasma and platelets.

An AP solution for WB or RBC units must fulfill three requirements:

- prevent coagulation of the stored blood unit;
- maintain RBC viability and function;
- be nontoxic when reinfused into the recipient.

WB can only be stored in nonadditive AP solutions; RBCs

Table 32.1 Contents of selected anticoagulant/preservative solutions. Adapted from information supplied by the manufacturers.

Content (g/volume)	CPDA-1 (63 mL)	Adsol™ system		Nutricel™ system		SAG-M

Shelf-life of WB units	35	28		28		28	

^a Shelf-life varies from country to country according to licencing authorities.

AS, additive solution; CPDA-1, citrate-phosphate-dextrose-adenine anticoagulant.

SAG-M, sodium chloride, adenine, glucose, mannitol.

may be stored in nonadditive or additive AP solutions. All AP solutions contain dextrose, which is a source of metabolic energy; phosphate, which acts as a buffer; and citrate, which, based on its ability to chelate calcium, serves as an anticoagulant. Most contain adenine to maintain the RBC adenine nucleotide pool. Mannitol, which is part of some additive solutions, prevents the hemolysis of RBCs, which can occur in a plasma-poor medium. Licensing of AP solutions, including the accepted duration of RBC storage (the “shelf-life”), depends on the ability of the AP solution to assure 75% recovery of transfused RBCs 24 hours after infusion; hemolysis should be less than 1%.^{1,2} RBCs in AP solutions generally have a shelf-life of 42 days, while RBCs stored in citrate-phosphate-dextrose-adenine anticoagulant (CPDA)-1 have a shelf-life of 35 days. In addition to a longer shelf-life for RBCs, the advantages of additive solutions are a lower hematocrit in the RBC unit (which facilitates infusion) and the possibility of extracting larger amounts of plasma (which then can be used for the production of pooled fractionated plasma products) from the original WB unit. Their one disadvantage is a concern (albeit theoretical) about their safety for large volume transfusions in the neonate (see below). The contents of some of the most commonly used AP solutions for RBC storage are shown in Table 32.1.

Increasingly, additive solutions for platelets, rather than plasma, are being used for the storage of platelets, especially where the BC method of platelet preparation is used. As for RBCs, additive solutions for platelets allow the removal of larger amounts of plasma and may increase the shelf-life by improving storage conditions while maintaining viability and hemostatic functions.³ The decreased amounts of plasma in RBCs and platelets preserved in additive solutions could lead to fewer allergic reactions and increased ease of introduction of pathogen inactivation systems (see below).

The separation of WB into the most commonly used blood components using additive solutions and either the BC or PRP method is shown in Fig. 32.1.⁴

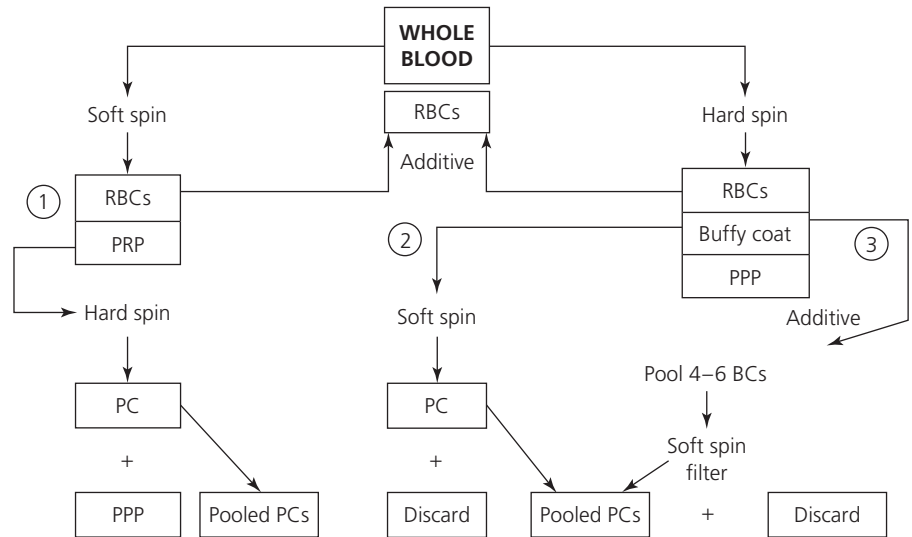

Preparation of components by apheresis techniques

Automated apheresis instruments use computer-controlled technology to draw and anticoagulate blood, separate the blood components either by centrifugation or filtration, collect the desired component, and recombine the remaining components for return to the donor. Automated apheresis procedures are routinely used to separate and collect platelets, granulocytes and plasma. Each apheresis collection can procure larger quantities of one of these components than can be extracted from a single whole blood donation. Because RBC loss for the donor is minimal, repeat donations can be performed at more frequent intervals than is permissible for WB donations. Recently, it has also become possible to collect RBC units using apheresis procedures. Similar to the advantages of apheresis collections for other components, an advantage of this technique is the possibility (depending on donor size and donation intervals) of collecting the equivalent of two WB-derived RBC units in one collection procedure.

Prestorage leukocyte reduction of cellular blood components

Several countries now use only WB, RBC and platelet products that have had the majority of leukocytes removed at the time of preparation, so-called prestorage leukocyte reduction. Other countries use these products only selectively for certain patient populations. Leukocytes are removed from WB or WB-derived components by specially designed

Fig. 32.1 Three ways of preparing platelets from whole blood (see text), BC, buffy coat; PRP, platelet-rich plasma; RBCs, red blood cells; PC, platelet concentrate; PPP, platelet-poor plasma. Reproduced with permission from Reference 4.

leukocyte reduction filters. Leukocytes are removed from apheresis products either by filtration or as an integral part of the apheresis production procedure. The current AABB and US Food and Drug Administration define a leukocyte-reduced component as one with a residual leukocyte count of less than 5×10^6 per unit of RBCs or apheresis (or apheresis equivalent) platelet concentrate.⁵ European standards are more stringent and require a leukocyte count less than 1×10^6 per unit.⁶

Leukocyte reduction was introduced in the UK in 1999 primarily as a potential way to avoid prion transmission. However, a recent study suggests that leukocyte reduction may reduce but will not eliminate (in an animal model) transmissible spongiform encephalopathies infectivity.⁷ Established advantages of leukocyte reduction (and the reasons for the introduction of universal leukocyte reduction in other countries) include the reduction in febrile non-hemolytic reactions,⁸ the prevention of CMV transmission⁹ and the prevention of human leukocyte antigen (HLA) alloimmunization.^{10,11} A possible reduction in the risk of postoperative infection¹² and post-operative mortality^{13,14} is still debated – further research is needed to establish clearly whether or not these are definite advantages of leukocyte reduction.

Pathogen reduction

The risk of the transmission of infectious diseases, in particular human immunodeficiency virus (HIV) and hepatitis C virus, has decreased dramatically over the past 20 years by careful attention to donor selection and improvement in infectious disease testing of donated blood (see Chapter 33). However, this has occurred gradually, and in parallel there has been research to develop the capability to inactivate pathogens in blood components. Efficacious techniques to

inactivate pathogens in pooled fractionated plasma products have been available for many years but until recently there were no techniques that could be applied to cellular components and still preserve the function of these components.

Technologies for pathogen inactivation or reduction of RBCs and platelets are in various stages of clinical trials and/or have received licensure in some countries.^{15,16} Two methods of pathogen reduction for plasma are in routine clinical use in Europe: treatment of individual units with methylene blue and solvent/detergent treatment of plasma pools.¹⁷

Whole blood

Description and storage

A unit of WB has a volume of approximately 510 mL (450 mL WB plus 63 mL CPDA-1) and a hematocrit of 0.30–0.40. It must be stored at 1–6°C and, if collected into CPDA-1, has a shelf-life of 35 days. Within 24 hours of collection the platelets as well as the granulocytes in the unit are dysfunctional and after a few days of storage the labile coagulation factors FV and FVIII have fallen to suboptimal levels.

Indications for transfusion

Theoretically, the transfusion of WB could be used in situations such as rapid, massive blood loss, which require the simultaneous restoration of oxygen-carrying capacity and blood volume. However, in most cases, the resuscitation of such patients can be achieved by the use of RBC concentrates and crystalloids or colloid solutions (either albumin or non-blood-derived colloid solutions such as pentastarch or hexastarch). Should plasma coagulation factor replacement

become necessary, the levels of coagulation factors V and VIII in stored WB are rarely sufficient to correct the corresponding deficiencies. Given these considerations, most centers preparing blood components provide little or no WB (except possibly autologous blood) but rather separate WB donations into the more commonly required blood components. Should both coagulation factors and RBCs be required, components are given separately or, in specific situations (e.g., exchange transfusion in the neonate), can be given in the form of reconstituted WB (i.e., the combination, in one blood bag, of an RBC unit and a plasma unit).¹⁸ Debate has existed over the advantages of the use of fresh WB for surgery with cardiopulmonary bypass in neonates. This issue is discussed in the section Red blood cells.

Dosage and administration

WB should not be used unless the donor and recipient are ABO-identical (for use in neonates, see below). The volume of transfusion depends on the clinical situation. In an adult, 1 unit of WB will increase the recipient's hemoglobin (Hb) concentration by approximately 10 g/dL. In pediatric patients, a WB transfusion of 8 mL/kg will result in a similar increase. WB must be administered through a blood filter, either a standard 170 to 260 μ m macroaggregate filter or a microaggregate filter. After an initial slow drip (to allow observation for immediate, severe transfusion reactions), the rate of infusion should be as fast as clinically indicated or tolerated, and in all cases must be completed within 4 hours of removal from a temperature-controlled refrigerator (to avoid bacterial contamination).

Red blood cells

Description and storage

RBC concentrates are usually prepared from WB donations (Fig. 32.1) although some blood suppliers now also prepare RBC components using apheresis techniques. RBC concentrates can be further modified for use in specific clinical settings. Characteristics of the various RBC preparations, including their contents and storage conditions, are summarized in Table 32.2.

Indications for transfusion

There are only two valid reasons for transfusing RBCs to children: the most common is to correct an inadequate (or avoid an imminent inadequacy of) oxygen-carrying capacity that is caused by an inadequate RBC mass; the second and rarer indication is to suppress endogenous hemoglobin (Hb)/RBC production in selected thalassemia or sickle-cell disease patients.

Indices of oxygen delivery and tissue oxygenation may accurately indicate the need to transfuse RBCs; however, invasive monitoring is required to generate these indices. Decisions about RBC transfusions are usually made on the basis of easily available but less precise clinical data. Although Hb concentration is certainly one important factor to consider in the decision to administer an RBC transfusion, most experts agree that it is not the only factor; in certain situations such as acute hemorrhage without volume replacement, it may even be misleading. As discussed in detail in several reviews, healthy adults and children have an impressive capacity to increase oxygen delivery to tissues.^{20–23} A recent study (albeit in a small number of patients/volunteers) demonstrated that healthy adults subjected to acute normovolemic hemodilution were able to tolerate an Hb concentration of 5 g/dL with no adverse effects.²⁴ It seems reasonable to assume that this would also be the case for otherwise healthy adolescents and older children.

Studies on indications for RBC transfusions in infants and children

Although there are published clinical guidelines for allogeneic red blood cell transfusions in the pediatric/neonatal population,^{25–28} they are poorly substantiated by randomized, controlled trials. A systematic review of the literature addressing allogeneic RBC and plasma transfusions in children (excluding studies addressing neonates or very young infants, or patients with thalassemia or sickle-cell disease) was published in 1997.²² The literature search identified only three randomized, controlled trials of allogeneic RBC blood transfusion therapy in children.^{29–31} Two addressed transfusion issues in the treatment of leukemic children in the 1970s^{29,30} and one reported on RBC use in African children with severe anemia and malaria.³¹ We performed a similar search using the same keywords that were used in 1997 for the period 1996–2004. No additional randomized, controlled trials on allogeneic RBC transfusion in children were identified. Thus, despite the large numbers of RBC transfusions administered to children, there is a remarkable paucity of scientific data on which to base RBC transfusion decisions. Recommendations and guidelines for RBC transfusions in children are, therefore, for the most part based on expert opinion and experience and not on scientific studies.

RBC transfusions for acute blood loss

In the presence of acute hemorrhage it is important to remember that the first priorities are to correct the hypovolemia (with crystalloids and/or colloids) and to attempt to stop the bleeding. In patients with hematologic problems, the latter will often include the need to correct thrombocytopenia and/or deficiencies of coagulation factors, treatment to decrease bleeding from damaged mucosal barriers (e.g., with

Table 32.2 Characteristics of various preparations of red blood cells.

Component	Preparation	Minimum Hb content*	Approximate volume	Hematocrit	Approximate leukocyte count	Storage	Indication(s)
RBCs in CPDA-1	WB with 200–250 mL of plasma removed	45 g	250 mL	0.70–0.75 L/L	10^9 – 10^{10}	35 days at 1–6°C	Standard RBC component (see text)
RBCs in AS	WB with most of the plasma removed and AS 100 mL added	45 g	350 mL	0.50–0.60 L/L	10^9 – 10^{10}	35–42 days at 1–6°C†	Standard RBC component (see text)
RBCs, buffy coat/poor in AS	WB with most of the plasma and some leukocytes removed and AS 100 mL added	43 g	300 mL	0.50–0.70 L/L	< 10^9	35–42 days at 1–6°C†	Standard RBC component or history of repeated febrile and/or allergic reactions
RBCs, leukocyte-reduced by filtration	RBCs in CPDA-1 or AS (with or without BC removed) and leukoreduced by filtration	40 g	Approx. same as non-LR component	CPDA-1: 0.70–0.75 L/L AS: 0.50–0.60 L/L	< 1 – 5×10^6	Prestorage LR: as for non-LR components. Post-storage LR: for immediate infusion	Standard RBC component in some countries History of repeated febrile nonhemolytic reactions Prevention of HLA alloimmunization and/or CMV transmission
RBCs, washed	RBCs in AS or CPDA-1 washed then resuspended with USP	40 g	Variable depending on quantity of USP used for resuspension	Variable depending on quantity of USP used for resuspension	10^8 – 10^9 if prepared from non-LR component or as per LR component	24 h at 1–6°C‡	History of repeated febrile and/or allergic reactions unresponsive to BC-poor or LR RBCs Prevention of severe allergic reactions or anaphylaxis due to anti-IgA
RBCs, frozen-deglycerolized	RBCs frozen with glycerol (a cryoprotectant); thawed and deglycerolized by washing before transfusion. Resuspended in USP	36 g	Variable depending on quantity of USP used for resuspension	Variable depending on quantity of USP used for resuspension	10^8 – 10^9 if prepared from non-LR component or as per LR component	May be stored frozen for up to 10 years After thawing: storage at 1–6°C for 24 h‡	Prolonged storage of autologous units or allogeneic units with rare RBC phenotypes

* Council of Europe Standards.¹⁹

† Shelf-life varies from country to country depending on licensing authorities.

‡ There are now systems that allow washing or thawing of RBC units in a closed system so that storage may be extended to 7–14 days.

AS, additive solution; BC, buffy coat; CPDA-1, citrate-phosphate-dextrose-adenine anticoagulant; CMV, cytomegalovirus; HLA, human leukocyte antigen; LR, leukoreduced; RBC, red blood cell; USP, 0.9% sodium chloride injection; WB, whole blood.

Table 32.3 Classification of hemorrhagic shock in pediatric patients based on systemic signs.

System	Class I: very mild hemorrhage (<15% TBV loss)	Class II: mild hemorrhage (15–25% TBV loss)	Class III: moderate hemorrhage (26–39% TBV loss)	Class IV: severe hemorrhage (≥40% TBV loss)
Cardiovascular	Heart rate normal or mildly increased Normal pulses Normal blood pressure Normal pH	Tachycardia Peripheral pulses may be diminished Normal blood pressure Normal pH	Significant tachycardia Thready peripheral pulses Hypotension Metabolic acidosis	Severe tachycardia Thready peripheral pulses Significant hypotension Significant acidosis
Respiratory	Rate normal	Tachypnea	Moderate tachypnea	Severe tachypnea
Central nervous system	Slightly anxious	Irritable, confused, combative	Irritable or lethargic, diminished pain response	Coma
Skin	Warm, pink	Cool extremities, mottling	Cool extremities, mottling or pallor	Cold extremities, pallor or cyanosis
Renal	Capillary refill brisk Normal urine output	Delayed capillary refill Oliguria, increased specific gravity (urine)	Prolonged capillary refill Oliguria, increased BUN	Prolonged capillary refill Anuria

BUN, blood urea nitrogen; TBV, total blood volume.

Reproduced with permission from Ref. 33.

antifibrinolytics) and/or reversal of the effects of anticoagulant therapy. In patients with normal or near-normal Hb levels prior to the onset of hemorrhage, RBC transfusions are usually only necessary if the patient remains unstable following volume resuscitation. However, careful ongoing evaluation of children with acute blood loss is essential as the signs of shock may initially be subtle in the child. If acute hemorrhage totals more than 15% of blood volume, signs of circulatory failure (tachycardia, decrease of intensity of peripheral pulses, delayed capillary refill and cool extremities) will be observed. However, hypotension will not be present until 25–30% or more of the child's blood volume is lost.³² It is also important to realize that in the setting of rapid ongoing hemorrhage with hypovolemia, the Hb concentration may not be an accurate indication of the actual RBC mass, so that the clinical evaluation of the blood loss is critical. The classification of hemorrhagic shock in children based on systemic signs is shown in Table 32.3.³³ Guidelines for the resuscitation of pediatric patients with acute blood loss have been published and should be followed.³⁴

RBC transfusions for acute hemolysis

Unlike acute hemorrhage, where the patient suffers from both hypovolemia and a decreased RBC mass, patients with acute hemolysis are usually normovolemic. The Hb concentration therefore more accurately reflects RBC mass. The decision to administer an RBC transfusion depends upon a combination of factors, including ongoing clinical evaluation,

presence or absence of underlying cardiovascular disease, actual Hb concentration, rate of decrease in Hb concentration and possibility of alternate treatments (e.g., corticosteroids for IgG autoimmune hemolytic anemia). The management of a patient with acute severe hemolytic anemia due to the presence of a warm autoantibody presents a particularly difficult challenge to the hematologist. There are two potential problems: the first concerns the provision of appropriate blood should transfusion be necessary, and the second is the possibility of hemolysis of the transfused blood because most autoantibodies also react with transfused allogeneic RBCs. If the autoantibody is present in the patient's plasma (as well as on the surface of the patient's red cells), it is usually impossible to provide cross-match-compatible blood and, in patients who have been previously transfused or pregnant, the autoantibody may mask the presence of clinically significant alloantibodies. With respect to the second problem, transfused RBCs will have a shortened survival in patients with autoimmune hemolytic anemia but immediate transfusion reactions are rare.³⁵ If possible then, in this setting the choice of blood to administer and the decision to administer an RBC transfusion should be made in consultation with a transfusion medicine physician, because special serologic techniques might be indicated in order to identify clinically significant alloantibodies, and decisions about transfusing cross-match-incompatible blood will often have to be made. However, life-saving RBC transfusions should not be withheld from patients with autoantibodies even if such blood is cross-match-incompatible.³⁵

RBC transfusion for chronic anemia

The majority of patients for whom a pediatric hematologist/oncologist will consider administering an RBC transfusion have a slowly developing subacute or chronic anemia. In this setting, decisions regarding RBC transfusion rarely need to be taken rapidly. It is therefore possible to consider several factors in the decision to administer an RBC transfusion or series of transfusions and to involve the patient and/or the patient's parents in the decision. Factors to be considered should include:

- presence or absence of symptoms and/or abnormal physical signs and the likelihood that these are due to anemia;
- presence or absence of underlying diseases, particularly cardiac diseases, which may decrease the patient's capacity for cardiovascular compensation;
- likely evolution of the underlying disease causing the anemia;
- likely evolution of the anemia and its consequences with or without transfusion in both the short and long term;
- possibility of using alternate, safer therapies for the treatment of the anemia.

In general, when deciding to administer an RBC transfusion the above factors are often more important than the Hb concentration *per se*. For example, patients with Diamond-Blackfan anemia unresponsive to corticosteroids are usually placed on a chronic transfusion program with minimum pretransfusion Hb levels of 6–7 g/dL in order to maintain growth and an acceptable long-term quality of life. In contrast, young, otherwise healthy children with severe iron deficiency anemia may temporarily tolerate Hb levels as low as 4 g/dL provided they are being monitored and iron therapy has been initiated. Patients with anemia due to chronic kidney disease are usually treated with iron supplementation and recombinant erythropoietin.

RBC transfusions for patients receiving chemotherapy for leukemia or solid tumors are often given according to a predetermined protocol based on Hb level alone. However, there is no scientific basis to this practice, and in the absence of appropriate studies, clinical judgment as to the benefit:risk ratio should be used for these patients too.

The transfusion support of children with sickle-cell disease or clinically significant thalassemia syndromes requires several special considerations as discussed below.

RBC transfusions for sickle-cell disease

The administration of RBC transfusions in the management and/or prevention of the complications of sickle-cell disease (SCD) is so frequent that almost all adult HbSS patients and many HbSC or HbS/β-thalassemia patients have been transfused at least once and often multiple times. RBC transfusions are administered to SCD patients for two reasons: to increase oxygen-carrying capacity in the anemic patient

and/or to replace the abnormal HbS by normal HbA. Depending on the complication and goal of transfusion, RBC transfusions may be administered as simple transfusions or exchange transfusions, with either being used acutely or in a chronic transfusion program.^{36,37}

Simple RBC transfusions (10–20 mL/kg) are used acutely to treat major splenic sequestration and aplastic crises. In acute splenic sequestration, the spleen rapidly increases in size, leading to sequestration of blood within it. In young children, the splenic sequestration may be sufficiently severe to lead to life-threatening hypovolemic shock. Parvovirus B19 infection in patients with SCD results in temporary aplasia, which may be severe, with hemoglobin levels of 4 g/dL or less. RBC transfusions are also used episodically to manage acute chest syndrome, acute stroke or severe anemia with infection, in particular malaria. Management of leg ulcers and acute or recurrent priapism with RBC transfusion is more controversial.

Transfusions are not indicated for uncomplicated painful crises. However, occasionally an exaggerated hemolysis, associated with an episode of pain, may herald the onset of multiorgan failure syndrome, which appears to respond to RBC transfusion.

The necessity of RBC transfusion prior to surgery in the SCD patient (either simple transfusion to attain a certain total Hb level or exchange transfusion to reduce the HbS level) has been debated in the literature. A large multicenter study comparing an aggressive transfusion regimen (decreasing HbS level less than 0.30%) to a conservative regimen (increasing the Hb level to 10 g/dL without consideration of the HbS concentration) in HbSS or S/β-thalassemia patients showed no difference in perioperative complications between the two groups.³⁸ However, transfusion-related complications were twice as common (14%) in the exchange transfusion arm, compared with the simple transfusion arm (7%). These data confirm the safety of using simple transfusions to raise the Hb level to 10 g/dL for common surgical interventions such as tonsillectomy, cholecystectomy, splenectomy and orthopedic procedures in these patients. The role of blood transfusion in SCD patients undergoing very minor procedures (such as myringotomy) or for patients with HbSC disease has not been well studied.

In children with cerebral vascular accidents (CVAs) associated with SCD, the administration of regular RBC transfusions to maintain an HbS level below 0.30% in the first 2 years after the CVA and below 0.50% thereafter has been shown to prevent recurrent CVAs.^{39–41} Moreover, it has been shown that a transfusion program in children with SCD who have abnormal results on transcranial Doppler ultrasonography can reduce the risk of a first CVA by 90%.⁴² A study to determine if these transfusions could be stopped after 30 months (STOP 2,^{42a}) showed that discontinuation of transfusion in children whose Doppler readings had become normal resulted in a high rate of reversion to abnormal readings and

stroke. Another potential indication for a chronic transfusion program is the presence of silent cerebral infarct (SCI) on magnetic resonance imaging (MRI). The Silent Cerebral Infarct Transfusion Trial (SIT) is a multicenter, randomized, controlled study that is investigating whether prophylactic transfusion therapy in children with SCI will result in reduction in the proportion of patients with clinically evident stroke or new or progressive SCI.⁴³ Chronic transfusion programs may also be indicated in selected patients with severe or recurrent acute chest syndrome or recurrent, debilitating painful episodes.

A major problem in the transfusion support of SCD patients is RBC alloimmunization due partly to the racial (and hence RBC phenotype) differences between the donor (often mainly Caucasian) and recipient populations.⁴⁴ Alloimmunization rates as high as 47% have been reported in adult patients with SCD.⁴⁵ A number of experts therefore recommend providing blood that is phenotypically matched (in addition to ABO and D antigens) for at least C, c, E, e and Kell antigens,^{36,46,47} and this is now standard practice in many comprehensive sickle-cell programs.

RBC units for transfusion to SCD patients should be screened for the presence of HbS and transfused only if negative. This will avoid confusion when the goal of transfusion is to decrease the HbS level to a predetermined level and will prevent the use of blood from a donor with undiagnosed HbSC disease.

In vitro, the viscosity of HbS has been shown to increase to potentially clinically significant levels if the hematocrit exceeds 0.35 L/L.⁴⁸ Therefore, when transfusing SCD patients, especially in the presence of high HbS levels, the hematocrit should not be allowed to increase above 0.35 L/L. Neurologic events, including headache, seizures and CVA, have been described after exchange transfusion in SCD.⁴⁹ It has been postulated that some of these events may have been caused by hyperviscosity, although other factors may also have been important in at least some of the patients.

A rare but potentially fatal complication occurring in patients with SCD is a hyperhemolytic transfusion reaction. Patients typically present about a week following an RBC transfusion and, in addition to evidence of hemolysis, may have symptoms of an acute painful crisis.^{50–53} Both donor and recipient red blood cells are destroyed, and reticulocytopenia may be a feature of the syndrome. Further transfusions can exacerbate the hemolysis and should be avoided if at all possible; alternative treatment with steroids and intravenous immunoglobulin (IVIG) may be life-saving.^{53–55}

SCD patients in chronic transfusion programs will develop secondary iron overload. The net amount of iron infused can be decreased by using partial exchange transfusion.⁵⁶ Another option is the use of automated erythrocytapheresis to delay or even prevent the development of hemochromatosis.^{57–59} Chelation therapy is an effective treatment of iron overload but compliance can be problematic

RBC transfusions for β -thalassemia

Before the introduction of RBC transfusion therapy for β -thalassemia major in the 1950s, β -thalassemia major was a uniformly fatal disease. Initially, children were transfused only to hemoglobin levels of 5–6 g/dL, a level sufficient to ensure survival but insufficient to suppress the exuberant erythroid bone marrow hyperplasia characteristic of this disorder. Consequently, patients survived into their second decade but developed severe skeletal deformities, osteoporosis and splenomegaly. So-called hypertransfusion regimens, in which endogenous erythroid production is suppressed by maintaining a minimum pretransfusion hemoglobin level of 9–10 g/dL, were therefore gradually introduced in the 1960s and 1970s, and remain the commonest approach today.^{60,61} During the 1980s, investigators evaluated the possibility of further improving the quality of life of thalassemic patients by introducing a “supertransfusion” regimen in which the minimum pretransfusion hemoglobin level was kept entirely within the normal range.⁶² However, this regimen led, not surprisingly, to a significant increase in transfusion requirements and has since been abandoned by most physicians caring for thalassemia patients.

Another approach investigated during the 1980s was the possibility of decreasing transfusion exposure and increasing transfusion intervals through the use of young RBCs. These “neocytes,” with an average age of 12–21 days, can be collected by erythrocytapheresis or by fractionation of standard whole blood units using a cell processor. The studies performed in the 1980s reported only modest decreases of 12–16% in transfusion requirements; the use of neocyte transfusions was therefore abandoned.^{63,64} In the mid-1990s, the use of a newly developed neocyte-separation set (Neocel System, Cutter Biological, Berkeley, CA) was reported.^{65,66} Using this system, there is a 15–20% reduction in transfused iron load. Nevertheless, the costs of this system are higher and donor exposure per transfusion episode is approximately doubled.

Chronic transfusions in β -thalassemia patients will lead to iron overload and its associated complications, mainly liver disease, endocrine complications and cardiomyopathy.^{60,61,67} Chelation therapy with subcutaneous deferoxamine has been the standard treatment for years but its cost and mode of administration can interfere with compliance. Recently two oral iron chelators, deferiprone and deferasirox, have been licensed for use in some countries. The availability of these oral agents may change the approach to the management of iron over-load in the future.⁶⁷

One of the most difficult decisions facing physicians treating patients with thalassemia is the necessity of instituting a chronic RBC transfusion program for patients with thalassemia intermedia and hemoglobin levels of 6–7 g/dL. In addition to the considerations discussed above for patients with chronic anemia, the physician must take into account

the fact that nontransfused thalassemia intermedia patients may develop bone deformities due to bone marrow erythroid hyperplasia, and even without RBC transfusions, these patients may develop clinically significant hemochromatosis secondary to the increased intestinal iron absorption induced by their inefficient erythropoiesis.⁶⁰ If a transfusion program is embarked upon, the goals of transfusion therapy are the same as those outlined above for thalassemia major patients. The transfusion intervals can usually be longer, although it may be more difficult to completely suppress endogenous erythropoiesis in thalassemia intermedia patients than in thalassemia major patients.

Blood group choice, dosage and administration

Acceptable choices of ABO blood groups for RBC, plasma and platelet transfusions in children are shown in Table 32.4. For RBC transfusions, these choices are based on the principle that the recipient plasma must not contain antibodies (anti-A/B) corresponding to donor A and/or B antigens. For plasma transfusions, donor plasma must not contain A/B antibodies corresponding to recipient A/B antigens, and as far as possible this rule should also be followed for platelet transfusions (see Platelets below). Patients who are RhD-antigen positive may receive RhD-positive or -negative RBCs; patients who are RhD negative should receive only RhD-negative RBCs (except possibly in life-threatening hemorrhagic emergencies if RhD-negative blood is not available). The choice of ABO blood group for RBC as well as platelet and plasma transfusion is more complicated for allogeneic hematopoietic progenitor cell transplantation patients receiving transplants from ABO-mismatched donors. Recommended choices of ABO group for blood components for these patients are shown in Table 32.5.⁶⁸

All pediatric patients who are likely to receive multiple RBC transfusions should have an extended RBC phenotype prior to the first RBC transfusion. In addition to ABO and RhD phenotyping, an extended RBC phenotype usually includes the determination of the other common Rhesus antigens (C, c, E and e) as well as the common antigens of the Kell, Kidd, Duffy and MNS blood group systems. Patients for whom this should be done include those with congenital or acquired aplastic anemia, autoimmune hemolytic anemia, SCD, thalassemia major or intermedia, or other transfusion-dependent congenital anemias and patients undergoing hematopoietic progenitor cell transplantation. Knowing a patient's extended RBC phenotype will assist in the identification of irregular RBC antibodies should they develop. In addition, RBC units matched for antigens other than ABO and RhD may be desirable for patients with thalassemia syndromes or SCD to prevent the development of alloantibodies (see above).^{36,46,47,69}

The quantity of blood administered in simple RBC transfusions depends on the hematocrit of the RBC unit, the pre-

Table 32.4 Choice of ABO blood groups for red blood cell (RBC), plasma and platelet transfusions in children.

Recipient blood group	Acceptable ABO group of blood component to be transfused			
		RBCs*	Plasma	Platelets†
O	First choice	O	O	O
	Second choice	None	A, B, AB	A, B, AB
A	First choice	A	A	A
	Second choice	O	AB	AB

	Second choice	O	AB	AB
AB	First choice	AB	AB	AB
	Second choice	A, B, O	None	See footnote

* The choices of ABO blood groups for RBC transfusion may not be appropriate for newborns and infants < 4 months of age in whom the potential presence of maternal anti-A/B must also be considered.

† In emergency situations platelets in plasma with A/B antibodies against recipient A/B antigens may be transfused. However, where possible such units should not be used unless the anti-A/B is of low titer and/or the plasma has been removed. This is especially important for infants and young children (see text).

transfusion Hb level and the patient's weight. If the patient's Hb level is 5 g/dL or greater, and blood stored in an additive solution (hematocrit 0.50–0.60 L/L) is used, 15 mL/kg is usually administered. This can be expected to raise the hemoglobin level by approximately 2 g/dL. To obtain the same result using blood stored in CPDA-1 (hematocrit 0.70–0.75 L/L), a transfusion of 10 mL/kg is needed. For patients who weigh < 20 kg, the volume of an entire RBC unit is too large to be administered during one transfusion. In order to minimize donor exposure, attempts should be made to use the entire unit, either by giving two or three small transfusions over a 24-hour period if the unit is opened in a non-sterile manner, or by entering the unit using a sterile docking device and transfusing appropriately sized aliquots before the unit's original expiry date.

If the anemia has developed slowly and the hemoglobin level is < 5 g/dL, it may be necessary to administer RBC transfusions more slowly and/or in smaller quantities to avoid precipitating cardiac failure from circulatory overload. A transfusion regimen for the treatment of children with severe anemia of gradual onset without clinical signs of cardiac decompensation has been published.⁷⁰ The authors successfully treated 22 such children using RBCs with a hematocrit of 0.70–0.80 L/L at a continuous infusion rate of 2 mL/kg/h until the desired Hb level was achieved. If a severely anemic child has signs of cardiac decompensation, a partial exchange transfusion should be performed.

* Phase I: from the time when the patient/recipient is prepared for HPC transplantation.

† Phase II: from the initiation of myeloablative therapy until:

For RBC, DAT direct antiglobulin test is negative and antidonor isohemagglutinins are no longer detectable.

For FFP, recipient's erythrocytes are no longer detectable (i.e., the forward typing is consistent with donor's ABO group).

‡ Phase III: after the forward and the reverse type of the patient are consistent with donor's ABO group.

§ Platelet concentrates should be selected in the order presented.

Reproduced with permission from Ref. 68.

Guidelines for performing partial manual exchange transfusions have been published.^{56,71} Alternatively, where available, automated red blood cell exchanges can be performed even in critically ill pediatric patients.^{57,72,73}

RBC units must be administered through a blood filter, either a standard 170 to 260- μ m macroaggregate filter or a microaggregate filter or, if the unit was not leukocyte-reduced prestorage, a leukocyte-reduction filter may be used. RBC transfusions must be completed within 4 hours from the time the unit is removed from a temperature-controlled refrigerator.

Special considerations for newborns

Indications for RBC transfusions

Very-low-birthweight (VLBW) infants frequently require small-volume (10–20 mL/kg) RBC transfusions. In the early 1990s, it was estimated that approximately 80% of infants weighing < 1.5 kg born in the USA received RBC transfusions in the first weeks of life.⁷⁴ Currently, transfusion practices and/or requirements for VLBW infants appear to be changing. In a recent observational clinical study from a single institution, the authors report that over a 9-year period (1989 to 1997), with the use of more restrictive transfusion guidelines, the number and volume of transfusions per infant weighing < 1000 g decreased by 71% and donor exposure by 80%; 25% of infants weighing < 1000 g born in 1995–1997 were never transfused compared with 3% born 1989–1991.⁷⁵

There are three major factors contributing to small-volume RBC transfusion requirements in VLBW infants.

1 *The rapid decline in Hb levels that occurs in the first weeks of life.* In the healthy term infant, the mean cord blood Hb level is 16.8 g/dL, rising to 18.4 g/dL in venous blood by 24 hours of life and then gradually decreasing to a mean nadir of 11.5 g/dL (with a lower limit of normal of 9.0 g/dL) at 2 months of life.⁷⁶ Because this decline in Hb level occurs in all neonates, and in term infants, at least, is not associated with any adverse events, it is called the physiologic anemia of infancy. In preterm infants Hb levels at birth are slightly lower than those of term infants (14.5 g/dL and 15.0 g/dL at 28 and 34 weeks gestation, respectively), and the decline in Hb level occurs earlier and is more pronounced. For example, the hemoglobin concentration may drop to 8.0 g/dL in neonates with birthweights of 1.0–1.5 kg, and to 7.0 g/dL in neonates with birthweights below 1.0 kg.⁷⁶ Erythropoietin levels in preterm infants at the time of the nadir of hemoglobin levels are lower than those usually found in children or adults with similar hemoglobin levels and therefore probably explain, at least partly, the drop in hemoglobin levels.⁷⁷

2 *The associated respiratory illnesses often present in these infants.* Early in life VLBW infants are at risk for respiratory distress syndrome, which in some may lead to bronchopulmonary dysplasia with continuing requirements for respiratory support. Even relatively stable infants may develop cardiopulmonary irregularities such as apnea and/or bradycardia. The necessity of maintaining hemoglobin values at a predetermined level in infants with these problems is somewhat

controversial and has been the subject of several studies and review articles.^{78,79}

3 Phlebotomy losses. Because of the need for laboratory monitoring of ill neonates and the relatively large volumes of blood required in relation to these tiny infants' total blood volumes, phlebotomy losses contribute significantly to the need for RBC transfusions in VLBW infants. Care must be taken to avoid blood overdraw. A recent study estimated that the mean volume of blood overdraw for all blood tests was 19% in a neonatal intensive care unit, and this could account for 5–15% of the RBC transfusion received by VLBW infants.⁸⁰

Adhering to strict transfusion guidelines can reduce the need for transfusions.^{75,81} Several guidelines for small-volume RBC transfusions for newborns have been published in recent years.^{25–27,82–84} Two sets of guidelines are shown in Tables 32.6 and 32.7. However, controlled trials evaluating

transfusion thresholds are rare. A multicenter randomized, controlled trial "Prematures in Need of Transfusion" (PINT) investigating whether a higher Hb transfusion threshold is superior to a lower one with respect to morbidity and mortality in extremely low-birthweight (<1000 g) infants has recently been completed. In a preliminary presentation, the investigators reported that the higher Hb transfusion threshold was not superior, suggesting that conservative transfusion regimens may be safely used in preterm infants.⁸⁵

There are three clinical settings in which newborns may require large-volume RBC transfusion: exchange transfusion, surgery with cardiopulmonary bypass or during treatment with extracorporeal membrane oxygenation (ECMO). The mechanics, blood product choice and complications associated with each of these procedures have been thoroughly reviewed.^{25,86}

Practical considerations

RBC units for transfusion to neonates are often chosen exclusively from group O donors, although ABO isogroup (or compatible) units can be used providing the technologists preparing the blood are experienced in the choice of units for those patients in whom the potential presence of maternal A and/or B antibodies needs to be considered. RBC units stored in any of the currently available storage media, including additive solutions, are suitable for small-volume (<20 mL/kg) RBC transfusions.⁸⁷ Several studies have demonstrated the safety of assigning a fresh (<5 days old) RBC unit to a neonatal patient at the time of his/her first small-volume RBC transfusion and, using a sterile connection device, of continuing to use this same unit up to its normal expiry date for subsequent small-volume RBC transfusions.⁸⁸ Precise descriptions for preparing small-volume RBC aliquots for neonates have been published.^{89,90}

In settings of large-volume RBC transfusion, replacement of plasma coagulation factors is often also required so that WB or reconstituted WB, that is, an RBC unit mixed with a unit of fresh frozen plasma (FFP) or frozen plasma (FP), is usually used. For WB, or the RBC unit for reconstituted WB, the choice of ABO group is the same as that described above for small-volume RBC transfusions. The ABO group of the FFP or FP must also be compatible with the baby's RBCs (see Table 32.4). This may mean that the ABO groups of the RBC unit and the FFP or FP unit are different; for example, for a group A baby with maternal anti-A in his plasma, a unit of reconstituted WB would be prepared using a group O RBC unit and a group A FFP or FP unit. To limit donor exposure, some physicians use group O whole blood in this setting, although units from group O donors with high anti-A titers should not be used.

WB units or RBC units for large-volume transfusions should be relatively fresh, i.e., not > 5–7 days old. The main reason for this precaution is the high potassium concentration in

Table 32.6 British guidelines for RBC transfusion thresholds for infants under 4 months of age.

Anemia in the first 24 hours	Hb 12.0 g/dL (Hct 0.36)
Cumulative blood loss in 1 week, neonate requiring intensive care	10% blood volume
Neonate receiving intensive care	Hb 12.0 g/dL
Acute blood loss	10% blood volume
Chronic oxygen dependency	Hb 11.0 g/dL
Late anemia, stable patient	Hb 7.0 g/dL

Reproduced with permission from Ref. 25.

Table 32.7 Suggested guidelines (USA publication) for RBC transfusion thresholds for infants under 4 months of age.

Hematocrit	Threshold criteria for RBC transfusion
<0.35 L/L	Patient is on mechanical ventilation requiring fraction of inspired oxygen (F_{iO_2}) > 40% or mean arterial pressure > 9 cmH ₂ O Patient has hypotension
<0.28 L/L	Patient is on mechanical ventilation but F_{iO_2} is < 40% and mean arterial pressure is < 9 cmH ₂ O Patient has been weaned from mechanical ventilation, but still has a significant oxygen requirement (>40%) Patient has signs of anemia such as: Unexplained apnea, 12 spells per day or two spells per day that require bag-mask resuscitation Unexplained heart rate greater than 165/min for more than 48 hours Unexplained poor weight gain, <10 g/kg daily over 1 week with adequate caloric intake Unexplained lethargy
<0.20 L/L	No signs of anemia are required

Modified with permission from Ref. 84.

stored WB or RBC units. While this does not pose a problem in the setting of small-volume transfusions (<20 mL/kg) administered slowly (over 3 or 4 hours), the potassium content of stored blood, when administered rapidly and in large volumes, may be lethal for a neonatal patient.⁹¹

The debate over the use of WB versus reconstituted blood in surgery with cardiopulmonary bypass (CPB) in neonates and infants is still not resolved. In one prospective, controlled study the use of very fresh WB (<48 h storage) postoperatively resulted in less bleeding in patients younger than 2 years old undergoing complex procedures and, additionally, in neonates a decrease in the rate of reexploration for bleeding.⁹² However, in a more recent randomized, controlled trial the use of fresh whole blood (<48 h) for cardiopulmonary bypass priming in neonates had no advantage over reconstituted whole blood, and fresh whole blood was associated with an increased length of stay in the intensive care unit and an increased perioperative fluid overload at 48 hours.⁹³

A screening test for the presence of a sickling Hb should be performed and found to be negative on RBC or WB units for large-volume transfusions in neonates.⁹⁴

Finally, there are at least theoretical concerns that the constituents of additive solutions may be harmful to newborns if infused in large quantities, as could occur with exchange transfusion, CPB surgery or ECMO. In these situations it is recommended that the additive solutions be removed either by washing the RBCs or by centrifuging the unit and removing the supernatant.⁸⁷ The packed RBCs are then reconstituted in saline, albumin, FFP or FP as required. Alternately RBCs collected in nonadditive solutions may be used.

Strategies to decrease RBC allogeneic donor exposures

The first and possibly the most important strategy in limiting donor exposure is to administer an RBC blood transfusion only in the presence of an appropriate indication. The risks versus the anticipated benefits should be individually considered for every transfusion a physician orders. A second and equally simple strategy is to ensure the optimum utilization of each blood unit. When transfusing RBC units to very small patients, attempts should be made to use the whole unit (see above). In some situations, described below, allogeneic donor exposure may be avoided or limited using additional, special strategies.

Autologous transfusions

Autologous blood transfusion, that is, the collection and reinfusion of the patient's own blood, can be used for selected pediatric surgical patients. Three types of autologous blood transfusion can be used in surgical patients:

- preoperative blood collection and storage with reinfusion intraoperatively or postoperatively;

- immediate preoperative phlebotomy (following anesthetic induction) accompanied by normovolemic hemodilution with colloids or crystalloids;

- intraoperative salvage and reinfusion of shed blood.

Guidelines for the use of autologous blood transfusion in the surgical setting have been published.^{95–99}

The majority of the published experience with autologous blood transfusion for pediatric patients addresses the use of preoperative autologous blood deposit (PAD). For both adults and children, PAD is considered most appropriate for patients predicted to have significant postoperative longevity who are scheduled to undergo a procedure in which there is a significant likelihood of transfusion and for whom the PAD procedure is likely to be well tolerated.^{95–102} PAD is usually reserved for older pediatric patients, for example adolescents undergoing orthopedic procedures, in particular spinal fusion.^{103–105} In this setting, preoperative collection of autologous blood is clearly feasible and decreases the need for allogeneic blood transfusion.

There are published reports describing the use of predeposit autologous blood collections in smaller and younger pediatric patients (with several patients 3 years old or younger and/or weighing as little as 10–12 kg).^{106–108} Autologous blood collection is feasible in these patients but consideration must be given to several aspects unique to the pediatric setting. These include both psychologic factors such as the creation of an appropriate environment and the need for parental encouragement and commitment to the program, as well as technical considerations such as the use of local anesthesia at the venipuncture site, the use of needles smaller than the standard size (this can be accomplished using a sterile connection device), and the need to adjust the amount of anticoagulant in the collection bag according to the amount of blood collected. In the published reports, deposit of autologous blood appears to decrease the requirements for allogeneic blood transfusion in these smaller patients. However, the decision to embark on such a program should be individualized and should include a realistic prediction of whether or not sufficient blood can be collected to avoid the need for allogeneic blood transfusion.

Pediatric patients participating in autologous predeposit programs should receive iron supplementation, beginning if possible at least 3 weeks before the first donation and continuing into the postoperative period. Although the risks of autologous blood transfusion are less than those associated with allogeneic transfusion, autologous blood is not entirely risk free. Many experts therefore recommend using the same criteria for the transfusion of autologous blood as for allogeneic blood.²⁸

The use of acute normovolemic hemodilution and intraoperative RBC salvage in adult patients has been extensively reported.^{98,99} There are some studies examining the use of these two modalities in children.^{109–112} While these approaches to decrease the requirement for allogeneic blood

transfusion in pediatric patients will probably prove to be useful in selected patients, their exact roles remain to be defined.

The use of placental blood as a type of autologous blood transfusion for neonates has been investigated. A simple way to administer placental blood at birth is to slightly delay cord clamping. Most (but not all) studies show a clinical, or a theoretical, benefit for delayed cord clamping in preterm infants.^{113–118} A second method, namely the collection, storage and reinfusion of placental blood, is obviously considerably more complicated and currently must be considered experimental.^{119–123}

Erythropoietin

The efficacy of recombinant human erythropoietin (rHuEpo) for the correction of the anemia of chronic renal failure is now well established in both pediatric and adult patients.¹²⁴ In pediatrics, outside of the setting of uremia, the role for rHuEpo has been most extensively studied in preterm infants with anemia of prematurity. Despite a relatively large number of studies (reviewed in Refs 79 and 125), this indication remains controversial. It is generally agreed that rHuEpo is not indicated for infants with birthweights > 1300 g because they rarely require RBC transfusions. It also appears unlikely that rHuEpo can avoid the requirement for RBC transfusion in VLBW infants, for example those with birthweights < 800 g. In infants with birthweights between 800 and 1300 g, rHuEpo administration (in association with relatively large amounts of iron supplementation) does enhance erythropoiesis, and in several studies has decreased the number and/or quantity of RBC transfusions. However, these studies have not convincingly shown that donor exposures would in fact be decreased. If stringent transfusion guidelines are followed, methods to decrease iatrogenic blood loss are implemented and dedicated RBC units reused up to their expiry date, there is unlikely to be a role for routine use of erythropoietin in preterm neonates.

In October 2002, the American Society of Hematology and the American Society of Clinical Oncology jointly published guidelines for the use of erythropoietin in adult patients with anemia associated with cancer, chemotherapy, radiotherapy or bone marrow failure. These guidelines recommend that erythropoietin be a treatment option for patients with an Hb level of 10 g/dL or less.¹²⁶ Similar guidelines have recently been published in Europe.^{127,128} However, the systematic reviews on which these recommendations were made were based on studies in adults. This, plus the differences in normal Hb concentrations between children and adults, means that these guidelines cannot be extrapolated to children. Definitive guidelines for the use of rHuEpo in pediatric oncology and hematopoietic progenitor transplant patients are therefore yet to be defined. Likewise there are no definitive guidelines for rHuEpo in the treatment of children undergoing surgical procedures.

Directed donations and limited-exposure blood donor programs

A directed blood donation is one in which an individual, at the request of a patient, or in the case of a child, a parent, donates blood that is reserved specifically for the subsequent transfusion of the requesting patient. When parents wish to be directed donors for their children, or request other family members or friends to do so, it is presumably because they believe that blood from such donors is less likely to be a source of transfusion-transmitted diseases than blood from an anonymous volunteer blood donor pool. Whether or not this is in fact true has been a source of controversy in the literature.^{129,130} The few studies that have been performed suggest that directed donations are neither more nor less safe than donations from volunteer anonymous donors.^{131–133}

Apart from the question of safety with respect to the transmission of viral infections, there are additional safety issues to consider when parents give blood for their children. In the case of neonates, blood from biologic mothers poses a potential danger because their plasma may contain HLA antibodies that could react with HLA antigens on the infant's leukocytes and/or platelets leading to neutropenia, thrombocytopenia and/or transfusion-related acute lung injury. *In utero* the placenta provides a natural barrier to these antibodies, one that obviously would be bypassed with a blood transfusion. For this reason, it has been suggested that biologic mothers should not provide blood components containing plasma for their neonates and that maternal red cells and platelets be given as washed products.¹³⁴

Biologic fathers may also pose certain difficulties. A father may possess a red cell antigen, not inherited by his infant, to which the mother may have developed an IgG antibody. These antibodies cross the placenta but obviously would cause no harm *in utero*. Most such antibodies are easily detected by routine pretransfusion testing. However, should such an antibody be directed against an uncommon or private antigen, it may not be detected by routine pretransfusion testing if this does not include a full antiglobin cross-match.

Another potential risk of parental blood transfusion is chimerism and graft-versus-host disease. For patients of all ages (including adults), all cellular blood components obtained from biologic relatives must be irradiated before transfusion (see Chapter 33).

Finally, as for all allogeneic blood transfusions, there remain the risks related to alloimmunization, allergic reactions and bacterial contamination (see Chapter 33). In addition, as for autologous donations, it is possible that the added complexity of providing directed donations could lead to an increased frequency of errors.¹³⁵

One situation in which directed blood donors may provide an increased level of safety is a limited-donor

blood program. For example, a single donor can often provide all the RBC and/or plasma needs of a small pediatric patient ineligible for autologous donation who must undergo elective surgery for which multiple blood units are normally required.¹³⁶ Likewise, the RBC transfusion requirements of small pediatric patients with chronic anemia, for example Diamond–Blackfan anemia or β -thalassemia major, may be supplied from a small pool of two to four donors.¹³⁷ While the feasibility and success of such limited-donor programs in decreasing the number of donor exposures in small pediatric patients has been demonstrated, there are no data to support or refute the superiority with respect to safety of these programs.

Plasma

Description and storage

Plasma for transfusion is prepared from a WB donation by separation following centrifugation (see Fig. 32.1). Larger volumes of plasma may be collected using automated apheresis techniques. A typical unit of plasma has a volume around 250 mL if obtained from a WB donation or approximately 500 mL when obtained by plasmapheresis. Methylene blue-treated frozen plasma (MBFP) and solvent/detergent-treated frozen plasma (SDFP) units have a similar volume to that of a regular unit of WB-derived plasma.

Immediately following collection from a normal donor, plasma contains approximately 1 unit/mL of each of the coagulation factors as well as normal concentrations of other plasma proteins. Coagulation factors V and VIII, known as the labile coagulation factors, are not stable in plasma stored for prolonged periods at 1–6°C so plasma is usually stored in the frozen state at –18°C or lower. Plasma frozen within 8 hours of collection, known as fresh frozen plasma (FFP), contains about 87% of the FVIII present at the time of collection and according to standards in most countries must contain at least 0.70 IU/mL of FVIII. Several countries also use plasma frozen within 24 hours of collection, known as frozen plasma (FP). FVIII levels in FP are approximately 70–75% of the levels present at the time of collection. The levels of FV as well as the levels of other coagulation factors are not significantly decreased from baseline in plasma frozen within 24 hours of collection.^{138,139} MBFP contains less FVIII than FFP (minimum levels of 0.5 IU/mL) and approximately the same levels of other coagulation factors. FVIII levels in SDFP are somewhat higher than those in MBFP and approximately the same as in those FP.^{17,140} The levels of the anticoagulant protein S are lower in SDFP than in other frozen plasma products.¹⁷ Depending on the exact temperature at which plasma is stored, the relevant national requirements/regulations, and the precise product, frozen plasma can be stored for periods from 3 to 24 months.

Indications and contraindications for transfusion

A systematic review of allogeneic transfusions in children or infants > 4 months of age published in 1997 identified only three controlled trials addressing FFP use in this group.²² Two examined the use of FFP for pediatric hemolytic uremic syndrome.^{141,142} Both trials failed to identify any benefit of FFP infusions with respect to mortality or long-term renal outcome measures. The other examined the use of FFP as one of the components of reconstituted WB to replace blood losses following open heart surgery.⁹² More recently, a systematic review of randomized, controlled trials of FFP use in adults and children identified a total of 57 trials.¹⁴³ As noted by the authors, most enrolled small numbers of patients (and few of even these small numbers of patients were children) and few provided adequate information on the ability of the trial to detect meaningful differences in the outcomes between the two patient groups. Thus, as for RBC transfusion, guidelines for administering FFP transfusions to children (as indeed is also the case for adults) are not evidence-based but are based on expert opinion.^{25–28,144–147} Most guidelines (with the exception of the recently published UK guidelines¹⁴⁷) refer only to FFP. This term will be used in the remainder of this section although unless noted otherwise the other frozen plasma products (FP, MBFP and SDFP) can usually be used interchangeably with FFP.

There is broad, general consensus that the appropriate use of FFP is limited almost exclusively to the treatment or prevention of clinically significant bleeding due to a deficiency of one or more plasma coagulation factors. Such situations potentially include the presence of:

- a diminution of coagulation factors due to treatment with vitamin K antagonists;
- severe liver disease;
- disseminated intravascular coagulation (DIC);
- massive transfusion;
- isolated congenital coagulation factor deficiencies for which a safer and/or more appropriate product does not exist.

The use of FFP in each of these settings is discussed below.

FFP is also used in plasma exchange (PE) in the treatment of thrombotic thrombocytopenic purpura (TTP)/hemolytic-uremic syndrome (HUS), when PE is indicated. The use of FP, MBFP and SDFP rather than FFP for TTP/HUS has not been fully evaluated.

There is a consensus among the experts who develop the guidelines that FFP is *not* indicated in the following situations:

- intravascular volume expansion or repletion (where crystalloids, synthetic colloids or purified human albumin solutions are preferred);
- correction or prevention of protein malnutrition (where synthetic amino acid solutions are preferred);
- correction of hypogammaglobulinemia (where purified human immunoglobulin concentrates are preferred);
- treatment of hemophilia A or B and von Willebrand

disease (where desmopressin or virus-inactivated plasma-derived or recombinant factor concentrates are preferred);

- treatment of any other isolated congenital procoagulant or anticoagulant factor deficiency for which a virus-inactivated plasma-derived or recombinant factor concentrate exists;
- treatment of HUS unless plasma exchange is indicated;
- as replacement fluid in therapeutic apheresis procedures for disorders other than TTP/HUS unless proven to be beneficial.

Reversal of warfarin effect

Patients who are anticoagulated with warfarin are deficient in the functional vitamin K-dependent coagulation factors II, VII, IX, X and proteins C and S. Reversal of the warfarin effect prior to elective surgery can usually be accomplished by stopping warfarin 4 days before the procedure. Selected patients at high risk of thrombosis may require heparin coverage. For children with an international normalized ratio (INR) > 8.0 and no significant bleeding vitamin K at a dose of 30 µg/kg (given orally or intravenously) may be used. In the presence of significant bleeding, immediate reversal with FFP, prothrombin complex concentrates or recombinant FVIIa may be required.^{25,147–148}

Severe liver disease

Severe liver disease is associated with multiple abnormalities of hemostasis and coagulation including thrombocytopenia from hypersplenism, decreased circulating levels of coagulation factors, and abnormal fibrinogen due to impaired hepatic synthesis.¹⁴⁹

Patients with severe liver disease usually have significantly abnormal coagulation studies that raise questions about the need for plasma transfusion. Most guidelines recommend that patients who are neither bleeding nor about to undergo an invasive procedure should not receive plasma merely to correct abnormal coagulation tests. One exception to this may be patients with life-threatening acute fulminant hepatitis and extremely elevated INRs who are awaiting emergency liver transplantation. These patients are sometimes given prophylactic plasma transfusions. However, no studies have specifically addressed this issue, and it is difficult to determine whether or not such transfusions actually improve the outcome of this devastating disease.

The INR at which liver biopsy can be safely performed has not been established and may be different in those with liver failure compared with those without liver disease. For patients with acquired multiple coagulation deficiencies, Canadian guidelines published in 1997 do not recommend prophylactic FFP administration prior to invasive procedures, including liver biopsy, unless the INR is > 2.0.²⁸ By contrast, more recently published British reviews suggest that in practice clinicians wish to have an INR < 1.4 before liver biopsy.¹⁴⁷ If FFP is used to prepare a patient with

liver failure for liver biopsy coagulation studies need to be repeated before biopsy as the coagulopathy in liver disease does not always respond to FFP.

Disseminated intravascular coagulation

Acute DIC is characterized by the abnormal consumption of coagulation factors and platelets and may lead to thrombocytopenia, hypofibrinogenemia and increased prothrombin time (PT), INR and/or activated partial thromboplastin time (APTT) with uncontrollable bleeding from wound and puncture sites. Retrospective and uncontrolled evidence suggests that the transfusion of plasma, along with other blood components, may be useful in limiting hemorrhage. The efficacy of treatment with FFP (or cryoprecipitate or platelets) has not been studied in randomized, controlled trials but would seem reasonable, and is generally recommended in guideline documents, for patients with DIC who are bleeding or at risk for bleeding and who have laboratory evidence of a significant depletion of coagulation factors. This assumes, of course, that aggressive measures are simultaneously undertaken to overcome the triggering disease. Plasma transfusion is generally not recommended in acute DIC in the absence of bleeding (or risk of significant bleeding) nor for the treatment of chronic DIC.^{28,147,150,151}

Massive transfusion

Massive transfusion is usually defined as the replacement of a patient's total blood volume with stored blood within a period of 24 hours. However, even within this definition, the degree and rapidity of blood loss can be quite variable as are the underlying etiologies and associated complications. When plasma-poor red cells are used, clinically significant fibrinogen deficiency, that is, a fibrinogen level of 1.0 g/L or lower, occurs after a blood loss of about 150% of the patient's total blood volume. Decreases of prothrombin, FV, platelets (platelet count < 50 × 10⁹/L) and FVIII to critical levels will occur after blood loss in excess of two blood volumes.¹⁵² Previous recommendations advocated routine transfusion of plasma to reduce the risk of abnormal bleeding due to coagulation factor depletion during massive transfusion. However, there is no evidence to support the routine or prophylactic administration of plasma in this scenario.¹⁵³ Thus, assessment of the need for replacement of coagulation factors by FFP transfusion should be guided by both the ongoing clinical evaluation of the patient and laboratory measurements of hemostasis. A thorough review of the pathophysiology of coagulopathy in massively transfused patients has been recently published.¹⁵⁴

Congenital coagulation factor deficiencies

Plasma has long been used to treat congenital deficiencies of

Table 32.8 Reference values for coagulation tests in healthy full-term infants during the first 6 months of life.

Test	Day 1		Day 30		Adult

hemostatic or anticoagulant proteins. However, more appropriate alternatives such as recombinant factor concentrates now exist for most of these disorders. Physicians with special expertise in pediatric hemostasis or thrombosis should supervise the care of children with these disorders and the choice of products for their treatment. These disorders are discussed in detail in Chapters 26–28.

Special considerations for newborns

The approach to determining the indications for FFP transfusion in the newborn is the same as that for the older patient; that is, FFP is indicated for the treatment of clinically significant bleeding, or its prevention in the case of an invasive procedure, due to a decrease in one or more coagulation factors, where a safer, appropriate, alternative therapy does not exist.^{25,26,147} In particular, specific factor concentrates should be used in neonates with congenital coagulation factor deficiencies, if available. As for older patients, FFP is not indicated for the treatment of volume expansion or resuscitation alone. However, the application of these underlying principles to decisions concerning FFP administration may be more difficult in newborns than older patients for a number of reasons. First, it may be difficult to obtain blood specimens of the quality and quantity necessary to obtain reliable laboratory measurements of coagulation parameters in tiny, critically ill preterm infants. Secondly, newborns and infants under 6 months of age have relatively lower levels of the vitamin K-dependent coagulation factors (factors II, VII, IX and X), as well as the four contact factors and the

vitamin K-dependent coagulation inhibitors.^{155,156} PT and APTT are correspondingly prolonged. Normal values for coagulant and anticoagulant proteins as well as coagulation tests in healthy, full-term and preterm infants are shown in Tables 32.8 and 32.9, respectively. These values usually reach adult levels by 6 months of age. On the one hand, these differences in the newborn versus the older infant and child may render the correlation of laboratory values to the clinical situation difficult; on the other hand, it is likely that the coagulant and anticoagulant factors that are already relatively low in newborns are more rapidly depleted in situations such as acute hemorrhage or DIC. It may thus be reasonable to administer FFP transfusion relatively sooner in these situations to newborns and infants under 6 months of age than in older infants and children.

In most countries, newborns receive vitamin K prophylactically at birth. Newborns who do not receive vitamin K prophylaxis and who are breast-fed may develop the classic form of hemorrhagic disease of the newborn (HDN). A late form of HDN may occur in newborns with a variety of diseases that can compromise the supply of vitamin K. First-line treatment is the subcutaneous or intravenous administration of vitamin K (see also Chapter 30). Clinically significant bleeding may require FFP treatment, and life-threatening bleeding may require treatment with coagulation factor concentrates. The latter should only be used in consultation with an expert in pediatric hemostatic disorders.

In addition to the contraindications for FFP transfusion listed above, in the newborn FFP should not be used as a fluid for hematocrit adjustment in erythrocyte transfusions nor as

Table 32.9 Reference values for coagulation tests in healthy preterm infants during the first 6 months of life.

a replacement fluid in partial exchange transfusion for the treatment of neonatal hyperviscosity syndrome (because these two situations essentially represent the use of FFP as volume replacement). Also, the use of prophylactic FFP to prevent periventricular–intraventricular hemorrhage in preterm neonates is not recommended as this has been shown to confer no benefit.^{25,157}

FFP is used in newborns to prepare reconstituted whole blood when this product is indicated.

Dosage and administration

Compatibility tests before plasma transfusion are not necessary. Plasma should be ABO compatible with the recipient's RBCs (see Table 32.4). The Rh group need not be considered.²⁵ However, when large volumes of FFP are given to RhD-negative females of childbearing potential (such as in intensive plasma exchange) some authors recommend the prevention of RhD immunization by the use of RhD immune globulin.^{25,158} Although RBCs are hemolyzed during freezing, sensitization can rarely occur because FFP contains a small amount of red cell stroma.

FFP may be thawed in a waterbath at 30–37°C (the unit must be placed in a watertight protective plastic overwrap to prevent bacterial contamination) or in a microwave specifically designed for this purpose.

The dose of FFP depends on the clinical situation and the underlying disease process. When FFP is given for coagulation factor replacement, the dose is 10–20 mL/kg. This dose will usually raise the level of coagulation factors by

approximately 20% immediately after infusion,^{159,160} although in situations where coagulation factors are being actively consumed larger doses may be necessary. FFP is transfused through a standard 170–260 µm blood filter and is usually administered over 2–4 hours or as rapidly as the patient's clinical situation dictates. Posttransfusion monitoring of the patient's coagulation status (PT, APTT and/or specific coagulation factor assays) is important for optimal treatment. Information on *in vivo* properties of coagulation factors, which may guide plasma transfusion therapy, is summarized in Table 32.10.^{159,160}

Platelets

Description and storage

A platelet concentrate (PC) may be prepared from a WB donation using the platelet-rich plasma (PRP) or buffy coat (BC) method of preparation (see Fig. 32.1), or by an apheresis procedure using a variety of different systems. PCs prepared from WB using the PRP method contain a minimum of 5.5×10^{10} platelets/unit suspended in approximately 50 mL of plasma. PRP-PCs are usually supplied to hospitals as single units. The hospital blood bank then supplies these units to the wards singly, or more often after pooling an appropriate number of units. BC platelets are pooled together by the blood supplier before issuing to hospitals; pools usually consist of platelets derived from four or five WB donations. The platelet content and unit volume are approximately the same

Table 32.10 *In vivo* properties of blood clotting factors.

Factor	Plasma concentration required for hemostasis*	Half-life of transfused factor ^{††}	Recovery in blood (as % of amount transfused)
I (fibrinogen)	1.0 g/L	3–6 days	50
II	0.4 IU/mL	2–5 days	40–80
V	0.10–0.25 IU/mL	12 h	80
VII	0.05–0.20 IU/mL	2–7 h	70–80
VIII	0.10–0.40 IU/mL	8–12 h	60–80
IX	0.10–0.40 IU/mL	18–24 h	40–50
X	0.10–0.15 IU/mL	2 days	50
XI	0.15–0.30 IU/mL	3 days	90–100
XIII	0.01–0.05 IU/mL	6–10 days	5–100
VWF	0.25–0.50 IU/mL	3–5 h	–

For treatment of recessively inherited (rare) coagulation disorders the reader is also referred to Ref. 160.

* Upper limit usually refers to surgical hemostasis.

†† Refers to the half-life following FFP transfusion.

Adapted with permission from Ref. 159.

as would be present in a corresponding number of PRP-PCs. The number of platelets in an apheresis unit depends on the production method and may vary with national/regional requirements. The volume of plasma is determined according to the amount necessary to maintain platelet viability given the platelet content; it is a maximum of 1.5×10^9 platelets/mL plasma. Typically an apheresis unit intended for transfusion to an adult patient will contain $300\text{--}400 \times 10^9$ platelets in 250–300 mL of plasma. Alternately, as noted above, platelets (either apheresis platelets or BC platelets) may be stored in platelet storage media. PCs are stored at 22–24°C with continuous gentle agitation. In most jurisdictions PCs may only be stored for a maximum of 5 days. However, if bacterial detection has been performed (see Chapter 33) and platelet viability has been proven, some countries now permit a 7-day storage period.¹⁶¹

Indications for transfusion

Platelet transfusions are mainly indicated to treat or prevent hemorrhages in thrombocytopenic patients or patients with dysfunctional platelets.

Decreased platelet production

Decreased platelet production occurs in children with congenital or acquired aplastic anemia, bone marrow infiltration with leukemic or other malignant cells and/or following myeloablative chemotherapy. The majority of studies addressing the indications for platelet transfusions for patients with decreased platelet production have been performed in patients with acute leukemia. It is, however, reasonable to use results of these studies to guide platelet transfusion therapy for the majority of patients with hypoproliferative thrombocytopenia.

Prior to the availability of platelets for transfusion, hemorrhage in patients with leukemia and severe thrombocytopenia was frequently fatal. In a report from the National Cancer Institute in the USA, hemorrhage was considered to have been the major cause of death in 52% of 414 acute leukemic patients studied from 1954 to 1963.¹⁶² With the introduction of plastic blood collection systems in the late 1960s, platelets became available for the treatment of patients with thrombocytopenic bleeding. By the 1980s, deaths due to hemorrhage gradually decreased to the point that only 3% of adults with acute nonlymphoblastic leukemia (ANLL) had lethal hemorrhagic complications.¹⁶³

In the 1970s and 1980s several studies (reviewed in Ref. 164) addressed the issue of prophylactic versus therapeutic platelet transfusions for thrombocytopenic patients with acute leukemia. These studies demonstrated that platelets given prophylactically do decrease the incidence of significant bleeding episodes in patients with leukemia, but they did not demonstrate a longer survival in patients transfused prophylactically versus those transfused only in the presence of active bleeding. Despite this, several experts began to recommend the use of prophylactic platelet transfusions,^{165–168} and this is now the main indication for platelet transfusion in hematology-oncology patients.^{169,170}

In the reviews cited above, published in the late 1970s and early 1980s, and advocating the use of prophylactic platelet transfusions for patients with leukemia, it was often suggested that the platelet count be maintained above 20×10^9 /L. This figure appears to have been derived from a much-quoted study by Gaydos *et al.* published in 1962.¹⁷¹ In this study gross hemorrhage was visible on < 1% of days at all platelet levels $> 20 \times 10^9$ /L and on 4% of days where platelet counts were $10\text{--}20 \times 10^9$ /L. When this study was performed the platelet inhibitory effects of aspirin were not yet appreciated and many of these patients were probably receiving

aspirin, which could also have contributed to the observed bleeding. The authors concluded that no clear “threshold” platelet count could be identified; nevertheless the study appears to have been the basis for the practice that developed in the 1980s of using a platelet count trigger of $20 \times 10^9/L$ for prophylactic transfusion.

In the late 1980s and the early 1990s, due to the increased awareness of transfusion-transmitted diseases and the cost and difficulty of maintaining adequate supplies of platelet concentrates, the necessity of maintaining a minimum platelet count of $20 \times 10^9/L$ in all patients with decreased platelet production began to be questioned. At a Consensus Development Conference addressing platelet transfusion therapy sponsored by the National Institutes of Health in the USA in 1986, the panel concluded that patients with severe thrombocytopenia may benefit from prophylactic transfusions but that the commonly used threshold value of $20 \times 10^9/L$ may sometimes be safely lowered.¹⁷² During the 1990s a number of studies were performed investigating the safety of lowering the trigger for prophylactic platelet transfusions for patients with thrombocytopenia due to decreased platelet production but without other risk factors for bleeding.^{164,173–180} All investigators concluded that this practice is safe, and a lower threshold for prophylactic platelet transfusions is now advocated in several published reviews and guidelines for platelet transfusion.^{181,182} However, there is not complete consensus with respect to which factors may actually constitute increased risk for bleeding, and there remain concerns about the lack of accuracy when counting very low numbers of platelets. Most current guidelines are similar to those published in 2003 by the British Committee for Standards in Haematology which state the following.

- A threshold of $10 \times 10^9/L$ is as safe as higher levels for patients without additional risk factors. Risk factors include sepsis, concurrent use of antibiotics or other abnormalities of hemostasis.
- For patients without any risk factors, a threshold of $5 \times 10^9/L$ may be appropriate if there are concerns that alloimmunization could lead to platelet refractoriness. However, accurate counting of low platelet numbers may create difficulties when trying to reduce the threshold below $10 \times 10^9/L$.
- A specific threshold for transfusion may not be appropriate for patients with chronic stable thrombocytopenia who are best managed on an individual basis depending on the degree of hemorrhage.¹⁸²

Prophylactic platelet transfusions are also indicated for thrombocytopenic patients undergoing invasive procedures. At least one study suggests that major surgical procedures can be safely performed in leukemic patients at platelet counts of $50 \times 10^9/L$.¹⁸³ However, there are limited published data concerning appropriate platelet counts for patients with hematologic or other malignancies undergoing common invasive procedures such as the insertion of permanent indwelling central venous catheters or lumbar punctures.

Most authors recommend a platelet count $\geq 40 \times 10^9/L$ for these procedures. It is possible that lower levels may be adequate when these procedures are performed by experienced personnel.^{184–188} Bone marrow aspiration and biopsy can be safely performed (with respect to local bleeding) at any platelet level by providing adequate surface pressure at the procedure site.

Increased platelet destruction

Patients with thrombocytopenia due to autoimmune thrombocytopenic purpura (AITP) should only be treated with platelet transfusions in the presence of central nervous system or other life-threatening bleeding.^{189,190} Before surgical procedures, such as splenectomy or cesarean section, the platelet count can usually be raised preoperatively, using corticosteroids or intravenous immunoglobulins, to levels sufficient to assure adequate hemostasis. A variety of conditions other than AITP (e.g., septicemia, trauma, obstetrical complications) may result in platelet consumption that is sufficiently severe to require platelet transfusion. Platelet increment and survival are usually decreased in these patients and a larger number of units administered at more frequent intervals may be necessary.

Massive transfusion

The average adult patient will have a platelet count $< 50 \times 10^9/L$ after losing two blood volumes.^{153,155} Depending on the underlying etiology of the bleeding, the thrombocytopenia may be dilutional from platelet loss through hemorrhage and/or due to platelet consumption. Platelet transfusion therapy should be based on a consideration of several factors including platelet count, an assessment of the role of the thrombocytopenia in the observed bleeding and the estimated hemostatic platelet count necessary for the patient's given clinical situation.^{146,152} Most guidelines do recommend administering platelet transfusions to maintain a platelet count of at least 50×10^9 in an actively bleeding patient.^{25,26,146,182}

Platelet dysfunction

Platelet dysfunction, possibly requiring platelet transfusion, is most commonly encountered in three situations: in patients taking platelet inhibitory drugs; following surgery with cardiopulmonary bypass pump (CBP); and during ECMO.

Platelet inhibitory drugs, such as aspirin, nonsteroidal anti-inflammatory agents and newer platelet aggregation inhibitors such as clopidogrel bisulfate and ticlopidine hydrochloride, and glycoprotein (Gp)IIb/IIIa receptor antagonists, should be avoided in thrombocytopenic patients and, if possible, in all patients before invasive procedures. Treatment with desmopressin acetate or antifibrinolytics may be helpful in selected patients on aspirin or other nonsteroidal anti-

inflammatory medications who are bleeding or who require invasive procedures.^{191,192} The published literature examining the role of platelet transfusions in patients taking platelet aggregation inhibitors has recently been summarized; the authors concluded that studies do suggest a role for therapeutic platelet transfusions in bleeding patients with recent exposure (within 7 days) to these medications but do not support the use of prophylactic platelet transfusions.¹⁹³ GpIIb/IIIa receptor antagonists have relatively short half-lives (a few hours to 48 hours) so that platelet transfusion support, if required, would only be over that time frame.

Patients who have undergone surgery with CBP may have a dilutional and/or consumptive thrombocytopenia, although the platelet count usually remains above $100 \times 10^9/L$. Platelet dysfunction lasting 4–6 hours post-CBP has been well documented.^{194,195} Nevertheless, studies have not shown any benefit for the use of prophylactic platelet transfusions for patients undergoing CBP.¹⁹⁶ Platelet transfusions should be reserved for those patients who, following CBP, have excessive bleeding thought to be due to platelet function abnormalities and/or thrombocytopenia. Platelet dysfunction and thrombocytopenia also occur during ECMO.¹⁹⁷ It is usually recommended to maintain the platelet count above $100 \times 10^9/L$ in patients during ECMO.^{25,26}

Patients with congenital thrombopathies (e.g., Glanzmann thrombasthenia) may occasionally require platelet transfusions. These patients should be managed by a subspecialist with expertise in this area.

Special considerations for newborns

Newborns should receive platelet transfusions in the same clinical settings as described above for older children. However, because newborns frequently manifest thrombocytopenia and because preterm infants are at risk for periventricular/intraventricular hemorrhage, it is possible that the platelet level at which prophylactic platelet transfusions should be administered to newborns is higher than that recommended for other patients. Only one prospective randomized study, published in 1993, has addressed this issue. In that study prophylactic platelet transfusions sufficient to maintain platelet counts $> 150 \times 10^9/L$ failed to influence the incidence or extension of intraventricular hemorrhage.¹⁹⁸ No other prospective controlled trials have addressed this issue. The authors of a retrospective study published in 2002 concluded that a neonatal prophylactic transfusion trigger threshold of $< 30 \times 10^9/L$ is likely to represent “safe” practice for the majority of neonatal intensive care unit patients (i.e., stable preterm neonates).¹⁹⁹

With only such limited evidence-based information available, definitive guidelines for platelet transfusions in newborns cannot be formulated, and published guidelines actually vary considerably in their recommendations.^{25,26,84,200} One recommended set of guidelines is summarized in Table 32.11.

Table 32.11 Suggested guidelines for platelet transfusions in neonates.

Platelet count $< 30 \times 10^9/L$ in a neonate with neonatal alloimmune thrombocytopenia
Platelet count $< 30 \times 10^9/L$ with failure of platelet production
Platelet count $< 50 \times 10^9/L$ in a stable preterm infant:*
with active bleeding
prior to invasive procedure with failure of platelet production
Platelet count $< 100 \times 10^9/L$ in a sick preterm infant:†
with active bleeding
prior to invasive procedure with disseminated intravascular coagulation

* British guidelines suggest a platelet count of $< 20 \times 10^9/L$ for term infants.¹⁷⁹

† British guidelines do not state specific recommendations in these situations.¹⁷⁹

Adapted with permission from Ref. 26.

Prospective, randomized, controlled trials are needed to firmly establish optimal platelet transfusion thresholds in neonates.

Neonates with thrombocytopenia due to maternal platelet alloantibodies should receive platelet transfusions from donors lacking the antigen corresponding to the maternal antibody in order to maintain platelet counts $\geq 30 \times 10^9/L$.²⁶ In emergency situations if antigen negative platelets are unavailable (or, pending the availability of antigen negative platelets) transfusion of a platelet concentrate from an random donor may lead to an adequate platelet increment.^{200a}

Product choice, dosage and administration

Platelets possess intrinsic ABH antigens and extrinsically absorbed A and B antigens.¹⁹⁸ Nevertheless, ABO-incompatible platelets (i.e., platelets with A and/or B antigens given to a donor with a corresponding antibody) are usually clinically effective. However, there are several reports of acute intravascular hemolysis following the transfusion of platelet concentrates containing ABO antibodies incompatible with the recipient's RBCs.^{201,202} Therefore, ABO-matched platelets should be used in pediatric patients, especially for neonates and small children where the volume of plasma may be relatively large with respect to the patient's total blood volume. If ABO-matched platelets are not available, units with plasma compatible with the recipient's RBCs should be chosen. If this is also not possible, units with low titers of anti-A or -B should be selected or alternatively the plasma can be removed from platelet concentrate (i.e., use a volume-reduced platelet concentrate).²⁵

Platelets do not carry Rh antigens.²⁰¹ However, the quantity of RBCs in platelet concentrates is sufficient to induce RhD sensitization even in immunosuppressed cancer patients. Hence, as far as possible, platelets from an RhD-negative donor should be used for RhD-negative patients. If

platelets from an RhD-positive donor, or platelets from a donor of unknown RhD phenotype, are given to an RhD-negative recipient, administration of anti-D immunoprophylaxis should be considered, especially for female patients.^{25,181} The amount of anti-D immunoglobulin necessary to prevent sensitization depends on the number of contaminating RBCs in the platelet concentrates. A dose of 25 µg (125 IU) of anti-D immunoglobulin will protect against 1 mL of RBCs.²⁰³ An adult dose of platelets usually contains less than 2 mL of RBCs. If available, it is preferable to use a preparation of anti-D that can be administered intravenously.

Studies have not been performed to determine the most appropriate platelet doses for pediatric platelet transfusions, and recommended doses do vary. North American guidelines generally recommend a dose of 5–10 mL/kg of either WB-derived or apheresis PCs, with the larger dose (i.e., 10 mL/kg) being used in neonates and the smaller dose (5 mL/kg) being used in infants and children.²⁶ Practically speaking, when using WB-derived PCs (that have not been previously pooled) this corresponds to approximately one WB-derived PC per 10 kg body weight. UK guidelines recommend slightly higher doses, namely 10–20 mL/kg for children weighing less than 20 kg.¹⁸²

In adults the question of the optimal platelet dose (i.e., the number of platelets administered per platelet transfusion), particularly in the setting of prophylactic transfusions for patients with hypoproliferative thrombocytopenia, is currently a subject of debate and ongoing clinical trials.^{204–206} Potential advantages of lower doses (i.e., $< 300 \times 10^9$ platelets per transfusion) include the use of fewer platelets thereby potentially reducing donor exposure and costs, while potential advantages of higher doses include longer intervals between platelet transfusions.^{207,208} To date studies with small numbers of patients that lower doses do not lead to an increased risk of serious or life-threatening bleeding but further studies are required before definitive statements can be made. Currently, a standard platelet dose for an adult is $300\text{--}600 \times 10^9$ platelets/dose; alternatively, a dose can be more specifically calculated.¹⁸² Patients with platelet consumption (e.g., with septicemia or DIC) or splenomegaly may require larger doses of platelets.

Platelet concentrates may be volume reduced before infusion. However, this extra manipulation leads to platelet loss and, if not carefully performed, may adversely affect platelet function and/or be a cause of bacterial contamination. Volume reduction should therefore be limited to patients who require severe volume restriction or situations where ABO-incompatible platelets are the only available product. Many patients requiring platelet transfusions should receive irradiated products only. Indications for irradiation of PCs (and other blood components) are discussed in Chapter 33. PCs must be filtered using a standard 170–260 µm filter. PCs must be filtered, using either a standard 170–260 µm filter, or if the unit has not been leukoreduced prestorage, a bedside

leukoreduction filter (depending upon the requirement for leukoreduction). Platelet counts should always be performed following platelet transfusion to assure that the platelet count has increased as expected. This is particularly important for platelet transfusions given before surgery or invasive procedures.

Platelet refractoriness

The response to a platelet transfusion, known as the corrected platelet count increment (CCI), is determined using the following formula, which takes into account the recipient's body surface area and number of platelets transfused:

$$\text{CCI} = \frac{[(\text{Posttransfusion} - \text{pretransfusion}) \text{ platelet count} (\times 10^9/\text{L})] \times \text{body surface area} (\text{m}^2)}{\text{Number of platelets transfused} (\times 10^{11})}$$

In general, a platelet transfusion is considered successful if the CCI is $> 7.5 \times 10^9/\text{L}$ within 10–60 min of a transfusion and $> 4.5 \times 10^9/\text{L}$ if measured 18–24 h after transfusion.

Refractoriness to platelet transfusions is defined as a consistently inadequate response to platelet transfusion, for instance, a CCI of $< 5 \times 10^9/\text{L}$ following two separate transfusions of an adequate number of platelets. Refractoriness may be due to immune causes (i.e., the presence in the recipient of HLA- or platelet-specific alloantibodies) or nonimmune causes, such as infection, DIC, splenomegaly, medications (in particular amphotericin B, vancomycin, antithymocyte globulin) and hematopoietic progenitor cell transplantation.^{209–211}

If platelet refractoriness is suspected, the first steps in the management of the patient are to assure that ABO-identical platelets are used and to carefully assess the patient for nonimmune causes. The use of fresh as opposed to stored platelets may result in increased CCIs, particularly in clinically unstable patients.²⁰⁹ If no increment in platelet count is observed following the transfusion of ABO-identical platelets, the recipient should be phenotyped for HLA class I antigens and screened for the presence of HLA class I antibodies. If an HLA alloimmunization is confirmed, the usual approach is then to transfuse single-donor, apheresis, HLA-matched platelets using the best HLA match available.²¹² Other approaches include the selection of platelets on the basis of HLA antibody (e.g., a patient with an HLA-B27 antibody would receive platelets from an HLA-B27-negative donor) or the use of platelet cross-matching.^{182,213–215} The rare patient with platelet-specific alloantibodies should be treated with platelets lacking the corresponding antigen. The use of antifibrinolytic agents such as ε-aminocaproic acid may also be helpful in these patients (as well as in nonrefractory patients).²¹⁶ Some alloimmunized patients may lose their antibodies over time and again become responsive to random donor platelet transfusions.^{217,218}

The management of alloimmunized patients who do not

respond to the above measures is problematic. It is unlikely to be of benefit to administer prophylactic platelet transfusions to such patients. In the presence of clinically significant bleeding, approaches such as the use of larger and/or more frequent random-donor platelet transfusions may be attempted. The administration of intravenous immunoglobulin may result in improved posttransfusion platelet increments but does not usually increase platelet survival.²¹⁹

Granulocytes

Description and storage

To assure clinical efficacy, granulocyte concentrates for transfusion to adults should contain a minimum of 10^{10} and preferably closer to 10^{11} polymorphonuclear cells (PMNs)/unit. To obtain this number of PMNs, concentrates are prepared by automated leukapheresis using an erythrocyte sedimenting agent such as hydroxyethyl starch to enhance the efficacy of separation of granulocytes from erythrocytes. Donors are usually stimulated with oral corticosteroids before collection, but even with this only about 10% of collections contain an adequate PMN dose. Stimulation of donors with granulocyte colony-stimulating factor (G-CSF) in addition to corticosteroids results in collections with PMN counts closer to 10^{11} /dose.²²⁰ However, the use of corticosteroids and G-CSF in donors, particularly unrelated donors, does require special ethical considerations. The platelet and RBC content varies with the collection method. The plasma volume is 200–400 mL. Granulocyte function deteriorates rapidly during storage. Thus, granulocytes should be transfused as soon as possible following collection, preferably within 12 hours, and should not be given if stored for > 24 hours. For the time between collection and infusion, granulocyte concentrates should be stored at 20–24°C and kept unagitated.²²¹

Indications for transfusion

There is no evidence to support the role of prophylactic granulocyte transfusions, and even the use of granulocyte transfusions in established bacterial or fungal infections remains controversial.²²² However, the use of G-CSF-stimulated granulocyte transfusions may be reasonable in the following situations.

- A resistant severe clinical infection in a neutropenic (neutrophil count $< 0.2\text{--}0.5 \times 10^9/\text{L}$) patient who has shown no response to aggressive antibiotic treatment with no recovery in neutrophil count expected for more than 7 days.
- Severe infections, e.g., systemic fungal infections/necrotizing fasciitis or severe neutropenic typhlitis progressing on appropriate antifungal or broad-spectrum antibiotics, in neutropenic patients where no recovery in neutrophil count is expected for more than 7 days.²²⁰

Nevertheless, at least one study using G-CSF-stimulated donors found no difference in survival between such patients treated with granulocyte transfusions and those not receiving granulocyte transfusions.²²³ Thus, given the lack of adequate trials upon which to base decisions for this costly and logistically difficult treatment, which also includes medicating donors, further appropriate trials should be performed to determine the indications for granulocyte transfusions.^{223,224}

Special considerations for newborns

Newborns normally have a transient neutrophilia in the first week of life, with mean normal absolute neutrophil counts ranging from $11.0 \times 10^9/\text{L}$ at birth to $5.5 \times 10^9/\text{L}$ at 1 week of life.²²⁵ Septic newborns frequently develop neutropenia, defined in the first days of life of a newborn as an absolute neutrophil count $< 3.0 \times 10^9/\text{L}$. A Cochrane Database Systematic Review to determine the efficacy and safety of granulocyte transfusions as adjuncts to antibiotics for the treatment of sepsis in neonates with neutropenia was published in 2003.²²⁶ Four eligible studies were identified, three comparing granulocyte transfusions versus no transfusion and one comparing granulocyte transfusions versus intravenous gammaglobulin. The reviewers concluded that there is inconclusive evidence from randomized, controlled trials to support or reject the use of granulocyte transfusions in this setting to reduce mortality and morbidity. Septic, neutropenic newborns may respond to treatment with G-CSF.²²⁷ Thus, the role for granulocyte transfusion in newborns also remains unclear.

Dosage and administration

Once the decision to administer granulocyte transfusions has been made, they are administered daily until there is evidence of recovery of peripheral neutrophil counts or clinical evidence of recovery from the infection. In order to provide granulocyte transfusions daily for several days and to assure both adequate viral testing of donors and/or units and administration of units within 24 hours of collection, special arrangements need to be made with the blood supplier. For neonates and small children, a daily infusion of $1\text{--}2 \times 10^9$ PMN/kg should be given, and for larger children an absolute dose of at least $2\text{--}3 \times 10^{10}$ PMNs.^{25,26} As there is significant RBC contamination, units must be ABO compatible and if possible RhD negative for RhD-negative recipients, and must undergo the usual compatibility testing. Because there is also a large amount of plasma the donor should ideally be ABO isogroup with the recipient. Patients should be tested for the presence of HLA (and if possible neutrophil) antibodies before the first granulocyte transfusion and periodically during a prolonged course of transfusions. Alloimmunization frequently occurs in patients receiving granulocyte transfusions and may render the transfusions ineffective and/or be associated with adverse reactions

including respiratory distress.²²⁸ For patients with HLA- and/or granulocyte-specific alloantibodies, only granulocytes from HLA- and/or neutrophil antigen-compatible donors should be used. In patients receiving amphotericin B the granulocyte transfusion should be separated in time as far as possible from the amphotericin B infusion to decrease the possibility of adverse pulmonary reactions.²²⁹ Granulocytes must be transfused through a standard 170 µm blood filter. A leukoreduction filter must not be used and microaggregate filters are also not recommended. The transfusion is usually administered over 2–3 hours.

Cryoprecipitate

Description and storage

Cryoprecipitate is the precipitate formed when FFP is thawed at a temperature between 1 and 6°C. The precipitate is then refrozen within 1 hour in 5–40 mL of the donor plasma and stored at –18°C or less for a period of up to 1 year. Each unit of cryoprecipitate contains at least 80 units of FVIII and 150 mg of fibrinogen, and usually contains 40–60 mg of fibronectin, 40–70% of the von Willebrand factor and 30% of the FXIII present in the original unit of plasma.

Indications for transfusion

The majority of situations in which cryoprecipitate has been used in the past, in particular as treatment for hemophilia A and von Willebrand disease, can now usually be managed with alternative, safer products (see Chapters 26 and 27). Cryoprecipitate has also been used to treat bleeding due to congenital deficiencies of fibrinogen or FXIII. Virus-inactivated plasma-derived concentrates are now commercially available for these disorders, although they are not licensed in all countries. If unavailable, cryoprecipitate may be used. Cryoprecipitate was also used as a source of fibrinogen for fibrin glue, but again there are now virally inactivated fibrin glue products. Finally, cryoprecipitate was previously used to treat bleeding in patients with uremia. These patients are now treated with dialysis, desmopressin and erythropoietin. Currently, the main indication for cryoprecipitate therapy is to control bleeding due to acquired fibrinogen deficiency, for example in severe liver disease, DIC or certain obstetrical disorders.^{25,26,147}

Dosage and administration

Compatibility testing of cryoprecipitate units is unnecessary. However, cryoprecipitate does contain anti-A and -B so the use of ABO-compatible units is preferable, especially when the infused volume is large relative to the recipient's red cell mass. The RhD group need not be considered. The number

of units of cryoprecipitate required is usually based on the amount necessary to obtain a hemostatic level of fibrinogen, that is, a fibrinogen level > 0.8–1.0 g/L. If the units are carefully pooled this can usually be accomplished by the transfusion of 1 unit/5–10 kg recipient weight.

Cryoprecipitate is prepared for transfusion by thawing at 30–37°C and mixing the thawed precipitate with 10–15 mL of sodium chloride 0.9%, if necessary, according to the amount of plasma in the cryoprecipitate unit. The required number of units is then pooled. Thawed cryoprecipitate should be kept at room temperature and transfused immediately after thawing. If not transfused immediately, recommended storage temperatures (i.e., room temperature versus 4°C) and storage times (4–24 hours) vary among countries. Cryoprecipitate is transfused through a standard 170–260 µm blood filter and is administered as rapidly as the patient's clinical situation permits.

Albumin

Preparation and storage

Albumin is derived from large pools of donor plasma obtained from either WB or plasmapheresis donations. It is prepared by the cold alcohol fractionation process (Cohn fractionation) followed by heat treatment at 60°C for 10 hours. Its composition is 96% albumin and 4% other plasma proteins. In North America, albumin is available as a 25% solution in distilled water or as a 5% solution in saline. Outside North America other similar concentrations are used in some jurisdictions (e.g., 20% and 4.5%). The 25% and 5% preparations have a physiologic pH and a sodium content of about 145 mmol/L (145 mEq/L). The 5% solution is osmotically and oncologically equivalent to plasma, while the 25% solution is osmotically and oncologically 5-fold greater than plasma. These products can be stored for up to 5 years at 2–10°C.

Indications for transfusion

Indications for albumin use generally fall into two categories: the treatment of patients with hypoalbuminemia or patients requiring intravascular volume expansion. Albumin should not be used to treat either mild hypoalbuminemia or a nutritional deficiency. However, albumin may be beneficial in the treatment of nephrotic syndrome resistant to diuretics²³⁰ or after large-volume paracentesis.^{231,232} Patients requiring intravascular volume expansion can be treated with crystalloids (e.g., saline or Ringer's lactate), synthetic colloid (e.g., pentastarch, hexastarch or dextran) or albumin (a human plasma-derived colloid).

A meta-analysis published by the Cochrane Injuries Group Albumin Reviewers in 1998 concluded that there was no evidence that albumin reduced mortality in critically

ill patients with hypovolemia, burns or hypoalbuminemia, and there was a strong suggestion that it could increase mortality.²³³ On the other hand, authors of two other meta-analyses came to different conclusions: one group examined the effects of resuscitation with albumin-containing fluid on the risk of death in a general population of patients and did not find a significant increase in the risk of death, while the other concluded that albumin may reduce morbidity in critically ill patients.^{234,235} In 2004, a randomized, controlled trial comparing albumin and saline for fluid resuscitation in critically ill adult patients (the SAFE study) was published.²³⁶ This study showed that in a heterogeneous population of adult patients in intensive care units the use of either 4% albumin or normal saline for fluid resuscitation results in similar outcomes at 28 days. The investigators did note that there were subgroups where there were suggestions of differences and further studies are needed (e.g., patients with trauma and brain injury where saline may be preferable, and patients with septic shock and hypovolemia where albumin may be preferable). Following the publication of this study, the Cochrane Review was updated and this time the reviewers concluded that there is no evidence that albumin reduces mortality in critically ill patients with burns and hypoalbuminemia, although they noted, as did the SAFE investigators, that there remain subsets of patients for whom albumin use should be further evaluated.²³⁷ Finally, there continues to be debate about the safety/efficacy of albumin versus synthetic colloids (and of different synthetic colloids).²³⁸ Most studies evaluating the use of volume expanders do not include pediatric patients, so that the optimal treatment of crystalloids versus synthetic colloids versus albumin in neonates and children remains even less clear in pediatric patients than in adults. However, at least two (albeit small) studies suggest that crystalloids or synthetic volume expanders are safe and efficacious in neonates or young infants, and presumably the results of adult studies can be extrapolated to older children.^{239–241}

Dosage and administration

Albumin does not need to be administered through a filter. Dosage and rate of infusion depend upon the patient's clinical condition. In shock the usual dosage of 5% albumin is 500 mL in adults and 10–20 mL/kg in children. The 25% solution should not be used in dehydrated patients unless it is supplemented by the infusion of crystalloid solutions.

Immunoglobulins

Plasma-derived immunoglobulins are available as nonspecific or specific antibody preparations for either intramuscular or intravenous use. All are prepared by fractionation from large pools of human plasma and all undergo efficacious viral

removal/inactivation procedures. Intramuscular immunoglobulin, commonly known as human immune serum globulin (ISG), is prepared by cold alcohol fractionation (Cohn fractionation). ISG is approximately 95% IgG with the remaining 5% consisting of other plasma proteins. ISG is for intramuscular use only; it must not be administered intravenously as it contains aggregated IgG complexes that can activate complement causing adverse reactions if administered intravenously. The commonest use of ISG is for hepatitis A or measles prophylaxis. Several specific intramuscular human immune globulin preparations are available. They are identical to ISG except that they have high titers to an infectious agent or the RhD antigen. The most commonly used preparations are hepatitis B immune globulin and varicella zoster immune globulin for the prevention of hepatitis B and varicella zoster infections, respectively, and RhD immune globulin for the prevention of RhD alloimmunization.

IVIG preparations are virtually free of immunoglobulin complexes and therefore safe for intravenous infusion. The protein content of IVIG preparations is > 95% IgG. Several nonspecific IVIG preparations are commercially available. They differ in the manufacturing processes used for immunoglobulin purification and for viral inactivation/removal and in their formulations, but for practical purposes are generally therapeutically equivalent. Some contain less IgA than others and are therefore preferentially chosen if treating a patient with anti-IgA. Licensed indications for IVIG administration vary among products and countries. Licensed indications include the use of IVIG as replacement therapy in primary immunodeficiency states and some secondary immunodeficiency states, including HIV infection in children and acquired hypogammaglobulinemia, and as an immunomodulating agent to treat patients with autoimmune thrombocytopenic purpura or Kawasaki disease.^{242,243}

IVIG is also commonly used for the treatment of several disorders that are not labelled indications. There is good or reasonably good evidence for the efficacy of IVIG in some of these indications, such as Guillain-Barré syndrome, chronic inflammatory demyelinating polyneuropathy, refractory myasthenia gravis, hemolytic disease of the newborn and neonatal alloimmune thrombocytopenia (selected women during pregnancy and severely thrombocytopenic newborns for whom appropriate platelet concentrates are not immediately available).^{242–248} The use of IVIG in other disorders for which it has been advocated is often based on the rationale that the disorder has a known or suspected autoimmune pathophysiology and the presence in the literature of anecdotal reports of efficacy. In these cases decisions as to the appropriate use of this expensive treatment are often problematic. A recent Cochrane Database Systematic Review evaluated the evidence for the use of IVIG for suspected or proven infection in neonates; the reviewers concluded that, at the present time, there is insufficient evidence to support the routine use of IVIG in this situation.²⁴⁹

There are intravenous immunoglobulin preparations with high-titer antibodies against infectious disease agents, such as cytomegalovirus or hepatitis B, which may be indicated for the prevention of the corresponding infections in selected patients (e.g., transplant recipients).^{250,251} Intravenous anti-D preparations are also available, and in addition to their use to prevent RhD alloimmunization may also be used in the treatment of selected patients with autoimmune thrombocytopenic purpura.^{252,253}

Hazards of transfusion

Naomi L.C. Luban and Edward C.C. Wong

There are many hazards to transfusion, some serious, others less serious and many undetected or poorly categorized. In the USA there is no established surveillance system for non-fatal transfusion events. In Europe and Canada, hemovigilance has become integrated into public health surveillance systems. Such systems provide important data on adverse outcomes, which provide opportunities for process improvement in all aspects of blood collection and administration. The ultimate goal of such systems is to use data on adverse events to reduce complications related to transfusion (Table 33.1). This chapter will review the more serious complications of blood component transfusion of importance to children with emphasis on recognition and prevention.

Table 33.1 Different types of adverse transfusion events.

Adverse event	Estimated risk
<i>Serious</i>	
Mistransfusion	1 in 14 000 to 1 in 19 000
ABO-incompatible transfusion	1 in 38 000
Death due to ABO-incompatible transfusion	1 in 1.8 million
Acute hemolytic transfusion reaction	1 in 12 000
Delayed hemolytic transfusion reaction	1 in 4000 to 1 in 12 000
Transfusion-related acute lung injury	1 in 2000 to 1 in 5000 (5–10% fatal)
Anaphylaxis	1 in 20 000 to 1 in 47 000 1 in 1600 (platelets) 1 in 23 000 (RBCs)
Graft-versus-host disease	1 in 1 million (Canada)
Posttransfusion purpura	1 in 143 000 to 1 in 294 000
Fluid overload	1 in 708 to 1 in 3200 1 in 7000 to 1 in 15 000
<i>Less serious</i>	
Febrile nonhemolytic transfusion reaction	1 in 500
Allergic (urticaria)	1 in 250

Acute transfusion reactions

Acute hemolytic transfusion reactions

Acute hemolytic transfusion reactions (AHTRs) occur most often when a recipient with circulating preformed antibody is transfused with red blood cells containing the antigen to which the antibody developed. Most AHTRs are the result of transfusion of antibodies against the major blood group antigens, A or B. Due to the absence of preformed anti-A and -B, infants under 4 months of age are not at risk for AHTRs. Most ABO hemolytic transfusion reactions are a result of misidentifying the intended recipient of a unit of blood due to mislabelling of the specimen or misidentification of the patient at the time of transfusion; these reactions are therefore avoidable. Hemolytic transfusion reactions can also occur following the passive transfusion of isohemagglutinins found in ABO-incompatible plasma-containing platelet concentrates.^{1,2} The severity of AHTRs is proportional to the rate and volume of transfused incompatible blood. When anti-A and -B binds to the C5–9 component of complement, intravascular RBC lysis occurs. The resultant interleukin (IL) inflammatory response is characterized by the generation of tumor necrosis factor (TNF)- α , IL-8, monocyte chemoattractant protein 1 (MCP-1), and the anaphylatoxins C3a and C5a, as well as the activation of Hageman factor.³

Nonimmune causes of acute hemolysis include those related to transfusion through mechanical devices and accessories like blood warmers, infusion devices, filters and catheters required to deliver blood and blood components, or to improper storage, exposure to hypotonic fluids, irradiation followed by storage of red blood cells and bacterial contamination.

Signs and symptoms of AHTRs include fever, chills, back and chest pain, nausea and shortness of breath. The patient may develop hypotension, vasoconstriction, ischemia and disseminated intravascular coagulation (DIC). Hypotension,

microthrombi formation and hemoglobinuria may compromise renal blood flow precipitating acute renal failure.⁴

When an AHTR is suspected, the transfusion must be stopped immediately and a full transfusion reaction investigation should be initiated. A posttransfusion direct antiglobin test (DAT) may demonstrate the presence of antibody on the RBC surface. The blood unit/segment should be cultured. Life-threatening complications are due to renal injury, DIC and pulmonary involvement. Vital signs should be carefully monitored. Aggressive intravenous hydration is required to maintain intravascular volume and urine output. AHTRs are medical emergencies that are often associated with mortality; the highest rates (44%) have been seen in patients receiving the greatest volumes of incompatible blood.

Transfusion-related acute lung injury

Transfusion-related acute lung injury (TRALI), a clinical syndrome similar to adult respiratory distress syndrome (ARDS), is characterized by acute respiratory distress occurring 1–6 hours after transfusion of a plasma-containing blood component. TRALI is a serious adverse reaction to transfusion that may be under-recognized in pediatric patients.⁵ There is usually fever, hypotension, bilateral pulmonary edema and severe hypoxemia with a normal central venous pressure. Chest radiography shows bilateral “white out” lung, i.e., pulmonary infiltrates without cardiac compromise. Patients with TRALI improve 2–3 days after the onset of symptoms, with aggressive respiratory support including oxygen and mechanical ventilation in the most severe cases.

Both HLA class I and class II and antigranulocyte antibodies have been implicated in TRALI reactions, but in about 10% or more cases,⁵ no specific antibody specificity can be identified. Two different pathophysiologic mechanisms have been proposed to explain TRALI. The first is that donor leukocyte antibodies attach to corresponding antigens on recipient leukocytes, inducing activation and sequestration of neutrophils, endothelial damage and increased vascular permeability. The antibodies may also attach to corresponding antigen on the pulmonary endothelium with recruitment of granulocytes and subsequent endothelial cell damage. In one unusual case,⁶ the transfusion of a nonleukodepleted blood product into a recipient with preexisting anti-HLA A2 antibodies produced TRALI.

The second mechanism involves neutrophil priming. In this two-hit model, surgery or infection primes the patient's neutrophils. The subsequent transfusion of stored red cell and/or platelet products with cytokines, IL6, IL8 and phosphatidylcholines then produces neutrophil sequestration.

TRALI has been reported rarely in children with malignancy (acute lymphoblastic leukemia),⁵ those undergoing bone marrow transplantation,⁷ with thalassemia undergoing chronic transfusion,⁸ following cardiopulmonary bypass,⁹ and recently in a mother–child designated donor pair.¹⁰ Evaluation and

confirmation of the phenomena is often difficult.¹¹ Methods to reduce the likelihood of TRALI include screening of donors for anti-white cell antibodies, deferral of donors with multiple pregnancies (and assumed anti-HLA and antineutrophil sensitization) and testing for lipid activators of neutrophils. None are practical. Leukodepletion of blood and blood products may or may not reduce the risk of TRALI.

Allergic reactions

Allergic transfusion reactions are the most common of all posttransfusion events. Allergy to soluble plasma proteins, drugs or other allergens may cause local reactions such as itching and urticaria or systemic symptoms such as bronchospasm or anaphylaxis. The severity of allergic reactions is not dose related; the patient who experiences urticaria during a transfusion will not develop anaphylaxis with continuation of the transfusion. Once established, most patients with allergic reactions respond to oral or parenteral antihistamines. For patients with a history of allergic reactions, pretreatment with an antihistamine may help to prevent recurrence. Severe allergic reactions with stridor or dyspnea are often associated with the development of anti-IgA antibodies in an IgA-deficient patient. Acute management includes intubation, oxygen and epinephrine (adrenaline). Management of such patients long term is often difficult and depends on confirmation of IgG and IgE anti-IgA antibodies.¹² Washed red blood cells and platelets and IgA-deficient plasma obtained from rare donor registries may be needed with premedication. Washing RBC or platelet concentrates will remove much of the plasma responsible for allergic reactions. Leukoreduction of cellular components will not decrease the incidence of allergic transfusion reactions.

Febrile reactions

Fever may be the first sign that a patient is receiving a component that is ABO incompatible or contaminated with bacteria, and such serious consequences must be considered when a patient develops fever during transfusion. A less serious but common adverse effect seen during transfusion of RBCs, platelets and plasma is the febrile nonhemolytic transfusion reaction (FNHTR), which complicates 0.5–2% of transfusions.¹³ The risk for FNHTR is highest following the transfusion of platelets (1–3%) compared with red blood cells (0.5–6%). Although the traditional view holds that FNHTRs are due to the interplay of white blood cells (WBCs) contained in the components with preformed antileukocyte antibodies in the recipient, recent studies have demonstrated that pyrogenic cytokines, IL-1 β , IL-6, IL-8 and TNF, in the plasma supernatant may induce prostaglandin E2 production in the thermoregulatory centers of the central nervous system. The intensity of the reactions correlates directly with the concentration of IL-1 β and IL-6. FNHTRs are more common

in individuals who have been previously transfused or pregnant, and are rare in infants with underdeveloped hypothalamic thermoregulatory centers. These reactions may make patients uncomfortable but are rarely associated with more serious problems. The incidence of FNHTRs can be reduced by removing leukocytes at the time of component collection (prestorage leukoreduction)¹⁴ or by removing the plasma supernatant of platelets.^{15,16} Leukoreduction by filtration of whole blood-derived platelets (platelet pools) at the time of transfusion may reduce but not prevent the reaction as the cytokines have already been released prior to the filtration. In such cases, plasma volume reduction or washing may be required.^{16,17}

Massive transfusion

Massive transfusion, the replacement of a child's blood volume over a 6-hour period, may be needed for the replacement of massive blood losses due to trauma or coagulation defects.¹⁰ The rapid infusion of large volumes of banked blood is also integral to several life-sustaining pediatric therapies such as extracorporeal membrane oxygenation (ECMO) and exchange transfusion. Certain hazards of massive transfusion occur secondary to the rapid rate of infusion of RBCs that have been stored in a refrigerator in anticoagulant/preservative solution for varying periods of time. Many of these hazards can be anticipated and avoided.

The adverse reactions associated with the rapid infusion of large volumes of cold, stored RBCs include:

- increased levels of extracellular potassium, which develop over the storage period of the RBC unit;
- poor function of the platelets contained in stored RBC components;
- progressively lowered levels of intraerythrocytic bisphosphoglycerate BPG (formerly known as 2,3 DPG);
- presence of citrate in the anticoagulant/preservative solution;
- metabolic consequences of the rapid infusion of a cold liquid.

Storage lesions

The storage of RBCs or whole blood in the liquid state results in biochemical derangements, which increase with storage time.

Hyperkalemia

Intracellular potassium leaks from the erythrocyte into the extracellular space. After 35 days of storage in citrate-phosphate-dextrose-adenine (CPDA-1), plasma K⁺ concentrations reach 27.3 mmol/L on average. Storage in additive solution (AS-1) results in significantly less potassium leak. The risk of hyperkalemia is relatively insignificant in the routine administration of small volumes of RBC and whole blood. However, fatal cardiac dysrhythmia associated with

hyperkalemia during neonatal exchange transfusion¹⁸ and following the rapid intracardiac infusion of old RBCs has been reported.¹⁹ Effective strategies for avoiding hyperkalemia-related dysrhythmias during massive transfusion include using RBCs that are < 5 days old or washed RBCs.²⁰ When whole blood is required and hyperkalemia is a concern, units should be < 5 days old, or reconstituted whole blood can be made by adding fresh frozen plasma (FFP) to washed stored RBCs.

Poor platelet function with increased storage time

The cold storage conditions that are ideal for RBCs are associated with poor *in vivo* platelet survival. The transfusion of large amounts of stored blood causes dilutional thrombocytopenia and does not provide viable platelets to participate in homeostasis. Platelet concentrates rather than whole blood are the preferred source for transfusion to thrombocytopenic, massively transfused patients who are hemorrhaging.

Low 2,3-diphosphoglycerate levels

The levels of intraerythrocyte 2,3 BPG affect the ability of RBCs to release oxygen at a given pH. After 2 weeks of storage, 2,3 BPG levels fall by > 50%, and reduced levels result in decreased ability to unload oxygen at the level of the tissues.²¹ Although 2,3 BPG levels are gradually restored once red cells are transfused, the repletion of 2,3 BPG is such that even after 8 hours, only one-third of the metabolite is regenerated.

Anticoagulant/preservative solution

The anticoagulant/preservative solution used for whole blood collection contains citrate to bind ionized calcium and prevent coagulation of the donation. Unbound citrate is metabolized to bicarbonate. Massive transfusion of citrated blood components may cause the patient to become hypocalcemic, alkalotic or hypokalemic, and these states are observed more often in conjunction with plasma transfusion or exchange than with RBC transfusion. Patients with hypocalcemia complain of perioral paresthesia, twitching of the extremities and later, tetany. Children with hepatic or renal insufficiency who become hypocalcemic may develop hypotension or myocardial irritability. Some physicians routinely supplement calcium using 10% calcium gluconate (2 mL/kg/hr), particularly in the context of massive plasma transfusion or plasma exchange. Calcium is routinely administered for younger children undergoing plasma exchange or peripheral stem cell collections and for those with poor hepatic function because children can rarely warn staff of the signs of citrate toxicity. The dose used is 94 mg of calcium/100 mL of blood processed to a maximum of 2 g administered intravenously at a flow rate no greater than

120 mg/kg/h. When replacing calcium, serum ionized calcium levels should be monitored to avoid overreplacement.

Cold storage conditions

RBCs are stored in a refrigerator at 4–6°C. The rapid transfusion of components that have been stored in the cold can result in hypothermia and subsequent cardiac dysrhythmia/asystole. In adults, hypothermia-induced cardiac arrest is reported in half of those who receive 3 L or more of refrigerated blood at rates of 50–100 mL/min.²² In infants, the transfusion of cold blood has been associated with apnea, hypotension and hypoglycemia. Blood warmers, devices which use either wet or dry heat, can raise the temperature of cold-stored RBCs to body temperature. The usefulness of such warmers is limited when large volumes of RBCs are required immediately. Microwave ovens should never be used to warm blood rapidly for transfusion because heating may be inconsistent and may cause *ex vivo* hemolysis.

Coagulopathy

Patients who require massive transfusion for treatment of severe hemorrhage are at risk for developing clinical and laboratory evidence of a coagulopathy. Coagulation abnormalities are due to dilution of circulating coagulation factors and platelets, local consumption of coagulation factors and DIC. The development of coagulopathy is strongly associated with the length of time during which a patient has been hypotensive. In the laboratory, the coagulopathy is characterized by thrombocytopenia, hypofibrinogenemia and prolongation of the prothrombin time (PT) and partial thromboplastin time (PTT). The patient demonstrates microvascular bleeding characterized by oozing from mucosal surfaces, sites of injury and venipuncture sites. Patients with severe tissue injury and profound hypotension are more likely to develop diffuse microvascular bleeding. The development of coagulopathy is strongly associated with mortality.²³ Careful assessment of the patient's clinical course in conjunction with coagulation testing allows the clinician appropriately to support patients with consumptive coagulopathy associated with massive transfusion with platelets, FFP and cryoprecipitate.

Bacterial contamination

Bacterial contamination of blood and blood products accounted for 10% of transfusion fatalities between 1985 and 1999 (reviewed in Ref. 24). The severity of the septic reaction is variable and dependent on the species of organism (Gram-negative greater than Gram-positive), the number of bacteria infused, the propagation rate of the bacteria and the clinical status of the recipient. Recipients who are immunosuppressed are at higher risk, whereas those on antibiotics may

be protected especially if the antibiotic is cidal to the organism. Severe reactions have been reported most frequently with platelets stored at room temperature but also with refrigerated cellular components, plasma, cryoprecipitate and albumin, in both allogeneic and autologous transfusion. Fever, chills, hypotension, oliguria and DIC have been reported. High fever or hypotension during a transfusion suggest a contaminated blood transfusion. Symptoms suggestive of either hemolytic transfusion reaction or TRALI with dyspnea and cough may occur. In a review of five clinical studies, platelet-associated bacteremia was less severe, with a mortality of 26%, compared with RBC-contaminated reactions, where a mortality of 71% was reported.²⁵ Implicated are Gram-positive organisms, including coagulase-negative staphylococci, *Bacillus* species, *Staphylococcus* and *Streptococcus* species for platelets. Cold-loving organisms such as *Yersinia enterocolitica*, cryophilic pseudomonads such as *Pseudomonas putida* and *P. fluorescens*, and *Enterobacter* spp., are most commonly identified as sources of RBC contamination.²⁶ Transfusion-associated babesiosis was reported in three of four infants in a New York hospital; *Babesia* has the same tick vector as *Borrelia burgdorferi*, the Lyme disease spirochete, which is known to survive in platelets stored at 20°C, RBCs stored at 4°C and FFP stored at –18°C, but has not yet been implicated in a transfusion outbreak.

Confirmation of a septic reaction mandates that cultures of the blood component and the recipient's blood grow the same organism.²⁷ The patient culture should be obtained from a different site (line) from where the unit was transfused. Confirmation can sometimes be difficult as the patient may be on antibiotics that are cidal to the organism, or the blood bag may have been discarded, making culture impossible.

Estimates of bacterial contamination of blood and blood products vary widely throughout the world. The prevalence of bacterial contamination is 0.002–1% for red blood cells and 0.04–10% for platelets.^{24,27–30} There are multiple potential sources of blood component contamination, including unrecognized donor bacteremia and inadequate skin decontamination, which, in the case of pheresis donors, may be from a scarred phlebotomy site. Contamination can also occur during manufacturing of the blood bags or apheresis solutions used during collection. Pooling of products or contaminated water baths are other sources. The age of the product is also an important variable. Platelets older than 3 days and RBCs older than 21 days are more likely to be contaminated.^{24,29,31}

Preventive measures to decrease the risks of transfusion-associated bacterial sepsis include extensive donor screening, vigorous skin decontamination and water-bath decontamination. Donor questioning about diarrhea and travel to endemic Lyme disease areas has been particularly helpful for *Yersinia* and *Borrelia*, respectively. In March 2004, US/blood collection facilities implemented a number of strategies to limit bacterial contamination of platelet concentrates. These included new requirements for phlebotomy arm preparation,

institution of a diversion pouch where the initial 20–30 mL of the collection (where the maximal skin contamination source exists) is diverted, and a recommendation to use apheresis platelets. Additional methods to detect bacterial contamination of platelet units were implemented, including culture of the product, use of staining methods (Gram, acridine orange or Wright) and multiagent strips to measure pH and glucose. Feasibility studies for pretransfusion detection using endotoxin, RNA probes or polymerase chain reaction (PCR)-based methods have begun. Chemical or photochemical decontamination using psoralens hold promise, but are still being tested in clinical studies.^{30,32}

Adverse reactions with delayed occurrence

Transfusion-associated alloimmunization

The most common delayed reactions to transfusion include those related to the immunologic consequences. The development of alloantibodies directed against foreign antigens present on the cellular elements of blood/blood components is called alloimmunization. Several factors influence the recipient's risk of becoming alloimmunized to erythrocyte, leukocyte or platelet antigens. Immunogenicity and dose of the foreign antigen, frequency and route of exposure, and the recipient's immune response to antigenic challenge are clearly determining factors. The short- and long-term clinical sequelae of alloimmunization depend on the antigen(s) involved.

Erythrocyte alloimmunization

RBC alloimmunization may occur when there is a genetic disparity in erythrocyte antigens between donor and recipient. The immunogenicity, or ability to stimulate an immune response, of most blood group antigens is poor. The blood group antigens Rh (Cc, D, Ee) and A and B are by far the most immunogenic. ABO antibodies, however, have been referred to as “naturally occurring” because they develop without an allogeneic red cell stimulus. ABO antibody production is stimulated by elements that are ubiquitous in nature, such as bacteria that possess substances similar to human A and B antigens. These antibodies (isohemagglutinins) can generally be detected in sera of infants by 3–6 months of age. The Rh system D antigen is the RBC antigen that is considered to be the most immunogenic in terms of antibody production as a result of exposure to foreign RBCs. Approximately 80% of RhD-negative recipients who receive a single 200-mL transfusion of RhD-positive red cells develop detectable anti-RhD antibodies within 2–5 months.^{32,33} There has been some evidence that the minimum dose of RhD-positive red cells necessary for primary immunization is only 0.03 mL.³⁴ Therefore, it is easy to understand how the small numbers of RBCs present

in a RhD-positive platelet concentrate could be sufficient to immunize a RhD-negative recipient. The relative immunogenicity or potency of other red cell antigens depends, in part, on the frequency with which the particular alloantibodies are encountered. More than half of the alloantibodies that result from transfusion and pregnancy are Rh antibodies (other than anti-RhD), with anti-Kell (anti-K) and anti-Duffy (anti-Fy^a) accounting for an additional 40%. Studies have indicated that the relative likelihood of blood-group antibody formation is as follows: RhD > K > RhE > Fy^a > Jk^a.³⁵

The immunoglobulin subclasses IgG1 and IgG3 have greater affinity for Fc receptors on phagocytic cells and are more efficient at activating complement cells than IgG2 and IgG4; this accounts for the variability in the hemolysis that ensues, along with thermal range and antibody specificity.

Rates of immunization vary, with reported frequencies in hospital-based transfused populations ranging from 0.2 to 2.6%.^{13,36} With the exclusion of the RhD antigen, alloimmunization to RBC antigens is approximately 1% per unit transfused. However, there is evidence that the immune response to blood group antigens is different depending on the patient population and the disease state for which the transfusion was given. Some individuals become immunized after a few transfusions, whereas others rarely become immunized and may be tolerized to transfusion despite repeated transfusions. The pathophysiology of alloimmunization is not clearly defined and may be due, in part, to the number of transfusions given, the heterogeneity of the donor/recipient population (in terms of expression of RBC antigens), concordant activation of antigen-presenting lymphocytes and whether certain immune response genes, yet to be determined, influence the response.

Neonates

Despite the frequent need for RBC transfusions, several studies provide evidence that RBC alloimmunization occurs only rarely in neonates transfused during the first 4 months of life. In one study, no unexpected RBC antibodies were detected in 53 premature infants who received a total of 683 RBC transfusions, with at least half being tested 5 months after birth.³⁷ Ludvigsen *et al.*³⁸ could detect no antibodies at least 3 weeks after the last transfusion in 90 full-term infants who received a total of 1269 transfusions with an average of 8.9 donor exposures/neonate. Other reports have supported the relative infrequency of alloantibody production directed against RBC antigens in neonates.^{39,40} However, accurate transfusion histories could not be determined for all infants in these studies. There have been three reports of antibody formation in multiply transfused infants. Two cases involved development of allo-anti-E in infants at age 18 days and 11 weeks,^{41,42} respectively, and the third was an infant who developed anti-K at 12 weeks.⁴³ The failure of newborns to initiate an immune response to foreign RBC antigens is probably multifactorial,

and includes the immature immune status of the infant and inability of neonatal antigen-presenting cells to effectively prime self T-helper cells. Another contributing factor that may limit lymphocyte activation is the possibility that insufficient numbers of allogeneic lymphocytes are present in components prepared for neonates.⁴⁴

Sickle-cell anemia

There have been several studies reporting extreme variability in the rates of alloimmunization for patients with sickle-cell anemia. The discrepancies can be attributed to whether all or only clinically significant antibodies were included in the analysis, whether pregnancy history was clearly delineated, and which population base was studied: children, adults or both. Reported rates of alloimmunization range from 5.7 to 36%.^{45,46} The lower rate was reported in a group of 245 patients who had a median age of 10 years. In the largest prospective study of alloimmunization in patients with sickle-cell disease (SCD), 3047 patients were evaluated, of whom 1814 were transfused for an overall rate of RBC alloimmunization of 18.6%.⁴⁷ Alloimmunization rates were higher for patients with hemoglobin SS versus hemoglobin SC or (sickle- β^+ -thalassemia), reflecting lower transfusion rates in the latter group of patients. Patients transfused by the age of 10 years or younger had a lower rate of alloimmunization than those who were first transfused after the age of 10 years (9.6% vs. 20.7%, respectively). The majority (almost two-thirds) of the clinically significant antibodies that developed were in the Rh and Kell systems, with 17% of the immunized patients producing four or more antibodies. Vichinsky *et al.*⁴⁸ found a much higher rate of alloimmunization in chronically transfused black patients with SCD compared with transfused non-black patients with chronic hemolytic disorders; they suggested that the increased risk was related to the transfusion of racially discordant red cells. Luban,⁴⁹ reporting a study of 142 children with SCD, found a higher rate of alloimmunization in children of non-American Black descent versus American-born Afro-Americans, despite similar antigen phenotypes. The former group also developed more antibodies/child (3.17 vs. 1.25, respectively), perhaps due to differences in immune response genes.

Methods to reduce the risk of alloimmunization vary greatly. They include prevention by providing phenotypically matched red cells for all patients or matching only for those antigens that commonly cause alloimmunization. Other options include providing additional antigen matching only for patients who have become immunized, or providing antigen-matched blood only for patients who have a high likelihood of going on a chronic transfusion protocol.⁵⁰ When antigen-typed red-cell products are used preventively for sickle-cell patients, they are selected to be negative for Rhesus (D, C, E, c and e) and Kell (K and k) depending on the antigen typing of the patient. Additional typing for Kidd (Jk^a

and Jk^b), Duffy (Fy^a and Fy^b), the MNS system (M, N, S and s) and Lewis (Le^a and Le^b) may be performed. The use of racially matched blood has been suggested as a way to capitalize on variances in antigen frequencies between donors of European and African ethnicity.⁵¹ A recent report on the race/ethnicity of ABO and RhD phenotypes in the USA provides more robust data than have been available to date.⁵² In a single-institution study of 351 patients who received 8939 ABO- and RhD-matched units, 29.1% developed one blood group alloantibody. The authors calculated the percent of white donors that would be expected to match either a limited or extended protocol and concluded that extended matching was impractical.⁵³

The development of autoantibodies in patients with SCD has been reported to occur more often in patients receiving chronic transfusion and in whom alloantibodies have developed.⁵⁴ The commonest autoantibodies observed have been cold-reacting antibodies, which although classified as clinically harmless, have caused considerable difficulties in cross-matching. Experimental evidence has shown that autoimmunization may develop after blood transfusion whether or not alloimmunization has occurred.⁵⁵

The clinical outcome of RBC alloimmunization depends on the number and nature of the antibodies produced. Difficulty in finding compatible blood and an increased risk of delayed hemolytic transfusion reaction (DHTR) are two consequences of alloimmunization. DHTRs in patients with SCD pose additional problems in that they may often go unrecognized because the symptoms can mimic or induce a sickle-cell crisis.⁵⁶ This effect may be attributed in part to a low level of suspicion for DHTR or an inability clinically to separate the symptoms from SCD. A marked drop in hematocrit to levels lower than those before transfusion with reticulocytopenia has been observed in some patients with SCD experiencing a DHTR. This extreme decrease in hematocrit may be secondary to hemolysis of donor red cells in conjunction with suppression of erythropoiesis from transfusion. An alternative theory on the development of the extreme anemia is that autologous red cells are destroyed in concert with the transfused antigen-positive red cells; this is referred to as "bystander hemolysis."⁵⁵⁻⁵⁷ Bystander hemolysis probably results from complement deposition and activation on autologous cells, which are subject to hemolysis. Therapy has included steroids, recombinant erythropoietin and intravenous immunoglobulin.⁵⁷

Unique risks occur when there is concomitant alloantibody and autoantibody formation. First, the autoantibody can complicate the pretransfusion testing and mask the presence of coexisting alloantibodies. Secondly, the autoantibody may cause decreased survival of transfused cells. Thirdly, worsening hemolysis and volume overload may foster clinical deterioration. Close observation, steroid premedication and transfusing the smallest volume of red cells to maintain adequate oxygenation are advised.

Thalassemia

The reported incidence of clinically significant antibody production in children transfused for thalassemia has also been variable, ranging from 5.2 to 21.1%.⁵⁸ In certain areas of the world where there is heterogeneity of the donor population, higher rates are reported with autoantibody formation, as in SCD.⁵⁹ A consistent finding in most of these studies, however, is the association between the age at which transfusion is started and the risk of alloimmunization to RBC antigens.^{60,61} As suggested in the CSSCD study,⁴⁷ patients who received initial transfusions before the age of 3 years were found to have a considerably lower incidence of alloimmunization.⁶⁰ The benefits of regular transfusion are complicated by transfusional iron overload, discussed in Chapter 5.

Leukocyte and platelet alloimmunization

Alloimmunization to leukocyte and platelet antigens may develop in multiply transfused recipients, or as a result of pregnancy or organ transplantation. Class I human leukocyte antigens (HLA-A, HLA-B) are major immunogens and are expressed on all nucleated cells as well as platelets. The class II antigens have a more limited distribution, and are found primarily on B lymphocytes, macrophages/monocytes, dendritic cells, activated T cells, and endothelial cells. Studies have indicated that WBC reduction of cellular components to levels $< 5 \times 10^6$ /transfusion can diminish alloimmunization to HLA class I antigens (Table 33.2).^{62,63} Ultraviolet irradiation has been shown to interfere with the function of antigen-presenting cells.^{64–66} Studies evaluating the effectiveness of these technologies in reducing alloimmunization to platelet transfusion confirm effectiveness in adults. The Trial to Reduce Alloimmunization of Platelets (TRAP)⁶⁷ was a carefully controlled, multicenter, randomized trial that showed

that leukocyte-reduced platelets did not lower the incidence of refractoriness in pregnant women compared with controls, but halved the rate of alloantibody formation. Therefore, leukodepletion appears to eliminate primary sensitization but not secondary response.

Alloimmunization to transfused WBC antigens during infancy is rare. Studies have shown either no evidence of HLA antibodies associated with transfusion, whether or not attempts were made to leukocyte-reduce blood components, or transient detection of antibodies.^{68,69} There is some evidence to suggest that alloantibodies directed against maternal blood cell antigens may develop as a result of intrauterine or perinatal exposure to these antigens. Passive transfer of IgG antibodies against HLA-, platelet- and granulocyte-specific antibodies to the neonate as a result of maternal alloimmunization is known to occur.^{70,71}

The rate of HLA alloimmunization in older children and adults ranges from 30% to 70%.^{72–74} The rates are related to the number of transfusions, type of transfusion, underlying disease and chemotherapeutic regimen. In a series of 100 children with malignant disorders (leukemia, lymphoma, Ewing sarcoma) who were receiving intensive transfusion support, 27% developed cytotoxic HLA antibodies. Persistence of HLA antibodies, despite continued transfusions, was observed in only 13% of the patients.⁷⁵ In contrast to patients with malignancy, in one study seven of eight patients with aplastic anemia developed alloantibodies. The difference in the rate of immunization is most likely due to the immunosuppressive effects of chemotherapy. Compared with HLA antigens, platelet-specific antigens do not appear to be as potent immunogenically; however, alloantibodies directed against various platelet antigen systems have been characterized in multitransfused patients.⁷⁶

The clinical manifestations of alloimmunization to leukocyte and platelet antigens include febrile transfusion reactions, refractoriness to platelet transfusions, posttransfusion

Table 33.2 Blood component filters.

Generation	Pore size (μm)	Filter mechanism	Comment
First	170–260	Screen	Referred to as “clot” filter Used for all blood and blood components
Second	20–40	Micropore screen filter	Referred to as “microaggregate” filter Removes 75–90% of WBCs Only used for RBCs
Third	N/A	Adhesion, absorption	Referred to as “leukodepletion” filter Removes 99–99.9% of WBCs Used for cellular components including platelets collected by apheresis, platelet pools and RBCs
Fourth*	N/A	Adhesion, absorption, other	Under development

* Different manufacturers have variable claims about the degree of WBC removal and subsets of WBCs removed by their respective methods.

purpura (PTP) and TRALI. The latter is usually the result of passive transfusion of HLA-epitope-specific antibodies or leukoagglutinins directed against the recipient's antigen, which precipitates a chain of reactions that include cytokine release and complement activation. There has been, however, at least one report of a fatal pulmonary reaction in a multi-transfused child in whom antibody production was directed against donor leukocytes.⁸

Posttransfusion purpura

Posttransfusion purpura (PTP) is a rare manifestation of immune thrombocytopenia, first recognized by Shulman *et al.* in 1961.⁷⁷ This condition is characterized by the development of profound, but self-limiting, thrombocytopenia approximately 5–10 days after a blood transfusion in a recipient who has been previously exposed to platelet antigens through pregnancy or former transfusions. Alloantibodies are produced that destroy not only the transfused platelets, but the patient's own platelets. In the approximately 100 reported cases, the most commonly produced platelet antibody has been directed against the specific platelet antigen HPA-1a (PL^{A1}) located on glycoprotein IIIa (GpIIIa). Although the mechanism of autologous platelet destruction is unclear, several theories have been postulated, including:

- formation of a foreign antigen–antibody complex that binds to autologous platelets and mediates platelet destruction via a mechanism similar to that observed in drug purpura;⁷⁸
- development of a second antibody with autoimmune specificity that reacts with HPA-1a-negative platelets;⁷⁸
- transfused soluble platelet antigen in the donor plasma adsorbs to the recipient's platelets, thereby rendering them reactive with the alloantibody.⁷⁹

PTP is a disease of adults, usually in their late 40s or older, occurring more frequently in females as a result of a previous pregnancy. The youngest patient reported to develop PTP was a 16-year-old female with no previous history of pregnancy.⁸⁰ While approximately 3% of the White population is negative for HPA-1a antigen and, therefore, at risk for development of PTP, far fewer than 3% of transfused individuals are affected. Part of the reason for this is that cases that are not clinically apparent may go unrecognized or a specific immune response gene may be necessary to produce anti-HPA-1a. There does appear to be a strong link between the Drw52 allele and the production of anti-HPA-1a alloantibody.⁸¹ Packed RBCs and whole blood have been the components predominantly associated with the precipitation of PTP; however, platelets and plasma transfusion can also trigger the syndrome. Transfusion reactions, generally characterized by chills and fever, have frequently been reported in patients prior to or after the manifestation of PTP. Thrombocytopenia is usually severe, with platelet counts being $< 10 \times 10^9/L$. The duration of thrombocytopenia in untreated patients ranges from 7 to 48 days. In situations

where the patient is not bleeding or at risk of bleeding, careful observation may be all that is necessary. The most feared complication during the period of extreme thrombocytopenia is intracranial hemorrhage. Infusion of high-dose intravenous immunoglobulin (400–500 mg/kg/day for 10 days) has become the first line of therapy; however, this may require 3–4 days for a response. In severe cases of PTP, in the face of active bleeding, HPA-1a-negative platelets may provide transient benefit.⁸² The efficacy of splenectomy, corticosteroids and plasma exchange for treatment of PTP has not been well established.

Transfusion-associated graft-versus-host disease

Graft-versus-host disease (GVHD) results from the engraftment of immunocompetent donor T lymphocytes into a recipient whose immune system is unable to reject them. It is a common sequela of bone marrow transplantation (BMT), but is also recognized as a rare risk associated with blood transfusion. Early reports of transfusion-associated (TA)-GVHD were in immunocompromised hosts. However, cases have been documented in immunocompetent transfusion recipients.⁸³

Several factors play a role in the pathogenesis of TA-GVHD. Kinetic studies of donor leukocyte clearance after allogeneic transfusion have shown rapid clearance over the initial 2 days posttransfusion, followed by a transient increase in circulating donor leukocytes at 3–5 days prior to complete clearance by 7–10 days. It has been postulated that the transient increase represents an *in vivo* mixed lymphocyte reaction with activated donor T lymphocytes proliferating in an abortive GVHD.⁸⁴ By contrast, long-term chimerism (6 months to 1 year) has been observed in trauma patients who were transfused, and this has been postulated to be due to engraftment of stem cells.⁸⁵ It has been well recognized that immunocompetent T lymphocytes, capable of a proliferative response, must be present in the initial donor inoculum.

Virtually all cellular blood components have been implicated in reported cases of TA-GVHD. The syndrome has developed after transfusion of whole blood, red blood cells, platelets, fresh (nonfrozen) plasma and leukocytes harvested from both normal donors and donors with chronic myelocytic leukemia. The dosage of immunocompetent cells transfused is also important. Based on animal studies, a minimum dose of 1×10^7 cells/kg body weight is necessary to induce a "runt syndrome," and case studies suggest that a similar threshold is necessary to produce GVHD in humans.⁸⁶ However, there have been reports of fatal TA-GVHD occurring in children with severe combined immunodeficiency, in which a dose of only 8×10^4 lymphocytes/kg body weight were likely transfused.⁸⁷ The threshold number of viable cells necessary to produce a graft-versus-host reaction, therefore, may vary depending upon the immune status of the host as well as the antigenic similarity or disparity between donor

and recipient. There must be sufficient disparity between donor and host histocompatibility antigens for the host to appear foreign to the donor and, therefore, to be capable of inducing antigenic stimulation. The host, on the other hand, must be incapable of mounting an immunologic reaction against the graft, either as a result of an immature or defective cellular immunity or host tolerance of the foreign cells. The latter scenario may occur when there exists donor homozygosity for an HLA haplotype, for which the recipient is haploidentical. In this setting the recipient's lymphocytes see only self antigens on the donor's cells. However, the homozygous donor cells see non-self antigens on the recipient's cells stimulating an alloreaction that can initiate GVHD.⁸⁸

The immune response in GVHD is somewhat complex and is not completely understood. Two basic aspects involve (i) the afferent phase, in which recipient tissues stimulate T lymphocytes from the donor, which in turn undergo clonal proliferation and differentiation; and (ii) the efferent phase, in which donor effector cells damage recipient target tissues. The immunologic target is thought to be the host's major histocompatibility complex (MHC) antigens. In TA-GVHD, the recipient's B, T, epithelial and bone marrow stem cells become the main focus of attack. It was initially believed that the effector mechanism was the result of direct cytotoxicity by alloreactive donor T cells. The observation that the phenotype of many of the effector cells infiltrating target tissues was more consistent with natural killer (NK) cells than with mature T lymphocytes suggested a possible role for cytokines in the effector phase of GVHD. In this model, inflammatory cytokines, such as TNF- α and IL-1, released by host tissue damaged by chemotherapy, radiotherapy or infection, result in the increased expression of MHC and other adhesion molecules. This upregulation results in enhanced recognition of donor-recipient differences by alloreactive donor T cells present in the transfused component. The donor T cells then proliferate and secrete cytokines, in particular IL-2. Cytokine release in turn recruits additional donor T cells and macrophages, which are induced to secrete IL-1 and TNF- α . In this manner, the creation of a self-amplifying positive feedback loop eventually produces the clinical manifestations of GVHD.^{89,90}

GVHD following blood transfusions manifests as an acute syndrome, the onset typically occurring within 4–30 days. The syndrome is characterized by involvement of the skin, liver, gastrointestinal tract and bone marrow. The initial clinical manifestations are usually a high fever occurring 8–10 days after the transfusion, followed within 24–48 hours by the appearance of a central maculopapular rash, which subsequently spreads to the extremities. In severe cases, the rash may progress to generalized erythroderma and desquamation. Additional clinical findings may include anorexia, nausea, vomiting and watery diarrhea with or without elevated liver enzymes and hyperbilirubinemia. Unlike GVHD following BMT, pancytopenia is a prominent finding in

TA-GVHD. This typically results from the ability of the donor cells to recognize the recipient (host) marrow as antigenically foreign, leading to the destruction of stem cells and/or colony-forming units. In GVHD associated with BMT, the "host bone marrow" has been replaced by the donor's bone marrow, which, accordingly, is antigenically the same as the reacting donor lymphocytes. The development of bone marrow hypoplasia and aplasia associated with TA-GVHD places the patient at increased risk for hemorrhage or overwhelming infection. The duration of TA-GVHD is short, with the majority of patients dying within a few days to weeks (median time 21 days from onset), usually as a complication of marrow failure.⁹¹ While immunosuppressive therapies such as prednisone, ciclosporin and antithymocyte globulin have been used to treat GVHD associated with BMT, this approach has not been effective for TA-GVHD, which is nearly uniformly fatal unless bone marrow or hematopoietic stem cell transplantation can be performed. A review of the clinical manifestation of TA-GVHD in neonates has shown that infants present later (median time of onset 28 days) with a slightly prolonged course. However, they have a similarly high rate of mortality.⁹²

Diagnosis of TA-GVHD is usually based on the clinical presentation in conjunction with histologic findings on skin biopsy and supportive evidence of persistence of donor lymphocytes by cytogenetic, HLA or DNA analyses. Because there are several other clinical entities that may mimic TA-GVHD, including viral syndromes and drug reactions, it becomes important to make the correct diagnosis and to have an appreciation of those patients who are at greatest risk for TA-GVHD.

TA-GVHD has been reported in patients with several different clinical conditions. It has been difficult, however, to assess the risk of TA-GVHD for any particular group of patients for several reasons. First, the diagnosis may be difficult to make in the situation where there is a critically ill, multiply-transfused patient with infectious as well as other complications. Usually only severe cases are recognized, often only after death. Mild cases may go unrecognized. Secondly, because the development of TA-GVHD depends on several variables, including the number of viable T lymphocytes transfused, the extent of immune suppression in the patient, and the degree of HLA sharing between donor and recipient, each transfusion episode presents its own spectrum of risk. To assess the risk in any patient group, the number of blood components a particular category of patients will receive during the course of treatment must be taken into account. Finally, due to the high mortality rate, there are no prospective studies evaluating the risk of developing TA-GVHD in susceptible groups of patients.

Until recently, patients developing TA-GVHD all shared either a congenital or acquired deficiency of cell-mediated immunity. The first reported cases occurred in children with immunodeficiency syndromes involving a T-cell defect.⁹³

Infants known either to have or who are suspected of having a congenital deficiency of T-cell function, including DiGeorge syndrome, Wiskott–Aldrich syndrome, severe combined immunodeficiency syndrome, reticular dysgenesis and purine nucleoside phosphorylase deficiency, are at risk. Infants with humoral immunodeficiency (B cell), however, are not. Another group of infants who appear to be at risk are those who receive intrauterine transfusions (IUT) and subsequently exchange transfusion. It has been postulated that the lymphocytes in the IUT may induce a state of nonspecific tolerance through exhaustion of fetal immune defenses, which then, with subsequent exchange transfusion, induces GVHD. Other occurrences of TA-GVHD in the neonatal setting are assumed to be related to the relative immunologic immaturity of the premature infant combined with transfusion of large volumes of fresh blood, such as may occur with exchange transfusion. Transfusion of maternal components, as occurs in the setting of neonatal alloimmune thrombocytopenia, has also been associated with TA-GVHD.

A transfusion from blood relatives or unrelated donors who share HLA haplotypes with the recipient is a risk factor whether in the setting of transfusion to a neonate, older child or adult with or without immunoincompetence. The risk of TA-GVHD in premature infants, with no other identifiable risk factors, as a result of routine small-volume transfusion is rare.⁹⁴ TA-GVHD has been reported in patients with hematologic malignancies and solid tumors, who have received cytotoxic chemotherapy, radiation treatment or both. Once again, the overall risk is difficult to assess, especially as therapeutic approaches to various malignancies become more intensive. The strong association, however, between Hodgkin disease of any stage and the development of TA-GVHD is believed to be the result of the intrinsic T-cell defects known to occur with this disease.⁹⁵ TA-GVHD in association with ablative chemotherapy and autologous BMT for solid tumors has also been reported. The doses of chemotherapy given render these patients severely immunocompromised. In these settings it is important to remember that components transfused during harvesting of either bone marrow or peripheral blood stem cells (which occurs before ablative therapy) may also potentially be implicated in the development of TA-GVHD. Viable allogeneic T lymphocytes contaminating the harvested component may be reinfused to the recipient, with the recipient's own stem cells, at a time when the recipient is aplastic and immunosuppressed. Patients with autoimmune diseases receiving fludarabine or other purine analogs are also at risk.⁹⁶

There have been various clinical settings in which TA-GVHD has been reported to occur in patients presumed to be immunocompetent. While in a few cases no risk factors could be identified, the majority have been associated with transfusion of relatively fresh blood from an HLA-homozygous donor to a recipient who is a heterozygote for the donor's HLA haplotype. This is more likely to occur with

transfusions from blood relatives, but has been reported to occur with unrelated donor transfusion.⁹⁷ Cardiac surgery, in association with the use of relatively fresh blood from either family donors or in the context of donor/recipient haplotype sharing, has been the clinical setting for most of the reported cases. The frequency of blood transfusion from an unrelated donor homozygous for an HLA haplotype for which the recipient is heterozygous depends on the HLA homogeneity of the population.^{92,98}

No reports of patients with AIDS developing TA-GVHD have been published. An explanation for this apparent paradox, namely, why such an immunosuppressed group should not show signs of GVHD, is lacking. However, when an AIDS patient is transfused, the donor CD4 T lymphocytes may also become infected with human immunodeficiency virus (HIV) and thus are rendered unable to initiate the GVHD syndrome while intact CD8 T cells provide the host defense against GVHD.^{99,100}

Table 33.3 reviews the indications for the use of irradiated blood and blood products. Because the treatment of TA-GVHD is almost always ineffective, efforts are directed at prevention and minimizing risk by reducing or inactivating

Table 33.3 Irradiation of blood components for prevention of transfusion-associated graft-versus-host disease.

Clearly established indications

Congenital cellular immune deficiency

Confirmed

Suspected

Hematopoietic stem cell transplantation

Allogeneic

Autologous

Neonate/fetus:

Receiving intrauterine transfusion (IUT)

Who has received IUT

Weighing <1200 g

Any patient with Hodgkin disease

Any patient receiving blood from a biologic relative

Established but sometimes questioned

Any patient on high-dose chemotherapy, radiotherapy, or aggressive immunotherapy including fludarabine and other purine analogs

Recipients of HLA-matched, nonfamilial blood/blood products

Controversial

Solid organ transplantation recipients

Aplastic anemia not fitting category above

Neonates:

Receiving exchange transfusion

Receiving large-volume transfusion

On extracorporeal membrane oxygenation

Not indicated

Human immunodeficiency virus

Pregnant women

Elderly patients

transfused donor lymphocytes. Methods available in blood banks for physically removing T lymphocytes (washing or filtration) do not provide effective prophylaxis against TA-GVHD. Current 3-log leukocyte depletion filters do not remove sufficient lymphocytes to prevent TA-GVHD. Inactivation of transfused lymphocytes by gamma irradiation of blood components remains the most effective method for inhibiting lymphocyte blast transformation and mitotic activity and hence preventing TA-GVHD. The recommended dose of irradiation is 25 Gy to the midplane of the component with a minimum of 15 Gy to any other region of the component.¹³ The effect of this dose on platelet and granulocyte viability and function is not clinically significant. However, long-term storage of irradiated red cells at 4°C results in increased levels of potassium.¹⁰¹ This may be of clinical concern if large volumes of blood need to be infused over a short period of time into patients who may be susceptible to the development of hyperkalemia, such as premature infants and patients with severe renal impairment.

Although not yet approved or licenced, photochemical inactivation methods using psoralens and similar photoactive compounds and UV irradiation may well be an alternative to gamma irradiation in the future.^{102–104} Coupled with inhibition of viral and bacterial pathogens, such methods may reduce multiple transfusion risks.¹⁰⁵

Transfusion-related immune modulation

Blood transfusion has been known to alter immune function since the observation in the 1970s of improved renal allograft survival in transfused patients. In addition, there have been several reports of decreased rates of recurrent spontaneous abortion and inflammatory bowel disease in transfusion recipients.^{106–108} Recently, concern has developed over the immunosuppressive effects of transfusion and the potential clinical consequences, including increased rate of reactivation of viral infection, solid tumor recurrence and postoperative bacterial sepsis. Although the mechanism of the immunosuppressive effect of transfusion is poorly understood, it is probably related to a decrease in cell-mediated immunity. Observed effects include a shift from a T-helper (Th)1 to a Th2 immune response, decreased natural killer cell activity, decreased lymphocyte responses to mitogens, decreased cytotoxic T-cell number and anergy to intradermal antigens, reversal in the CD4/CD8 ratio, increased number of HLA-DR-activated lymphocytes and lymphocyte blastogenesis. Although the role of the cellular elements of components versus plasma is also not clearly delineated, animal models suggest that soluble inflammatory mediators found in stored blood and not fresh blood enhanced tumor growth.^{109,110} Furthermore, increased Fas/Fas ligand levels in stored blood, which may cause immune downregulation, is not observed in fresh blood or blood subject to prestorage leukoreduction.¹¹¹ The importance of both the cellular and noncellular facets of

transfusion-associated immune modulation is noted in a study of infants receiving washed, irradiated red cells in which infants were not observed to have the changes in cellular immunity associated with unwashed, nonirradiated red cells.⁴⁴

Three randomized clinical trials have examined the effect of allogeneic transfusion on cancer recurrence.^{112–114} Taken together, these studies failed to demonstrate an effect of allogeneic transfusion on tumor recurrence. However, a clinical trial examining the effect of leukoreduction on cancer recurrence has not been performed in the USA, and it remains a matter of debate whether leukoreduced products alter the risk of cancer recurrence.

Ten randomized clinical trials have examined the effect of transfusion on the rate of postoperative infections.^{113–121} Comparison of these studies is difficult given differences in study design, use of buffy-coat-removed RBCs (used in Europe) in all but one study and the small numbers involved. Both beneficial and adverse effects on postoperative infections were reported in these clinical trials. In a meta-analysis of six of the studies, the relative risk associated with allogeneic transfusion was 0.94 (95% CI = 0.85–1.04, $P > 0.05$); however, using mathematical modeling, a study involving at least 3000 patients would be necessary to detect a 10% difference in postoperative infections in patients transfused with leukoreduced blood. Thus, the demonstration of a beneficial relationship between transfusion and the postoperative infection remains elusive despite more than 30 observation studies, which have demonstrated that perioperative transfusion is associated with increased postoperative infections.

Observations that transfusions in patients infected with HIV led to more rapid progression to AIDS and a higher death rate, suggested that transfusions resulted in immune suppression or viral reactivation. This was supported by *in vitro* studies of increased HIV expression in infected cells in culture using allogeneic leukocytes.¹²² However, in a randomized clinical trial of non leuko reduced versus leukoreduced blood, there was no viral reactivation of HIV, cytomegalovirus (CMV), hepatitis B virus (HBV), hepatitis C virus (HCV), human T-cell lymphotropic virus I and II (HTLV-I/II) or human herpesvirus 8 (HHV-8).^{123,124}

Transfusion-transmitted infections

Advances in blood donor screening have supported the concept that a zero-risk blood supply may be possible in the future. While the application of numerous serologic and molecular tests and more stringent donor questioning have improved blood safety, risks still remain. Some of these risks result from donors in the window period of infection, which is defined as that period during which a potential donor is infectious without detectable viral marker positivity. Nucleic acid tests (NAT) have improved or “closed” the window, contributing to reductions in residual risk. NATs based on viral protein using polymerase chain reaction are now part

of the regular testing of blood donors in the USA, Canada and many other countries. Screening in the USA includes testing for HBV and HCV, HIV-1 and -2, HTLV-I and -II, syphilis and, in some centers, CMV, but many of these tests are antibody tests and therefore may miss active viremia. With NAT for HIV, the time of infection to detection has been reduced to 10 days. With NAT for HCV, there has been a reduction to 20 days.

Despite improvements in the questioning of donors, donors may still not be truthful about high-risk behaviors in which they engage.¹²⁵ New and emerging transfusion-transmitted diseases, such as Chagas disease, transfusion transmitted viruses (TTV) and hepatitis G and Epstein-Barr virus (EBV), continue to challenge transfusionists as some may result in transient illness or in asymptomatic infection. Other organisms have an exceedingly low or theoretical risk of disease; these include Creutzfeldt-Jakob disease (CJD), Lyme disease, HHV-8, parvovirus B19, ehrlichiosis and babesiosis.

The current estimates of the risk of transfusion-transmitted viral infection have been made possible through the Retroviral Epidemiology Donor Study and studies by the American Red Cross. Rates of seroconversion of large numbers of donors can be combined with estimates of the probability that blood was donated during a window period when donor testing would have been negative. Based on these studies, the current infectious risks in the USA are given in Table 33.4.

Hepatitis C virus

HCV is a single-stranded RNA virus belonging to the Flaviviridae family. It can be transmitted by cellular and noncellular blood and blood products, including intravenous immunoglobulin. The most notable characteristic of HCV is its persistence in host hepatocytes. Studies have found that 90% of posttransfusion non-A, non-B hepatitis is caused by HCV. Long-term follow-up of patients with posttransfusion hepatitis showed that approximately 70% of HCV-infected individuals develop chronic hepatitis.¹²⁶ The mechanism of persistence is probably due to the ability of the virus to mutate rapidly under immune pressure and to coexist as multiple mutants. These mutants have been termed "quasi-species" and they provide an excellent mechanism for the virus to escape the immune response.¹²⁷ In addition, HCV can persist in the liver in a dormant state by downregulating its replication to protect itself from immune clearance. While there may be an adequate humoral response to HCV, the neutralizing antibodies that develop rapidly become ineffective against emerging strains.¹²⁷

First-generation screening tests for HCV were used in 1990 and were targeted against the c100-3 antigen. Second-generation screening assays were introduced in 1992 and were directed against multiple epitopes: c100-3 antigen, core protein designated c22-3 and an NS3 protein designated c33c; antibodies to the latter two epitopes appear earlier than

anti-c100-3. Of HCV-infected individuals, 80% will develop specific antibody by 15 weeks from exposure and 100% by 6 months; in the majority of individuals, anti-HCV antibodies persist for very long periods. With the licensing of second-generation assays in March 1995, the incidence of transfusion-associated HCV declined from 5% in 1989 to <1%. In the late 1990s NAT for HCV was instituted, resulting in a further reduction in residual risk to 1 in 1.9 million in the USA and 1 in 3.1 million in Canada.^{128,129}

Acute posttransfusion hepatitis C infection is, in the majority of patients, asymptomatic and anicteric. The significance of infection with HCV lies in the propensity of the virus for persistent indolent infection. In both community-acquired and transfusion-associated HCV, the frequency of chronic hepatitis exceeds 60%, and that of persistent infection may exceed 90%.¹³⁰ Of those with chronic hepatitis, two-thirds develop chronic active hepatitis, cirrhosis and/or hepatocellular carcinoma (HCC). At least 20% of HCV-infected patients develop cirrhosis within two decades, and the risk for development of HCC is 1-5% after 20 years; once cirrhosis is established, the rate of development of HCC increases by 1-4% per year.¹³¹ Patients with chronic HCV hepatitis can also present with a variety of extrahepatic manifestations thought to be of immunologic origin, including arthritis, lichen planus, glomerulonephritis, keratoconjunctivitis sicca and mixed cryoglobulinemia.

HCV infection in children can be divided into that acquired prenatally or perinatally or through transfusion of blood and blood products. The majority of data concerning posttransfusion HCV infection in children come from studies on multiply transfused hematology and oncology patients, neonates, and children who underwent cardiac surgery diagnosed before implementation of HCV screening.¹³²⁻¹³⁵ In children treated for malignancy, the prevalence of HCV varies from 17 to 55% depending on the geographic area and detection method used. Ni *et al.* in Japan analyzed data from 61 children, most of whom had transfusion-dependent thalassemia, who were followed for 4 years. Twenty-six were HCV infected and of these 24 had elevated alanine aminotransferase (ALT), while only 10 of 34 noninfected patients had evidence of liver dysfunction. Six patients from each group had a liver biopsy. Five HCV-positive patients had evidence of portal fibrosis compared with two of the negative group. All specimens from both groups had evidence of hemochromatosis; iron overload is a known confounder of hepatic fibrosis and HCC development in adults. Similar degrees of liver damage were not seen in neonates and other children with malignancies. In neonates studied 35 years postexposure, minimal or no inflammatory activity was noted on liver biopsy.¹³²⁻¹³⁶ Taken together, these studies suggest that chronic HCV infection may produce more severe liver damage in transfusion-dependent children than in those with malignancy and infants exposed during the neonatal period¹³² or for open heart surgery.¹³⁵

Table 33.4 Infectious risks of transfusion in USA, Canada and other countries.

Infectious agent/blood component	USA/other countries	Canada
HIV (with NAT)	1 in 2.1 million: repeat donors (USA) 1 in 1 million: first-time donors (USA)	1 in 4.7 million
HCV (with NAT)	1 in 1.9 million: repeat donors (USA) 1 in 791 000: first-time donors (USA)	1 in 3.1 million
HTLV	1 in 641 000	1 in 1.9 million
HBV	1 in 30 000 to 1 in 250 000 (USA) 1 in 470 000 (France)	1 in 31 000
Syphilis	Virtually nonexistent	
HAV	1 in 10 million	
Malaria	1 in 4 million	
Chagas disease	Extremely low	
CMV	Unknown	
WNV	Unknown	
<i>Bacterial contamination</i>		
Platelets*	1 in 1000 to 1 in 3000 (USA) 1 in 14 000 to 1 in 38 000 (France)	
Platelet fatality*	1 in 140 000	
RBCs	1 in 172 000 (France) 1 in 5 million (USA) 1 in 66 000 (NZ)	
RBC fatality	1 in 1 million (France) 1 in 8 million (USA)	

* Without pretransfusion culture of component.

CMV, cytomegalovirus; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus; NAT, nucleic acid test; RBC, red blood cell; WNV, West Nile virus.

Adapted with permission from Ref. 167.

Treatment of HCV is with interferon- α 2b (IFN- α 2b at 15 mg/kg/d), with or without ribavirin, 3 million units three times weekly for 6 or 12 months. Biochemical and virologic remission rates in treated children are poorly studied and side-effects are substantial. The current consensus among hepatologists is that patients with chronic active hepatitis or active cirrhosis on liver biopsy with compensated liver disease should be treated. Because patients with lower serum titers of HCV-RNA tend to have a more favorable response to therapy, the controversy lies in whether to treat HCV carriers with mild disease. Given that HCV is a chronic disease with significant morbidity and mortality, early intervention has significant appeal. In children, abnormal hepatic pathology is seen early in the disease while titers of HCV-RNA are lower; identification of recipients of HCV-positive blood should target neonatal and pediatric transfusion recipients so that therapy can be instituted early in the course of the disease.

Hepatitis G virus

Hepatitis G virus (HGV), and its strain variant GBV-C, are human flaviviruses. HGV/GBV-C is transmitted by transfusion of blood products and is found in 1–2% of eligible

volunteer US blood donors; the occurrence is higher (3–14%) in Europe.¹³⁶ HGV/GBV-C can be detected by RNA PCR and by an antibody to the envelope region E2 of the virus. Anti-E2 is a recovery-phase antibody that is detectable only when HGV/GBV-C RNA has been cleared.¹³⁷ Studies have shown that the exposure rate among volunteer blood donors is three- to six-fold the rate of viremia. In high-risk groups such as hemophiliacs, intravenous drug users, homosexuals and prostitutes, the rate of exposure may be as high as 80–90%, with a viremia rate of 15–20%.^{138,139} This large difference between exposure rates and active infection rates suggests that most of the HGV/GBV-C carriers eventually clear the virus. In the National Institutes of Health (NIH) prospective transfusion study, Alter *et al.*¹³⁸ found HGV/GBV-C RNA in 23% of patients with transfusion-associated non-A, non-B, non-C hepatitis. However, there was a dissociation between the subjects' ALT levels and the HGV/GBV-C RNA levels. This casts doubt on the causality of hepatitis by this agent and raises the possibility that it may be an "innocent bystander" virus. Among HCV-infected individuals, 10–20% are co-infected with HGV/GBV-C. Many studies have shown that HGV/GBV-C has no impact on the clinical course of HCV infection.¹⁴⁰ Also, response to interferon is identical in

patients infected with HGV/GBV-C and HCV and in those infected with HCV alone.

There is evidence of HGV/GBV-C viremia in children, but the available literature on the subject is small. Vertical transmission from mother to infant has been demonstrated and preliminary data suggest persistent infection in those children without clinical or biochemical evidence of hepatitis.^{141,142} HGV/GBV-C RNA has also been detected in multiply transfused children with chronic hepatitis B and C infection and has persisted after interferon- α therapy.^{143–146}

As with other transfusion-transmitted viruses that are capable of causing persistent infection, there is no clear disease association, that the designation "hepatitis" virus may have been premature. More research is needed to evaluate the demographic and clinical characteristics of HGV/GBV-C infection, and to evaluate the association of HCV with aplastic anemia.¹⁴⁷

Human immunodeficiency virus

Transfusion-transmitted HIV, from either plasma-derived clotting factor concentrate or blood and blood products, has brought the inherent mortality risk from transfusion to the forefront for clinician, patient and lay public. No other transfusion-transmitted disease has generated as much fear in the minds of patients and as much action on the part of regulatory agencies and manufacturers of plasma-derived products. Current testing of blood donors for anti-HIV-1 and -2 and HIV NAT has reduced the residual risk of HIV to 1 in 2 million in the USA and 1 in 4.7 million in Canada.^{129,148} Since the implementation of HIV NAT testing in the USA, there have been two reported cases of HIV that occurred during the HIV window period. Of specific interest to pediatricians, one donor was an asymptomatic female recruited during a high-school blood drive.¹⁴⁹

Studies of adults receiving blood and blood products demonstrated an infection peak in 1984 for individuals transfused. Clinical presentation occurred several years later, supporting a long incubation period.¹⁵⁰ The NHLBI-sponsored, multicenter Transfusion Safety Study (TSS) traced individuals who received known infected blood units over time. About 90% of the recipients seroconverted, while the other 10% remained PCR- and viral culture-confirmed uninfected. Variables associated with infectivity included the level of donor viremia at the time of donation, duration of refrigerator storage and type of blood component transfused; blood product manipulations that reduce WBC number (leukoreduction) or free virus (washing) were thought to decrease inoculum and therefore infectivity.¹⁵¹

While there are several published cases^{152–3} and small cohort studies, only two studies have reported large numbers of children infected by transfusion. Jones *et al.*¹⁵⁴ described 212 cases reported to the Centers for Disease Control (CDC) from 1981 to 1987. The median age at HIV diagnosis was 4

years, with a range of 0.3–12.8 years. The median survival was 13.7 months, longer than the reported adult survival of 5.6 months. Of interest, 71% of cases were transfused in the first year of life. AIDS-associated illnesses were similar to those reported for perinatal transmission, except that there was less lymphoid interstitial pneumonitis and more encephalopathy. In a cohort study of infants transfused in Los Angeles (a high HIV-risk area of the USA) from 1980 to March 1987, 443 were traced and tested. Thirty-three had antibody to HIV and no other risk factor except for transfusion; 14 had unrecognized HIV infection and were identified through this lookback study. Estimates of the time interval from date of infection (birth) to date of HIV-related symptoms was on average 63 months (5.25 years) with a range of 3–95 months.¹⁵³

The authors' studies involving transfused neonates and older children in an urban area demonstrate children presenting symptom-free as late as 9.5 years after transfusion.¹⁵⁶ It is therefore recommended that parents of adolescents and preadolescents who present with positive HIV screening tests be questioned about transfusion occurring before the introduction of HIV testing. Medical record reviews may be needed, as many families are unaware that transfusion was a routine part of neonatal supportive care. HIV-infected children from areas of the world where blood is purchased from commercial donors or where HIV testing is not routinely performed will probably continue to present as transfusion-associated cases.

Cytomegalovirus

CMV is a ubiquitous virus of the herpesvirus family that is harbored in WBCs. A significant proportion of blood donors (30–70%) are CMV seropositive, although there are regional differences that may in part be due to different donor demographics such as age, sex, race and socioeconomic status. Older age, female sex and lower socioeconomic status predispose to higher seroprevalence rates. Despite studies confirming that seropositive donors can transmit CMV to seronegative recipients, few have been able to document viremia in blood donors. This has led to the concept that both actively infected as well as latently infected donors can transmit CMV.

Three types of CMV infection are seen in the transfusion recipient: primary infection and two kinds of secondary infection, reactivation and reinfection. Primary infection occurs in a seronegative recipient of blood from a donor who is actively or latently infected. Patients are frequently symptomatic with a mononucleosis-like syndrome that is heterophile-negative. Viremia, viruria, an IgM-specific and then IgG-specific anti-CMV antibody response can be demonstrated. Reactivation occurs when a CMV-seropositive recipient is transfused with blood from either a CMV-seropositive or -seronegative donor. The donor leukocytes

trigger an allograft reaction that reactivates the recipient's latent CMV. An IgG antibody titer rise and viral shedding may be found. Most of these infections are asymptomatic, except in immunocompromised hosts. Reinfection or coinfection occurs in a CMV-seropositive recipient of blood with a strain of CMV that differs from the strain that initially infected the recipient. An IgM and IgG response as well as viral shedding may be seen. The only way to distinguish reinfection from coinfection is to use molecular markers, wherein multiple strains of CMV may be identified in the coinfecting recipient.

CMV infection may be asymptomatic and discovered only because of serial serologic tests, or it may produce significant morbidity and mortality. Certain select patient groups are at risk for the pneumonia, cytopenias, hepatitis, graft rejection, unexplained fever, and increased risk of bacterial and fungal infections associated with posttransfusion CMV:

- neonates, specifically those weighing < 1250 g who are seronegative and who require large amounts of blood (>50 mL);
- recipients of hematopoietic stem cell and solid-organ transplants;
- infants who receive intrauterine transfusions;
- other severely immunocompromised individuals.

Other immunocompromised patients, either seronegative or seropositive, do not appear to be at increased risk for mortality and morbidity from CMV.

The use of IgG-seronegative blood is considered to be the gold standard, despite the fact that most IgG-seropositive units are not infectious. Depending on the donor demographics in an area, such products are sometimes difficult to obtain. Donors with IgM-specific CMV antibody may transmit CMV more readily, as they are more likely to have acute viral infection and replication.¹⁵⁵ IgM antibody assays, however, are not well standardized. Hence, several different methods have been used to prevent or ameliorate posttransfusion CMV. Because the virus is probably harbored in WBCs, manipulations that can reduce or attenuate leukocyte cell number should reduce the risk of transmission. These methods include washing, freezing followed by washing, and filtration. The third-generation leukocyte-depletion filters have been shown to be effective in preventing primary CMV infection in neonates, adult patients with hematologic malignancies, and patients post-BMT.

A study by Bowden *et al.*¹⁵⁸ suggested equivalence between CMV seronegative and leukoreduced products when no more than 5×10^6 WBCs remained in the product in an at-risk BMT population. This study, its design and outcome, have been debated widely.¹⁵⁷ This study's conclusions of these studies' conclusions has been questioned. In a retrospective analysis of CMV-transmission in adult hematopoietic stem cell transplant (HSCT) patients, leukocyte-reduced RBC units, but not platelets, from CMV-positive donors transmitted CMV.¹⁵⁸ This phenomenon

could have resulted from collection of the unit during an infectious, high viremic period where plasma viremia occurred, or might have resulted from insufficient leukodepletion due to filter failure or failure to produce a product at less than 5×10^6 WBC.

Some oncologists argue that patients who may undergo HSCT regardless of donor and recipient serology should have blood and blood products manipulated to prevent new infection, reactivation or second strain infection. More routine use of prestorage leukodepletion filters that have undergone stringent quality control checks in the setting of blood centers and transfusion services adhering to good manufacturing practices, may well provide an acceptable product that does not depend on donor serostatus. A Canadian consensus conference,¹⁵⁹ American Association of Blood Banks (AABB) guidelines¹³ and Food and Drug Administration (FDA) advisory committees are conflicted on the issue of seronegative/leukodepletion equivalency, which results in variable practices.

Gamma irradiation of blood to inhibit lymphocyte DNA replication will not prevent CMV infection. Many patients undergoing chemotherapy with or without transplantation receive irradiated blood for prevention of GVHD. Similarly, many patients who receive blood that is CMV seronegative or leukodepleted, receive CMV hyperimmune globulin or intravenous immunoglobulin with variable titers of CMV antibody and, in addition, may be receiving FFP for coagulopathies. They receive these plasma products to attenuate the development of graft-induced CMV or nosocomial acquisition of CMV. It is difficult to assess the serostatus of these individuals because of passive acquisition of CMV antibody. Tests for CMV early antigen, CMV, NAT or other molecular markers are necessary to establish posttransfusion CMV in these patients.

After establishing CMV serostatus before chemotherapy, many institutions use an algorithm that determines the nature of the CMV restrictions. CMV-seronegative and leukodepleted blood and blood products would then be provided to seronegative recipients on protocols that may result in HSCT and stem-cell rescue. The algorithm developed by the AABB is shown in Table 33.5.

Creutzfeldt-Jakob disease (CJD) and variant CJD (vCJD)

CJD occurs in one of several forms: sporadic, transmitted, familial and variant. CJD is characterized by the presence of the isoform of a prion protein (PrP^{Sc}) that is resistant to cellular protease degradation. The abnormal prion causes spongiform degeneration, neuronal loss and progressive dementia. Case-control, lookback and autopsy studies failed to show a link between CJD and receipt of blood/blood components and derivatives until the summer of 2003. A potential case of vCJD associated with blood transfusion was documented, with an additional case reported in July 2004.¹⁶⁰

Table 33.5 Recommendations of the American Association of Blood Banks (AABB) on use of CMV-safe blood.

Category	Clinical circumstance	CMV-seronegative blood (unmodified)	Leukocyte-reduced (LR) blood (CMV-unscreened)
I	CMV-positive patient	Not indicated	Not indicated
	CMV-negative patient	Not indicated	Not indicated
II	CMV-positive patient	Not indicated	Use of LR blood to prevent virus reactivation awaits further research
	CMV-negative patient	Either CMV-seronegative blood or LR blood is indicated	Either CMV-seronegative blood or LR blood is indicated
III	CMV-positive recipient	Not indicated	Not indicated
	CMV-negative recipient of CMV-positive organ	Not indicated	Not indicated
	CMV-negative recipient of CMV-negative organ	Either CMV-seronegative blood or LR blood is indicated	Either CMV-seronegative blood or LR blood is indicated
IV	CMV-positive recipient	Not indicated	Use of LR blood to prevent virus reactivation awaits further research
	CMV-negative recipient of CMV-positive organ	Either CMV-seronegative blood or LR blood is indicated	Either CMV-seronegative blood or LR blood is indicated
	CMV-negative recipient of CMV-negative organ	Either CMV-seronegative blood or LR blood is indicated	Either CMV-seronegative blood or LR blood is indicated
V	CMV-negative recipient of CMV-negative organ	Either CMV-seronegative blood or LR blood is indicated	Either CMV-seronegative blood or LR blood is indicated
	CMV-positive recipient	Either CMV-seronegative blood or LR blood is indicated	Either CMV-seronegative blood or LR blood is indicated
	CMV-negative recipient	Either CMV-seronegative blood or LR blood is indicated	LR blood may be slightly preferred to CMV-seronegative blood (passive CMV immunoglobulin)

Category I patients: general hospital patients and general surgery patients (including cardiac surgery); patients receiving chemotherapy that is not intended to produce severe neutropenia (adjuvant therapy for breast cancer, treatment of chronic lymphocytic leukemia, etc.); patients receiving corticosteroids (patients with immune thrombocytopenic purpura, collagen vascular diseases, etc.); full-term infants.

Category II patients: patients receiving chemotherapy that is intended to produce severe neutropenia (leukemia, lymphoma, etc.); pregnant patients; HIV-infected individuals.

Category III patients: solid organ allograft patients who do not require massive transfusion support.

Category IV patients: patients receiving allogeneic and autologous hematopoietic progenitor cell transplants.

Category V patients: low birthweight (<1200 g) premature infants.

The two cases developed despite the institution of donor deferrals, which includes donors who travel or reside in areas where bovine spongiform encephalopathy (BSE) epidemics have occurred. In the UK, no person who has ever received a blood transfusion can serve as a blood donor. An additional safeguard was mandated in Canada in the form of universal leukodepletion to reduce infectivity associated with the high concentrations of vCJD protein in peripheral white blood cells, especially lymphocytes. To date, no change in US or Canadian screening, deferral or testing for vCJD has been implemented.¹⁶¹

West Nile virus

West Nile virus (WNV) is an arthropod-borne virus transmitted via *Anopheles* mosquitoes between birds; humans are incidental hosts for this virus. The first cases of WNV via organ and blood transfusion were documented in 2002, with growing numbers of transfusion-related cases reported through 2004. In 20% of cases, infected humans, often the elderly and/or immunocompromised may develop severe

flu-like symptoms and lymphadenopathy. Death occurs in 1 in 1000 infections. To reduce WNV transmission to patients, donor history questions are aimed at detecting symptomatic donors. Since August 2003, all blood products in the USA have been tested for WNV by NAT, in a unique nationwide clinical trial that took place in advance of test licensure. In 2003, when NAT was implemented, 1000 units were confirmed positive. Residual risk since implementation of WNV NAT cannot be established at this time. Twenty-three cases of transfusion-associated infection were investigated with six confirmed as of April 2004 and six still open. The 2005 summer season saw clusters of WNV in donors and additional recipient cases reported to CDC.

Other transfusion-transmitted organisms

Other transfusion-transmitted disorders include the parasites *Trypanosoma cruzi*, known to cause Chagas disease, and *Plasmodium* spp., the etiologic agents of malaria. *Babesia*, the intraerythrocytic protozoan parasite attributable to contact with infected tick vectors of the *Ixodes* group, has raised

Table 33.6 Prevention of some transfusion complications by leukocyte removal.

Established indications	Threshold level of WBC reduction to prevent the reaction
Febrile nonhemolytic transfusion reaction	5×10^8
Alloimmunization to class I HLA antigens	$<5 \times 10^6$
Infectious disease transmission by leukocytes	Unknown and dependent on virus in question. Plasma viremia may transmit disease, despite leukodepletion. See text
Graft-versus-host disease	Unknown. Gamma irradiation should be used
Transfusion-related acute lung injury (TRALI)	Passive transfer of antibody in plasma will not be attenuated by leukocyte removal

concerns. For these and other agents, only a handful of transfusion-transmitted cases have been reported. Control strategies have included instituting seasonal deferrals, regional testing and earmarking specific donor pools for leukocyte reduction (Table 33.6). As the endemic ranges of these agents expand, more extensive interventions, like donor testing and pathogen inactivation, will be required.¹⁶⁴

Other emergency transfusion risks

TTV and hepatitis E are both viruses that are transfusion transmitted. TTV is highly associated with transfusion in areas endemic for TTV.¹⁶⁵ Hepatitis E, which is endemic in certain areas of the Near and Far East, has also been suspected of infrequent transfusion transmission.¹⁶⁶

Management of infection in children with bone marrow failure

Subarna Chakravorty and Ian M. Hann

During recent years, significant progress has been made in improving the outcome of children with malignancies; in the absence of new effective therapies, this has been mainly achieved by intensification of treatment using conventional drugs. However, such dosage intensification also increases the risk of infectious complications and can only proceed with improvements in supportive care in much the same way that heroic surgery requires advances in anesthesiology and intensive care methods. This chapter is not intended to deal with every possible infection or clinical manifestation of such, but rather to be a practical current guide to the management of infection. The last few years have seen major improvements in the development of hematopoietic growth factors, new antifungal agents and new antibiotics. Attempts are being made to identify good and poor risk factors for outcome of infection in order to facilitate shorter courses of antimicrobial agents.

Infections in neutropenic children

Comparison with adults

There are several large reviews of children with serious infections and neutropenia. The largest compared 759 children with 2321 adults admitted to four trials run by the European Organization for Research into the Treatment of Cancer (EORTC) International Antimicrobial Therapy Group (IATG).¹ This is the ideal way to look at patterns of infection and to determine whether risk factors predicting outcome can be identified. Children tended to have lower-risk disease with regard to outcome of infection compared with adults, despite common enrollment criteria within the EORTC centers, namely fever and neutropenia. Not surprisingly, the children had acute myeloid leukemia (AML) less frequently and acute lymphoblastic leukemia (ALL) more often, and proportionately more children were undergoing intensive therapy for solid tumors. The children had more upper

respiratory and fewer lower respiratory sites of infection. The incidence of bacteremia in these febrile neutropenic children was similar to that in the adults (22% vs. 24%), but pyrexia of unknown origin was more common in the younger patients (49% vs. 38% in adults) due to a lower incidence of clinically documented infections including pneumonias. The pattern of organisms causing bacteremia was also different, children experiencing more streptococcal species in blood cultures, whilst adults had more staphylococcal species. Most importantly, it was shown for the first time that the outcome in febrile neutropenic children was better, with an overall success rate for the initial empirical regimen of 66% versus 59% in adults. The mortality rate directly due to infection was only 1% in children compared with 4% in adults, and time to defervescence of temperature was shorter in the younger age group (median of 3 vs. 4 days).

Bone marrow transplant patients

One of the dramatic changes in practice over the last few years has been the introduction of unrelated donor or haploidentical allogeneic bone marrow transplants. Previously, such procedures were associated with an unacceptably high risk of rejection, graft-versus-host disease (GVHD) and infection. However, this picture has changed and a review from Minneapolis has looked at the pattern of late infection in these children.² The period after 7 weeks from the day of transplant was examined because the development of unrelated-donor bone marrow transplant (URD-BMT) has been associated with delayed infection problems, at least in part related to the prolonged immunosuppression (including high-dose steroids) and more frequent and severe GVHD. One hundred and fifty-one matched sibling donor (MSD) BMT procedures were compared with 98 URD-BMTs, of which 82 patients in the MSD group and 50 patients in the URD group were < 18 years of age. Of all the URD-BMT patients, 85% developed late infections compared with 68% in the MSD group. Two-thirds of infections occurred within the first 6 months and few after

the first year, but URD-BMT patients were at risk for longer. About half of the infections were bacterial, evenly split between Gram-negative and Gram-positive organisms. Slightly more than one-third were viral and of these a third were due to cytomegalovirus (CMV), with the remainder due to herpes simplex (HSV), varicella zoster virus (VZV), respiratory syncytial virus (RSV) and influenza viruses. Eleven percent was due to fungi; in the URD-BMT group, half were due to *Candida* and a quarter to *Aspergillus*. About a third of these late infections were considered life-threatening, causing hypotension or requiring central venous pressure monitoring or mechanical ventilation. Blood and lungs were the commonest site of these life-threatening infections, occurring in 60% and 20% of cases respectively, and bacteria were implicated in nearly two-thirds of these infections, of which more than 80% were by Gram-negative organisms. A third of all late life-threatening bacterial infections were lethal. Life-threatening viral infections occurred in 13% of cases, and life-threatening fungal infections occurred in 24% of cases. In both groups there was an 80% mortality rate.

Children on antileukemic therapy

Deaths due to infection

A recent review of causes and risk factors for death in childhood ALL and AML unrelated to refractory leukemia, disease recurrence or second malignancy, between 1983 and 2002 within their own institution, was undertaken by the St Jude's Hospital researchers.³ The estimated 10-year cumulative incidence of death was $2.9 \pm 5.3\%$ for ALL, and the estimated 5-year cumulative incidence of death was $7.6 \pm 1.9\%$ for patients with AML. For patients with ALL or AML, the incidence of death remained relatively constant during the time periods studied. Among 1011 patients in the ALL group, there were 36 deaths, of which 11 were due to infection during remission induction: eight fungal (five *Aspergillus* infections, two *Candida* infections and one other fungal infection), two viral (one patient had disseminated varicella and *Candida* infection) and one bacterial infection. There were 10 infection-related deaths during postremission chemotherapy, of which seven were due to proven or presumed bacterial sepsis: two *Pseudomonas*, two *E. coli* infections and three with septic shock with presumed bacterial infections. There were 23 infection-related deaths among the 260 children treated for AML, of which seven were at induction (six fungal infections – three *Aspergillus*, two *Candida* and one presumed fungal pneumonia – and one bacterial infection) and six were during postremission chemotherapy (all died due to fungal infections, of which five were due to *Aspergillus* and one due to presumed fungal pneumonia). Eighty percent of deaths in the ALL group were due to infections and nearly all non-leukemic deaths in AML were due to infections, the majority being due to *Aspergillus*.

Acute myeloid leukemia

Over the last decade, treatment for AML has become much more intensive and survival has dramatically improved. This has resulted in frequent infectious complications including overwhelming Gram-negative bacteremia and serious systemic fungal infections. A study conducted by the BFM group looks at the rate and nature of infections in children treated according to the AML-BFM-93 trial protocol,⁴ and also serves as a good contemporary review of the problem. Overall, 855 infective episodes occurred in the 304 children studied, of which 61.2% ($n = 523$) episodes were classified as fever of unknown origin (FUO) and 32.1% ($n = 275$) had microbiologically documented infections. The remaining 6.7% of episodes were deemed to be infectious in origin on clinical grounds alone. Neutropenia was present in 74.1% of the episodes. Bloodstream infections occurred in 228 episodes, in which 252 isolates were identified (203 Gram-positive and 49 Gram-negative). Of the Gram-positive organisms isolated, the commonest was coagulase-negative *Staphylococcus* (80 episodes) followed by viridans group streptococci (VGS) (56 episodes). Infection with VGS was significantly higher during cycles of chemotherapy that included high dose cytarabine. Eighty percent of the bloodstream infections occurred when patients were neutropenic. Invasive fungal infections were probable or proven in 15 episodes, among which pulmonary aspergillosis was proven in five and suspected in five children, and invasive candidiasis was proven in two and suspected in three children. In 13.3% episodes (113 out of 855), pneumonia was diagnosed radiologically. Twenty patients died of infection-associated complications, most of them during early induction therapy ($n = 11$) giving an overall infection-related mortality of 6.6%. Children with Down syndrome were significantly overrepresented in this group (5/28 or 17.9% vs. 15/276 or 5.4%). Of the five children with Down syndrome, two had microbiologically proven pulmonary aspergillosis and one had an isolate of *Streptococcus pneumoniae* in the blood. Eighteen out of these 20 patients with fatal infections had radiologic signs of pneumonia; Gram-negative organisms (*Pseudomonas*) were isolated in five patients, Gram-positive in four (*Streptococcus*, *Enterococcus*, coagulase-negative *Staphylococcus*) and invasive aspergillosis was proven in four patients. Notably, six out of nine patients who died during consolidation had not achieved complete remission. It is important therefore to have a very low threshold for readmitting patients with AML, particularly with pulmonary symptoms, while maintaining a careful watch for invasive fungal infections.

Acute lymphoblastic leukemia

Children with ALL have a better prognosis overall and fewer serious infections than those with AML. However, it is all the more tragic when an eminently curable child dies of an

infection induced principally by the antileukemic therapy. A review from the UK Acute Lymphoblastic Leukaemia (UKALL) trials run by the Medical Research Council⁵ between 1985 and 1990, examined 1612 children who were entered into the UKALL X trial. Thirty-eight (2.3%) died during the first four induction weeks: 31 died from infections, of which 19 were due to bacteria, nine to fungi and three due to unknown infections. Gram-negative bacteria accounted for 12 cases, and seven were Gram-positive. Of the nine fungal infections, four involved *Aspergillus*, four were *Candida* and one was a *Mucor* infection. Thus, the message is that Gram-negative cover (which we believe should include an aminoglycoside as well as another agent; see below), as well as Gram-positive cover in a broad-spectrum empirical antibiotic regimen given immediately to these febrile neutropenic patients, remains essential. Also, the physician must remain wary of deep-seated fungal infections, especially *Aspergillus* affecting the lower and upper airways (including the paranasal sinuses, where it is frequently mistaken for viral or anaerobic infections) and *Candida* involving the liver and spleen. The use of empirical amphotericin-based therapy must also be continued for patients who remain febrile after 3 or 4 days of broad-spectrum antibiotic therapy (see below).

Risk factors and prognostic factors with regard to outcome of infection

The UKALL X study showed clearly that children with Down syndrome and also girls with ALL are at increased risk of fatal infection. In addition, fatal infections occurred more frequently in patients with very high risk ALL receiving an allogeneic BMT in first remission.

There have been a number of other studies that have sought to predict who might be susceptible to serious infections and also, amongst those with fever, who will prove to have bacteremia.^{6–8} The aim of these studies was to try to predict who can safely receive attenuated courses of antibiotics or even be treated at home or on experimental monotherapy antibiotic protocols. Apart from absolute neutropenia, the above studies identified other risk factors for bacteremia during febrile episodes, such as: the presence of hypotensive shock, C-reactive protein levels of > 90 mg/L, temperature $> 39^{\circ}\text{C}$ at the time of presentation, absolute monocytopenia of $< 100/\text{mm}^3$ and diagnosis of relapsed leukemia.

Based on the observed risk factors for bacteremia, Santolaya *et al.* from Santiago, Chile, conducted a trial of early hospital discharge followed by outpatient management versus continued hospitalization of children with cancer, fever and neutropenia who were deemed to be at low risk for invasive bacterial infection.⁹ Low-risk children were randomly assigned after 24–36 hours of hospitalization to receive ambulatory or hospitalized treatment and monitored until the episode resolved. A total of 161 out of 390 febrile

neutropenic episodes were considered to be low risk, of which 149 were randomly assigned to ambulatory ($n = 78$) or hospital-based ($n = 71$) treatment. The outcome was favorable in 95% of ambulatory-treated patients and 94% of hospital-treated patients ($P = \text{NS}$). Of the eight patients with an unfavorable outcome (four in each group), seven children recovered completely with therapy modifications. One child died in intensive care with overwhelming *Pseudomonas* septicemia. No significant serious adverse effects of the drug treatments were reported. The mean cost of an episode was significantly lower in the ambulatory group ($P = 0.003$).

Patients with high temperature and persistent neutropenia and also those with hypovolemic shock are at highest risk of serious infection and these tend to be children with leukemia, especially those with AML, infants with ALL, other children receiving very intensive protocols for ALL and mature B-cell non-Hodgkin lymphoma, and following allogeneic BMT procedures.

Prophylaxis

Having defined the groups of patients who are susceptible to severe infection, it is of course logical to consider preventing such events. In fact this has proved to be a great deal more difficult than was ever envisaged. One of the overriding problems has been the difficulty of organizing large randomized trials. In this area, placebo-controlled and double-blind studies are undoubtedly the ideal because there is little evidence, with few exceptions, that anything works and the end points are open to observer prejudice, for example, the institution of therapeutic courses of antibiotics. In addition, it has not been possible to perform trials of prophylaxis with quinolone antibiotics, which are active in preventing Gram-negative infections in adults but which may carry a risk of arthropathy in children.¹⁰

Mouth care and oral nonabsorbable antibiotics

In real life, all mouth-care and oral nonabsorbable antibiotic (ONA) regimens are extremely difficult to manage in children. Although there have been many vogues for prevention of infection with ONA,^{11,12} the regimens are often complex, usually very unpalatable and may cause diarrhea, and compliance is almost impossible without psychologic disturbance in children. It is therefore not surprising that evidence of the effectiveness of such regimens in preventing infection in young patients is lacking. With regard to mouth care, there is no doubt that this modality of therapy is important and certainly improves the tolerability of therapy,¹¹ although which mouthwashes should be used is unclear, with evidence that chlorhexidine causes discomfort, taste change and teeth staining.¹² Regular cleaning of teeth with soft toothbrushes that are changed every 2–3 weeks helps prevent systemic dissemination of oral pathogens.¹³ Ideally, all patients should

have regular dental checks in order to reduce the risk of infections, gum problems and mucositis. The use of fluconazole and aciclovir prophylaxis in high-risk (usually AML and BMT) patients has significantly improved this problem.

Fungal infections

The increasing use of unrelated BMT and severely myelotoxic chemotherapeutic agents in children has led to the inevitable rise in the prevalence of fungal infections, posing one of the greatest challenges of modern antileukemic therapies. The major issues in the management of fungal infections are prevention, diagnosis and treatment. Treatment of these infections is difficult, often involves unacceptable costs and toxicity and is frequently unsuccessful.

It is clear from several studies that not all patients undergoing chemotherapy require antifungal prophylaxis, and in one review, Prentice *et al.* have stratified the risk groups according to degree and duration of neutropenia, underlying disease and therapy used, use of corticosteroids and prior candidal colonization. The group most at risk are those with neutrophil counts of $<0.1 \times 10^9/L$ for >3 weeks or $<0.5 \times 10^9/L$ for >5 weeks, with chronic GVHD, undergoing unrelated or mismatched donor BMT, corticosteroid therapy of >2 mg/kg for >2 weeks, receiving high-dose cytarabine, or colonized by *Candida tropicalis*.¹⁴

The use of high-efficiency particulate air (HEPA) filter systems has undoubtedly reduced the risk of *Aspergillus* infection in high-risk patients.¹⁵ Susceptible patients should be nursed in air-filtered rooms wherever possible, and avoid contact with spores from compost heaps and building sites, or food with a high spore content, such as pepper.

Three main oral drug prophylactic regimens have been tried. The original schedules contained frequent high-dose polyenes (nystatin and oral amphotericin) and these are still widely used, although the evidence for their efficacy is limited and they are often not well tolerated by children. A large multicenter trial in 502 children showed that once-daily oral fluconazole prophylaxis resulted in a significant reduction in invasive fungal infection: there were 2.1% in the fluconazole arm compared with 8.4% in the polyenes ($P = 0.002$).¹⁶ This drug is palatable, and the once-daily usage is a major bonus; however, it should only be used in patients with a high risk of *Candida* infection, because of the danger of emergence of resistant species, e.g., *Candida cruzi*, and *Candida glabrata*, and because it will probably not prevent infection with other fungi such as *Aspergillus*. Another imidazole, itraconazole, may have greater efficacy in also preventing *Aspergillus* infections and has been recently investigated in a nonrandom open-labelled study of 103 children mainly undergoing allogeneic BMT. Although around 50% of the children did not complete their course of prophylaxis due to poor compliance or adverse effects, no proven systemic fungal infection occurred and about a quarter received intravenous amphotericin

due to antibiotic-resistant fevers.¹⁷ Thus, this drug may be useful in very high-risk patients where compliance can be guaranteed via the nasogastric or intravenous route. However, it is hoped that the newer azoles such as voriconazole and the echinocandins may be more effective when tested in double-blind, placebo-controlled randomized trials.

Pneumocystis carinii infection

It has been known for 20 years that this infection can be prevented by co-trimoxazole prophylaxis.¹⁸ What has been more uncertain is whether this antibiotic can prevent other infections.¹⁹ In general, the prophylactic effect against bacterial infections is at best a weak one and thus co-trimoxazole is now used almost exclusively to prevent *Pneumocystis* infection. Reactions to it are very uncommon and other antibiotics and maneuvers, such as the use of inhaled pentamidine and oral dapsone, have a much shorter track record and may be more toxic and less effective. Patients at highest risk of *Pneumocystis* pneumonia are those undergoing allogeneic BMT, infants receiving intensive protocols for ALL, and other patients following induction therapy for ALL. Pentamidine inhalations and dapsone are usually reserved for children who do not tolerate co-trimoxazole and who are at continuing risk post-BMT or whilst receiving chemotherapy.

Antiviral prophylaxis

The most important preventive measure against viral infection is vaccination. Where vaccines are live or live-attenuated as with measles, the conventional policy is to rely upon herd immunity and vaccination of siblings and other child contacts. There is a continuing controversy over the prevention of VZV infections, which rarely cause fatal illnesses now that intravenous aciclovir can cure most infections and prompt use of zoster immune globulin (ZIG) following contact can prevent most serious episodes. However, the risk of infection is still quite high, with an approximate risk of 4.6 per 100 patient-years in children undergoing continuation therapy for ALL.²⁰ A recent report of a two-dose regime of live attenuated varicella zoster vaccine given to 17 children either on maintenance therapy for ALL or 3–6 months after the end of treatment for solid tumor found that 94% achieved seroconversion, one patient suffered from a mild self-limiting varicella-induced hepatitis, and no children suffered from herpes zoster at 27 months follow-up.²¹ Often, the problem with vaccination is that the chemotherapy treatment schedule has to be interrupted for several weeks and mild skin reactions are relatively common. Currently, this is an unresolved issue, although cost-benefit analysis indicates that vaccination is likely to be safe and to reduce the need for painful intramuscular ZIG injections.

Several studies have shown that herpes simplex infections can be prevented in patients undergoing BMT procedures

and treatment for leukemia.²² As a consequence, most BMT patients are given oral aciclovir prophylaxis during the period of neutropenia. Longer periods of prophylaxis for a number of months may prevent some VZV infections but the risk period is long and there is clearly a problem with diminishing returns. In childhood, herpes simplex infections are uncommon other than in BMT patients, and it is usually not considered justified to use aciclovir prophylactically when there will be a long period of relatively low risk and thus the possibility of allowing the development of resistant viral strains.

CMV infection remains a significant cause of transplant-related mortality in high-risk children and preemptive treatment based on surveillance using a real-time polymerase chain reaction (PCR)-based assay or an antigenemia assay using the pp65 antigen is the mainstay of the current anti-CMV strategies.²³ Although aciclovir is usually ineffective in preventing CMV infections, there has been recent interest in the oral agent valganciclovir for CMV prophylaxis; this has been shown to be as effective and less toxic than standard prophylaxis using intravenous ganciclovir.^{24,25}

Indwelling venous catheter sepsis

It is always assumed, although rarely proven, that many infections occurring in the modern era are caused or exacerbated by the now ubiquitous indwelling intravenous catheters. Thus, it would be good to prevent such infections. It is often forgotten that by far the most important means of preventing infection in any situation is by very careful hand-washing. This is particularly true when handling intravenous catheters, and it is everyone's experience that problems with infection increase when there is inadequate or overpressurized nursing. The value of continuous staff and family education regarding aseptic techniques in handling catheters was shown serendipitously in a well-designed trial.²⁶ Children with central venous catheters were entered into a placebo-controlled double-blind study of adding broad-spectrum antibiotics to the flush solution. By doing the trial, as is often the case, the authors heightened awareness of the problem and reduced the incidence of infection to a level that made it impossible to assess the effectiveness or otherwise of the antibiotic flush. Their conclusion is to be commended: "staff education is essential and probably the most effective factor in preventing catheter-related sepsis." It should be added that educating the parents is just as important. A recent randomized prospective study compared the rate of catheter-related infections in patients with malignancies using a minocycline-rifampicin-impregnated silicone catheter versus conventional catheters and found a significant reduction of infections ($P = 0.003$) using the former, with no reported incidence of allergic reactions to the antibiotic-impregnated catheters.²⁷ This interesting development in the prevention of catheter-associated sepsis needs further evaluation.

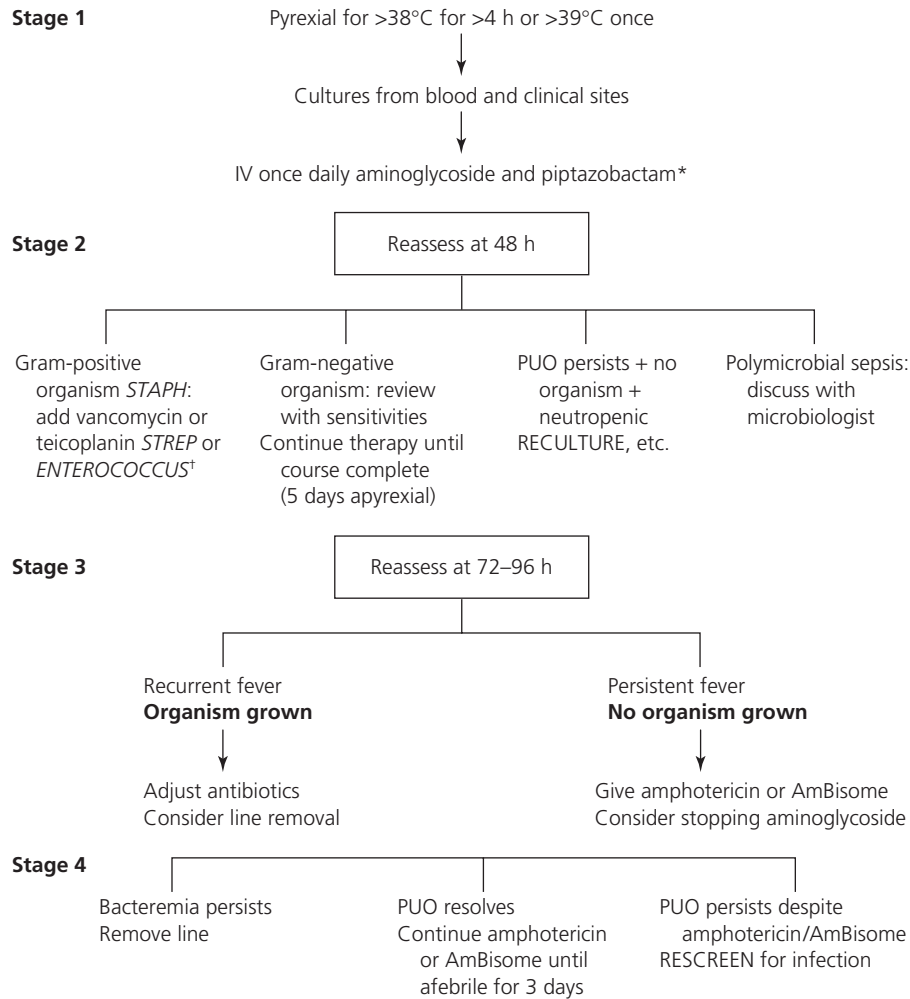

Planned progressive antimicrobial therapy

Antibiotics

Over the last 25 years since early empirical antibiotic therapy first came into routine practice, there have been a multitude of attempts to modify protocols.²⁸ When choosing which antibiotic combination to use empirically for fever and neutropenia, it is absolutely essential to know about the local flora and fauna. Close liaison with microbiologists and infectious disease specialists is never more important than when making these decisions. One major consideration, for example, would be the existence of multiresistant organisms within an individual institution. Thus, the recommendations below must *not* be regarded as being cast in stone; they must be regularly reviewed and should be adapted to local circumstances. It is not the only possible approach but is based on the larger available studies (Fig. 34.1).

The principle involved is that the regimen must have excellent Gram-negative cover and efficacy, with a broad spectrum of cover against other organisms. A large number of studies have proven the efficacy of piperacillin-tazobactam along with an aminoglycoside (amikacin), including one involving 858 febrile episodes in neutropenic patients.²⁹ The EORTC IATG trials have led the way in large multicenter trials whereby the number of patient entries meets statistical criteria for meaningful end points. Several important advances were made with this approach, including the demonstration that single daily dosing of an aminoglycoside (amikacin given with ceftriaxone in this trial)³⁰ was as effective as multiple daily dosing of an aminoglycoside (with ceftazidime). This was subsequently reproduced in many other trials.^{31,32} The conclusion of all these studies has been that once-daily aminoglycosides have a lower risk of nephrotoxicity, probably equivalent risk of ototoxicity and equivalent or possibly superior efficacy. There has not been a vast published experience in children, but where this has been examined, the above statements hold up.³³

The EORTC IATG investigated the possibility of dropping the aminoglycoside after 3 days in combination with ceftazidime.³⁴ This approach was adopted as a "halfway house" because of the potential damage of single-agent therapy in high-risk neutropenic patients. Although this study concluded that it would be detrimental to discontinue the aminoglycoside early, there has been a great amount of recent interest in monotherapy in febrile neutropenia, and several studies using carbapenems (meropenem) or fourth-generation cephalosporins (cefipime, not available in the UK) show no striking differences between monotherapy and multidrug combinations.³⁵⁻³⁷ The Infectious Diseases Society of America has recently published guidelines³⁸ for the use of antimicrobial agents in febrile neutropenic patients with cancer, but the reader is referred to Fig. 34.1 for the current practice in the UK in pediatric patients.

* If given i.v. piptazobactam within previous 2 weeks give ceftazidime and aminoglycoside. If ceftazidime-resistant organisms or ceftazidime within previous 2 weeks, give ciprofloxacin and aminoglycoside first.

[†] If on piptazobactam and aminoglycoside, review with sensitivities. If on ceftazidime or ciprofloxacin + aminoglycoside, add vancomycin or teicoplanin as in *Staph.* regimen.

Fig. 34.1 Planned progressive approach to infection in severely neutropenic children. PUO, pyrexia of unknown origin; i.v., intravenous.

The proposed planned progressive approach to therapy suggested in Fig. 34.1 contains a number of other features. An assessment on day 2 or 3 is valuable because this is the stage at which blood culture results become available. If Gram-positive organisms are grown and the patient is responding, it is reasonable to continue with the empirical regimen because in the EORTC studies such a policy was associated with a good outcome. However, the addition of vancomycin or teicoplanin in the presence of a microbiologically proven Gram-positive infection is an alternative approach. This does not mean that all patients with an inflamed central venous catheter exit site should be treated with an additional Gram-positive agent because there is only a poor correlation between this frequent clinical finding and the existence of serious Gram-positive infections; moreover, extensive use

of vancomycin in the empirical setting can lead to the rise of vancomycin-resistant organisms.³⁸

If the patient is afebrile within 3–5 days of treatment, broad-spectrum antibiotics should be continued until the patient is afebrile for at least 5 days. If fever persists beyond 96 hours and no causative organism has been identified, empirical antifungal treatment with amphotericin is recommended (see below) and the patient needs to be reassessed and rescreened for infection, including further blood cultures and radiologic investigations.

Management of unresponsive fever and antifungal therapy

Children with persistent severe neutropenia frequently do

not respond to a wide variety of antimicrobial agents. It must, however, be remembered that the mortality in this situation is very low and defervescence often occurs only when the blood counts begin to recover and probably irrespective of what therapy is given. Thus, a panic-stricken approach to the problem is entirely unjustified, especially when it involves multiple agents that are potentially toxic, inefficacious and antagonistic. For example, the use of metronidazole should be reserved for high-risk situations, for example children with serious perineal problems or gastrointestinal fistulas, because anaerobic infections are otherwise very rare in this situation. There is no justification for using this drug for every patient with diarrhea, sinusitis (where fungal infection is thus often consequently forgotten about) or oral mucositis. The most important point is regularly to repeat blood cultures and to look carefully for specific infections from a clinical standpoint. Another main strategy is to seek disseminated candidiasis in patients with splenomegaly (abdominal sonography) and aspergillosis in patients with rhinosinusitis (computed tomography, CT, of sinuses) and in those with suggestive clinical symptoms such as pleuritic pain or cough or with persistent pyrexia of unknown origin (PUO) or clinical deterioration (high-resolution chest CT).

Empirical antifungal therapy in antibiotic-resistant fevers in patients with malignancies and neutropenia has dramatically improved outcomes in a large number of patients, making it possible for many to undergo successful antineoplastic therapy.³⁹ Due to difficulties in diagnosis of fungal infection in patients with neutropenia, empirical antifungal therapy has now become the accepted clinical practice.⁴⁰ There have been a large number of recent additions to the antifungal armamentarium other than conventional amphotericin B, and these agents (liposomal amphotericin B, voriconazole and, more recently, caspofungin) have all been studied in the setting of empirical therapy in antibiotic-resistant fevers.^{41–43} Currently available evidence suggests that both voriconazole and caspofungin are suitable alternatives to liposomal amphotericin B in the empirical treatment of antibiotic-resistant fevers in neutropenic patients, but further evaluation in terms of costs and clinical effectiveness along with evaluation of these agents in the pediatric population are needed. At present, AmBisome is the only drug licenced for empirical therapy in children.

With the emergence of new antifungal drugs, it is important to avoid overtreatment of persistent fevers with these significantly more expensive agents. One way to achieve this would be to improve laboratory diagnosis of invasive fungal infections, and current techniques such as the ELISA-based galactomannan assay and PCR assay for detection of invasive aspergillosis are being evaluated. The PCR-based technique on blood samples has been shown to carry a sensitivity of 63.6% and a specificity of 63.5% whereas the galactomannan assay although showing an impressive specificity of 98.9%, is only sensitive in 33.3% of cases.⁴⁴ When used on CT-based

bronchoalveolar lavage fluid, the galactomannan assay showed a 100% sensitivity and specificity in diagnosing invasive pulmonary aspergillosis.⁴⁵ There is still a need to improve these tests to a level where they are as useful as they are in detecting cytomegalovirus infections because early presumptive therapy is crucial in treating such infections.

The role of secondary prophylaxis in patients undergoing high-risk procedures has been evaluated in a retrospective study using voriconazole with good results.⁴⁶ This, along with the use of granulocytes from granulocyte colony-stimulating factor (G-CSF)-stimulated donors⁴⁷ in patients with previous proven invasive fungal infection undergoing myeloablative chemotherapy or bone marrow transplants, need further evaluation.

The use of monocyte-macrophage growth factors to treat fungal infection is addressed below.

Viral infections and interstitial pneumonia

Most viral infections occur at times when patients are not neutropenic and thus this subject is not dealt with in great detail here. The only very effective antiviral agent is aciclovir, which is an active agent for herpes simplex and VZV infections. There is no really effective treatment for measles pneumonia or encephalitis, although various drugs such as interferons and ribavirin have been tried, along with intravenous immunoglobulin. More recently, adenovirus has emerged as a serious pathogen in immunocompromised patients such as those undergoing mismatched or unrelated BMT.⁴⁸ Children appear to be at greater risk of acquiring adenoviral infections in the BMT setting, and up to 27% of children⁴⁹ and 19.7% of adults⁵⁰ have been prospectively shown to acquire adenoviral infection 30–90 days post-BMT. Although cidofovir and ribavirin have been used to treat adenovirus infection, they have mostly proved to be unsuccessful in established disease. In the absence of an effective antiviral agent against adenoviral disease, attempts have been made to improve surveillance techniques by quantitative PCR assays, and to develop cellular therapies such as those using donor-derived adenovirus-specific cytotoxic T lymphocytes or using donor lymphocyte infusion and withdrawing immunosuppression upon detection of adenoviral infection on surveillance.⁴⁸

CMV infection does occasionally occur in neutropenic children, sometimes with hepatitis or gastroenteric problems, but usually with an interstitial pneumonia (Fig. 34.2). The management of pneumonia is tricky and there is again a temptation to indulge in polypharmacy. Figure 34.2 provides a suggested plan of action, and there are some additional points worth emphasizing. First, it is most important to institute a thorough diagnostic search at an early stage. Secondly, with the proposed approach, it is now very rarely necessary to proceed to lung biopsy with the attendant risk of bleeding, pneumothorax, etc., because the patients usually respond

CAUSES

- *Pneumocystis carinii*
- Cytomegalovirus
- Measles (usually no preceding rash)
- Varicella zoster (rare)
- Fungal infections
- *Mycoplasma*, *Legionella*
- Common respiratory viruses: influenza, parainfluenza, adenovirus, RSV

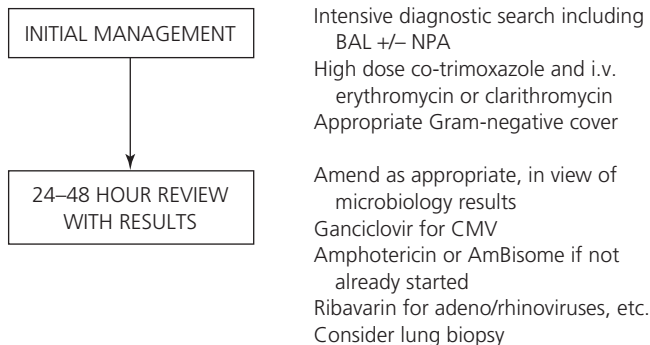

Fig. 34.2 Management plan for interstitial pneumonia.

BAL, bronchoalveolar lavage; NPA, nasopharyngeal aspirate;
CMV, cytomegalovirus; RSV, respiratory syncytial virus.

to therapy or there is an answer from less invasive tests. Finally, *Pneumocystis carinii* pneumonia will often respond to high doses of co-trimoxazole with or without pentamidine. Nonresponders usually respond to steroid therapy; if not, moribund patients have been rescued by surfactant therapy.

Hematopoietic growth factors

Very few good clinical studies have been carried out with these new agents, and these have been reviewed.⁵¹ It can be said that G-CSF reduces the duration of neutropenia and probably leads to a reduced number of febrile days and fewer days receiving antibiotics in adults and children undergoing BMT for nonmyeloid disorders. Their safety in children with myeloid disorders (i.e., mainly AML) is largely unproven, unlike in adults where several large, double-blind, placebo-controlled trials have shown that the use of G-CSF in adults postremission induction did not affect the overall and disease-free survival from AML but significantly improved neutrophil recovery, duration of fever, reduced parenteral antibiotic use and hospitalization.⁵² A recent meta-analysis looked at 16 studies involving 1183 children,⁵³ and concluded that colony-stimulating factors (CSFs) in children with cancer, including those undergoing high-risk ALL protocols and solid tumors, reduced the rate of febrile neutropenia by 20% and decreased the duration of hospitalization by about 2 days. Prophylactic CSFs reduced the documented infection rates by 22% and amphotericin use by 50%. However, CSFs were not associated with a reduction in infection-related mortality. A number of trials are underway, and currently it is probably reasonable to reserve G-CSF therapy for patients

with an expected incidence of febrile neutropenia of > 40%⁵⁴ or those who would previously have been given granulocyte-rich transfusions. The latter have been abandoned in most centers because of their dubious efficacy, infection transmission risk and the associated severe logistic difficulties, apart from the rare situation of localizing infections not responding to antibiotics.

There is some evidence that macrophage CSF (M-CSF) may assist the response of severe systemic fungal infection to amphotericin.⁵⁵⁻⁵⁷ This may be useful prophylactically or in patients who have failed to respond to amphotericin and its lipid formulations. This activity could be related to augmentation of the antifungal activity of monocytes, macrophages and neutrophils exposed to M-CSF and granulocyte-macrophage CSF (GM-CSF). In view of the life-threatening nature of these infections, this is a potentially important development and it is to be hoped that randomized trials in patients with systemic infections will be completed shortly.

Future developments

It is hoped that pharmaceutical companies will devise an answer to vancomycin-resistant enterococci because the macrolide antibiotics represent the last line of defense against methicillin-resistant *Staphylococcus aureus* and β -lactam-resistant enterococci.⁵⁸ It is probably only a matter of time before these defenses are more seriously breached. In fact, the main defense line is the human mucosal barrier, and the possibility of effective protective agents is at last on the horizon with the production of keratinocyte-derived growth factors. The ensuing years will hopefully see the completion of trials looking at a variety of "networked" cytokines, including mucosal protective agents, G-CSF and GM-CSF, and thrombopoietins. The biggest current challenge is the detection, prevention and treatment of fungal infections. We need even better agents and good randomized trials of prophylaxis and combination therapies in, for example, *Aspergillus* pneumonia and brain infection. Also coming to the horizon is the problem of adenovirus in the BMT setting, especially in the mismatched and unrelated BMTs, along with the need for quick, sensitive and effective methods of detection of the virus and development of effective therapies such as adoptive immunotherapies or development of newer viral agents. It should be an exciting era.

Conclusions

Clinicians can be forgiven for looking askance at the apparent cornucopia of antimicrobial agents that has been produced over recent years. What are the best agents, when should they be used, and why do they still fail? The fact is that there is still a lot to learn and there is a desperate need for better agents, including immunomodulatory agents, for example to

prevent the development of invasive fungal infections. The suggestions made above for a planned progressive approach to the management of infections is an attempt to adopt a rational, calm and hopefully scientific approach to the problem.

Hematologic effects of systemic disease and nonhematopoietic tumors

Angela Thomas

Introduction

Systemic disease can have both obvious and subtle effects on blood and bone marrow. Sometimes the clinician will be alerted to the disease because of these effects, whereas on other occasions the underlying disorder is known and the specific hematologic effects or complications are sought. Several different pathologic processes can contribute to the final picture, and drugs used to treat the conditions may also have predictable or idiosyncratic effects. Nonhematopoietic tumors are accompanied by an enormous range of hematologic abnormalities affecting peripheral blood and bone marrow; some are directly caused by the presence of a tumor within the tissue, some are secondary to the effects of the tumor, and others arise as a result of treatment. A pediatric hematologist has an important role in providing diagnostic help and support in the investigation and management of children with hematologic problems secondary to other disorders. Many of the conditions are covered in other chapters: disturbances of hemostasis are described in Chapter 29, and storage disorders are described in Chapter 36. The remaining disorders will be described either by the blood picture that they present, or the disease that they accompany depending on the likelihood of presentation.

Anemia of chronic disease

Anemia is the commonest hematologic manifestation of systemic disease and is the result of a number of contributing factors. It occurs in patients with a variety of chronic inflammatory and malignant conditions and can be complicated by bleeding, immune phenomena, nutritional deficiencies and other organ- or disease-specific features. Chronic inflammatory conditions may result from chronic infection such as tuberculosis or osteomyelitis or be secondary to connective tissue disorders such as systemic lupus erythematosus (SLE),

or chronic inflammatory bowel disease. Characteristically the red cells are normocytic and normochromic or mildly hypochromic and red-cell morphology is unremarkable; the reticulocyte count is normal or low. The anemia is usually mild, 2–3 g/dL below the lower normal limit for a given individual, and nonprogressive with the severity being related to the severity of the disease process. Serum iron, iron-binding capacity and transferrin saturation are reduced and serum ferritin is normal or raised. If a bone marrow aspirate has been performed, stainable reticuloendothelial iron is seen in the particles but with reduced numbers of sideroblasts reflecting defective incorporation of iron into hemoglobin. With prolonged severe inflammation or infection, the anemia becomes more marked and a microcytic, hypochromic picture can result. Associated features indicative of chronic inflammation such as neutrophilia, thrombocytosis and rouleaux formation may be present. In addition to hematologic tests, there may be low albumin, elevated fibrinogen and γ -globulin concentrations. It is not uncommon for a patient with anemia of chronic disease due to chronic inflammation or (less commonly in children) malignancy to develop iron-deficiency anemia. Indeed, iron deficiency is common in children, particularly toddlers and teenage girls (Chapter 5). The iron deficiency may well be a combination of dietary insufficiency coupled with gastrointestinal blood loss, which is seen particularly in inflammatory bowel disease or secondary to nonsteroidal antiinflammatory drugs or steroids used in the connective tissue disorders. Reduced serum ferritin unequivocally demonstrates iron deficiency but ferritin measurements may be in the normal range when chronic inflammatory conditions and iron deficiency coexist. Serum transferrin receptor measurements can help to tease apart the anemia of iron deficiency and chronic inflammatory conditions because high values are seen in the former but not in the latter, although this is not so discriminating in anemia secondary to malignancy.^{1,2}

The anemia is multifactorial although the molecular and cellular mechanisms are not well understood. There is a

moderately shortened erythrocyte lifespan, survival being reduced to the 60–90 day range, instead of the normal 90–120 days. This is possibly secondary to increased phagocytosis by macrophages and splenic activity.³ There is also a defective marrow response to anemia, with only a one- to two-fold increase in erythropoiesis rather than the normal 6–8-fold response. This is not associated with an endogenous deficiency of erythropoietin (EPO), or its defective release but to the inhibitory activity of other cytokines. During an inflammatory response there is increased production of the cytokines tumor necrosis factor (TNF)- α and interleukin (IL)-1 derived from macrophages. IL-1 is one of the stimulators of interferon (IFN)- γ production by T lymphocytes, and both TNF- α and IFN- γ have been shown to suppress erythropoiesis.^{4,5}

A third component of the problem is impaired release of iron from reticuloendothelial cells for use in the marrow, again possibly cytokine mediated; both TNF- α and IL-1 lead to reduced serum iron concentrations and a shift of iron into the storage form in the bone marrow.⁵ However, the anemia of chronic disease cannot be attributed simply to iron-deficient erythropoiesis;⁶ iron absorption from the gut remains normal or low.

It is important to explore any easily correctable component of anemia in any child simply assumed to have a low hemoglobin through chronic disease. The response to pharmacologic doses of EPO is variable but if the endogenous concentration is < 500 units/L, therapy can occasionally be clinically worthwhile particularly where the anemia is severe enough to warrant transfusion support.^{7,8}

Renal disease

The anemia of chronic renal disease is thought to result from a combination of the anemia of chronic disease and erythropoietin deficiency leading to impaired red-cell production, and is more marked than anemia of chronic disease alone. Generally there is a 2 g/dL fall in hemoglobin for every 10 mmol/L rise in blood urea. There is hypoplasia of the erythroid precursors in the bone marrow with little or no interference with normal leukopoiesis or megakaryocytopoiesis although lymphopenia may occur.⁹ The blood film characteristically shows normochromic, normocytic red cells, which may be spiculated (echinocytes or keratocytes); hypersegmented neutrophils may be seen. Red cell survival is variably reduced both in chronic and acute renal failure, and this may be exacerbated by hemodialysis. Blood loss during hemodialysis or secondary to defective platelet function seen in renal failure may result in iron deficiency. Treatment with recombinant EPO is highly effective and beneficial if given with care. It is expensive, however, and it is important to explore other correctable components of the anemia, for instance iron deficiency, before using it. Failure to respond to

EPO should provoke a search for compounding problems before dose escalation is considered.¹⁰ It is interesting that the mild bleeding tendency commonly seen in chronic renal failure can be improved after correction of the anemia by EPO.¹¹

Hemolytic–uremic syndrome

Hemolytic–uremic syndrome (HUS) is a combination of a microangiopathic hemolytic anemia, thrombocytopenia and acute renal failure. The thrombocytopenia is not associated with a disseminated consumptive coagulopathy, and tests of coagulation are usually normal or only mildly deranged. The platelet count may be modestly or profoundly reduced. Platelet survival is shortened, and platelet-aggregating activity has been found in the plasma of some affected children.¹² The disease occurs sporadically and in epidemics, and the majority of children have a prodromal illness of abdominal pain and bloody diarrhea.

The epidemic form of HUS is associated with infection by enteropathogenic Gram-negative bacteria, usually *Escherichia coli* serotype O157:H7, which produce exotoxins similar to those produced by *Shigella dysenteriae* type I and collectively referred to as Shiga toxins. These toxins bind to cell receptors, identified as ceramide trihexoside, which are expressed to varying degrees in different tissues (being particularly prevalent in infant glomerular endothelial cells).¹³

Most infants eventually recover without sequelae. Overall, mortality is 5% and long-term severe morbidity is around 10%.¹⁴ Older children have a greater chance of progressing to end-stage renal failure, and have a higher incidence of atypical HUS (that without prodromal diarrhea). It is more serious and has other distinguishing features including normal urine output, gross proteinuria, hypertension, a relapsing course and more severe changes on renal biopsy.¹⁵

Treatment is supportive with the addition of fresh frozen plasma (FFP) infusions or plasma exchange for severe cases. Platelet transfusions are seldom indicated except occasionally to cover the surgical insertion of dialysis catheters. As the mechanism producing the thrombocytopenia is *in vivo* aggregation, there are theoretical grounds for keeping such transfusions to a minimum to avoid further microvascular thrombosis.

Thrombotic thrombocytopenic purpura

Also known as Moschcowitz syndrome (after the first author to describe the disease in the early 1920s), this is a syndrome of often undetermined cause, although it has been reported following stem cell transplantation, particularly if the donor is unrelated,¹⁶ and infection.¹⁷ It chiefly affects young adults and is characterized by a pentad of features, which include the triad for HUS (microangiopathic hemolytic anemia, thrombocytopenia and renal dysfunction) with two additional features, fever and neurologic disturbances. There is no

evidence that the disorder observed occasionally in children differs from that encountered in adults.¹⁸ It is probable that thrombotic thrombocytopenic purpura (TTP) and HUS (at least the sporadic and atypical type of the latter, see above) represent a similar pathologic process, with TTP being the more serious multisystem form of the disorder. Congenital or acquired deficiency of the von Willebrand factor (vWF)-cleaving protease, ADAMTS-13, has been specifically associated with a diagnosis of TTP, although this is not found in all patients.¹⁹ The clinical course of TTP is variable, but the disease is serious with a high mortality if untreated. Two-thirds of patients die within 3 months;¹⁸ some patients pursue a chronic relapsing course.²⁰

The majority of patients respond to empirical plasma exchange with FFP.²¹ Based on the rationale that von Willebrand multimers may be involved in the pathogenesis of the disorder, some patients failing to respond have subsequently improved if cryosupernatant (i.e., plasma with cryoprecipitate and thus vWF removed) is used rather than whole plasma.²²

Liver disease

Anemia

Hematologic abnormalities in liver disease can affect both the cellular components of the blood and the coagulation system; the latter is dealt with in Chapter 29. Chronic liver disease is associated with anemia that is mildly macrocytic and often accompanied by target cells mainly due to increased cholesterol in the membrane. Leucopenia and thrombocytopenia may be present if there is hypersplenism but the hypersegmented neutrophils of megaloblastic anemia will not be seen and the macrocytes will be round rather than oval. Contributing factors to the anemia may include blood loss from bleeding varices and consequent iron deficiency, and poor iron absorption.

Hemolysis

Chronic immune hepatitis can be associated with immune hemolysis. Acute alcohol intoxication on a background of chronic alcohol ingestion can result in acute hemolysis, Zieve syndrome, but this has not been described in children. Wilson disease is a rare liver-based disorder of copper metabolism that is recessively inherited. Copper accumulates in the liver, brain, kidney and cornea, giving characteristic Kayser–Fleischer rings seen by slit-lamp ophthalmoscopy. It can cause both acute hemolytic anemia with no morphologic abnormality and an acute Heinz body hemolytic anemia due to sudden release of copper from the liver. If a child presents with an unexplained episode of hemolysis, it is important to exclude Wilson disease because it is fatal if left untreated.

Acute liver disease

Acute viral hepatitis, usually seronegative, may be followed by aplastic anemia. Clinical features and liver histology suggest a central role for an immune-mediated mechanism.²³ Bone marrow transplantation from a matched sibling donor or antithymocyte globulin and ciclosporin are the treatments available.

Reye syndrome is characterized by acute encephalopathy and fatty liver degeneration that typically follows a few days after apparent resolution of an unremarkable febrile viral infection. It has been linked to the use of aspirin as an antipyretic, and for this reason the drug is not recommended for children. Hematologic changes are those of acute hepatic disruption, chiefly disturbances of coagulation with occasional disseminated consumption and thrombocytopenia.

Gastrointestinal disease

Inflammatory bowel disease

Iron-deficiency anemia due to inadequate intake or loss of iron through bleeding and anemia of chronic disease are often encountered in patients with inflammatory bowel disease (IBD), which includes both Crohn disease and ulcerative colitis. Crohn disease can also be associated with folate deficiency due to malabsorption or vitamin B₁₂ deficiency if the terminal ileum is involved. The drug sulfasalazine, an antifolate agent, is used to treat both IBD and Crohn disease. Sulfasalazine can also cause oxidative hemolysis, with “bite cells,” similar to those in glucose-6-phosphate dehydrogenase deficiency, seen on the blood film. When iron deficiency coexists with folate deficiency, there may be hypochromic microcytes in addition to macrocytes, or the blood features of iron deficiency may dominate. Hypersegmented neutrophils may suggest a double deficiency but can occur with iron deficiency alone. Iron deficiency is sometimes unmasked when the folate deficiency is treated: after an initial rise in hemoglobin there is no further improvement, and microcytic, hypochromic cells appear on the blood film. An eosinophilia can accompany IBD and a thrombocytosis is often seen in ulcerative colitis, a reactive basophilia can be seen.

Celiac disease

Celiac disease is a gluten-sensitive enteropathy resulting in villous atrophy in the small intestine. Iron and folate malabsorption are common in untreated celiac disease as the proximal small intestine is predominantly affected. Vitamin B₁₂ deficiency is less common, as the terminal ileum is relatively spared, although when specifically sought has been reported in 41% of untreated patients.²⁴ In addition to the nutritional deficiencies, features of hyposplenism, such as Howell–Jolly

bodies and Pappenheimer bodies, may be present due to the splenic atrophy that occurs in this disease. Dapsone, used to treat dermatitis herpetiformis which may occur in celiac disease, can cause an oxidative hemolysis.

Endocrine disorders

Thyroid disease

Hypothyroidism is associated with mild or (occasionally) moderate anemia that is normochromic and mildly macrocytic. In addition, there may be small numbers of irregularly contracted cells, and a basophilia may be seen.²⁵ Red cell survival is normal. Hyperthyroidism conversely is associated with an increase in red cell mass, although hemoglobin concentration is usually normal, and can be associated with a lymphocytosis, neutropenia and basopenia, although as basophils are so infrequent in normal blood this is not diagnostically helpful.

Adrenal and pituitary insufficiency

These give rise to a mild normochromic anemia and are associated with lymphocytosis, eosinophilia, monocytopenia and neutropenia. Anemia associated with hypofunction of the pituitary is partly due to target endocrine organ failure but also to growth hormone deficiency, which affects erythropoiesis directly via its paracrine growth-promoting mediator, insulin-like growth factor 1. EPO levels are increased and there is a direct stimulatory effect on erythroid cells.^{26,27}

Heart disease

Congenital heart disease

Tissue hypoxia secondary to cyanotic congenital heart disease (CHD) stimulates erythropoietin production resulting in polycythemia. The blood film rarely shows polychromasia and nucleated red blood cells unless there is an acute-on-chronic hypoxic episode. Thrombocytopenia and platelet function defects are also recognized, and activation of the coagulation system has been demonstrated.²⁸ These hemostatic changes are described in detail in Chapter 29 along with those that occur in Noonan syndrome, in which CHD is a feature. Children with cyanotic CHD rarely have hemorrhagic problems unless they are undergoing surgery; paradoxically they are reported to be at risk of thrombotic complications. Phlebotomy has been recommended in this group of patients to improve cerebral circulation and theoretically reduce the risk of cerebral arterial thrombosis.²⁹ However, because the circulatory effects of phlebotomy are transient and because iron-deficient red cells are less deformable, phlebotomy-

induced iron deficiency results in symptoms of hyperviscosity at a level of hematocrit lower than in those who are not iron deficient. Low-dose iron therapy can be effective in relieving the symptoms of hyperviscosity.^{30,31} Phlebotomy should be reserved for the temporary relief of significant, intrusive hyperviscosity symptoms.³² Cyanotic CHD can result in functional hyposplenism (see below) due to poor perfusion of the spleen.

DiGeorge syndrome

DiGeorge syndrome, or velocardiofacial syndrome, is a rare disorder characterized by a spectrum of thymic and parathyroid gland abnormalities, conotruncal cardiac defects, typical facial dysmorphism and chromosome 22q11.2 deletion. It can also be associated with hypocalcemia and lymphopenia with reduced T cells. There have been reports of graft-versus-host disease secondary to blood transfusion in infants with this syndrome, and there is an argument for giving neonates with suspected DiGeorge syndrome irradiated products until the immune status is known.^{33,34}

Cardiac anomalies and hyposplenism

Cardiac anomalies, particularly situs inversus, may be associated with hyposplenism and thus the blood film may show Howell-Jolly bodies, Pappenheimer bodies, a lymphocytosis, monocytosis and platelets in the high normal or elevated range.

Lung disease

Hypoxia

Chronic hypoxia, which can arise from a variety of pulmonary disorders, may lead to a compensatory polycythemia. Occasionally, the increased hyperviscosity leads to decreased tissue blood flow. Acute hypoxia, such as may occur in severe pneumonia, gives a different picture, the blood film showing polychromasia and nucleated red blood cells, as the bone marrow tries to compensate rapidly for the fall in oxygen tension. Apart from these changes, the other hematologic manifestations of pulmonary disease are dependent on the disorder itself.

Pulmonary hemosiderosis

This term describes a number of rare childhood disorders where repeated intraalveolar microhemorrhages result in pulmonary dysfunction, hemoptysis and hemosiderin-laden macrophages being lost to the external environment through the gut by swallowing. A major feature is therefore anemia due to iron deficiency. There are primary and secondary causes, with the former being more common in children.

Apart from a primary idiopathic type, there is also a variant associated with hypersensitivity to cows' milk and one that occurs with a progressive glomerulonephritis (Goodpasture syndrome).

Loeffler syndrome

This is not a distinct clinical entity and probably represents an unusual allergic manifestation to a variety of antigens. It is characterized by transient widespread pulmonary infiltrates seen on radiography in association with a high eosinophil count. In the absence of an identifiable allergen (such as migrating parasites), the condition usually resolves after a few days or weeks. It is distinct from the rare hypereosinophilic syndrome, which is a chronic disorder of unknown cause involving higher counts (up to $100 \times 10^9/L$) and which may damage other organs, notably the heart.³⁵ Asthma and bronchoallergic fungal infections can also be accompanied by a mild eosinophilia.

Skin disease

Eczema

A mild eosinophilia may be seen with eczema. Severe eczema and psoriasis can be accompanied by a mild anemia that has features of the anemia of chronic disease. Wiskott–Aldrich syndrome is characterized by severe eczema, thrombocytopenia where the platelets are small, and immune dysfunction; it is discussed in Chapter 19.

Mast cell disease

Mast cells, which are found in peripheral tissue, play a central role in inflammatory and immediate allergic reactions; they are only rarely found in the peripheral blood. In mast cell disease, large numbers are found either in the skin (cutaneous mastocytosis) or internal organs, particularly the gastrointestinal tract (systemic mastocytosis). These cells can release histamine and heparin-like substances, which cause urticaria of the skin and a heparin-like coagulation defect that can cause significant hemorrhage.^{36–38} Cutaneous mastocytosis is the commonest form in children presenting under the age of 2 years, either as a solitary mastocytoma or more usually as urticaria pigmentosa. It is a benign disease and may regress spontaneously in children.³⁹ Involvement outside the skin is unusual, with bone lesions being the commonest; bone marrow infiltration is rare.⁴⁰

Connective tissue disease

Anemia of chronic disease is common amongst this group of

disorders but certain diseases may have their own distinctive characteristics.

Systemic lupus erythematosus

Many hematologic changes in addition to anemia of chronic disease have been described in systemic lupus erythematosus (SLE). Autoantibodies to red cells, neutrophils or (most commonly) platelets result in peripheral destruction reflected by cytopenias and increased marrow precursors. The disease can present as an immune cytopenia, mimicking chronic immune thrombocytopenic purpura (ITP), although the serology may be different, with lupus-associated antiplatelet antibodies more commonly fixing complement.⁴¹ As might be anticipated, thrombocytopenic babies can be born to mothers with SLE as they can to mothers with ITP if maternal antiplatelet antibodies cross the placenta. Therapy for SLE-associated thrombocytopenia is as for chronic ITP, and the problem tends to respond to steroids along with other manifestations of the disease. There is evidence that splenectomy is less likely to be successful than in "true" ITP,⁴² and severe refractory cases are difficult to manage. The presence or otherwise of thrombocytopenia has no prognostic importance in terms of other manifestations and progress of the SLE.⁴³

SLE may also be the cause of marrow aplasia, or selective granulocyte aplasia. Lymphopenia, with abnormalities of T-cell function proportional to disease activity, is common. Circulating antiphospholipid antibodies ("lupus anticoagulants"), seen in other conditions as well as SLE, are discussed in Chapter 29.

Systemic-onset juvenile rheumatoid arthritis

The anemia of chronic disease is often complicated by iron deficiency as a result of gastrointestinal blood loss from analgesics (particularly nonsteroidal antiinflammatory drugs) and steroids. The two causes can be difficult to distinguish as serum ferritin may be normal despite iron deficiency due to its being elevated as part of an acute-phase response. Response to oral iron is blunted, possibly due to high circulating concentrations of IL-6; however, parenteral iron has been recommended in children whose circulating transferrin receptor concentration is increased.⁴⁴ In the absence of iron deficiency, the anemia of rheumatoid arthritis can be corrected by erythropoietin.⁴⁵ As well as anemia, a modest secondary thrombocytosis is not uncommon. Neutrophilia, observed in flare-up of the disease, needs to be differentiated from secondary bacterial infections.

Of children with juvenile rheumatoid arthritis, 20% have splenomegaly, although not necessarily the triad of rheumatoid arthritis, splenomegaly and neutropenia described by Felty. Neutropenia may result from hypersplenism alone, or be immune-mediated with detectable antineutrophil IgG antibodies. It does not always resolve after splenectomy.

There is evidence in some patients for a granulocyte maturation arrest, with low levels of granulocyte colony-stimulating factor (G-CSF) activity.

Wegener granulomatosis

Wegener granulomatosis is a necrotizing granulomatous small vessel vasculitis and is rare in childhood. It preferentially involves the upper airways, lungs and kidneys and therefore presents with fever, cough, hemoptysis, epistaxis, nasal discharge, nodular pulmonary infiltrates and renal failure. Evidence suggests that there is an underlying autoimmune inflammatory process but with infections and environmental and genetic factors also contributing. Hematologic features variably include normochromic, normocytic anemia, red-cell fragmentation typical of microangiopathic hemolytic anemia, leukocytosis with neutrophilia and eosinophilia, and a secondary thrombocytosis. Introduction of combined treatment with cyclophosphamide and steroids has improved patient outcome although disease relapses are common as is the risk of long-term organ damage.⁴⁶

Polyarteritis nodosa

This is rare in childhood and is a cause of eosinophilia. If renal disease is present or there is severe hypertension, a microangiopathic hemolytic anemia may result.

Red-cell fragmentation syndromes

These occur as a result of physical damage to red cells such as heat damage from burns, abnormal surfaces (e.g., prosthetic heart valves), mechanical damage in exercise-induced "march hemoglobinuria" and turbulent flow in severe valvular disease. Hemolysis can also be due to a microangiopathic hemolytic anemia (MAHA). This last condition is characterized by the triad of anemia, thrombocytopenia and red cell fragments and is caused by the shearing of red cells by damaged endothelium, fibrin deposition in capillaries or both. Sometimes, the first feature identified will be an unexplained thrombocytopenia, and a search for fragments may reveal the underlying syndrome. It can be due to the presence of large-vessel lesions and vascular malformations including giant hemangiomas (i.e., Kasabach–Merritt syndrome) and may be the first indication that such a lesion is present. A search for vascular malformations should include the mesentery and gut, where they may not be clinically detectable and can also result in gastrointestinal bleeding. MAHA is also seen in disseminated intravascular coagulation (DIC) accompanying sepsis or renal vein thrombosis and in pathologic processes involving the small vessels of the kidney including HUS and TTP (see above).

In red-cell fragmentation syndromes, the blood film shows

microspherocytes, fragments and often polychromasia. If there is thrombocytopenia, large platelets may be seen. In childhood, the commonest cause is enteric infection with accompanying renal failure. In these cases, there is often a leukocytosis and neutrophilia and sometimes echinocytosis, probably reflecting the toxin-induced damage to the red cell contributing to the hemolysis. Hemolysis in microangiopathic and mechanical hemolytic anemias is intravascular and if severe and chronic can lead to iron deficiency from persistent hemoglobinuria.

Infection

The hematologic response to infection depends on the type of invading organism and the state of health of the patient prior to becoming infected. Serious or overwhelming infections can be associated with profound disturbances of hemostasis and DIC. Acute bacterial infections produce a neutrophilia, except where sepsis is overwhelming or in preterm neonates where a paradoxical neutropenia is common. An increase in the number of immature neutrophils (band or stab cells) is also seen, and an increased ratio of band cell to mature forms is a more reliable indicator of sepsis in the neonate than the absolute neutrophil count.⁴⁷

Subacute or chronic bacterial sepsis (such as that due to *Salmonella*, *Brucella* or tuberculosis) tends to increase the number of monocytes. Virus infections can produce a transient neutrophilia as part of an acute-phase response, and subsequently, if they produce hematologic changes, tend to cause disturbances in the number and/or morphology of lymphocytes. Parasites, if they penetrate tissues, cause an eosinophilia. Infections with many different organisms can occasionally provoke inappropriate hemophagocytosis (so-called infection-associated hemophagocytic syndrome; see Chapter 15), whereas others can result in leukemoid reactions or transient erythroblastopenia. Specific organisms and infections of particular hematologic importance are considered in more detail below.

Transient erythroblastopenia of childhood

This is characterized by profound normochromic anemia with absent or grossly reduced reticulocytes in an otherwise well child. Often there is an associated thrombocytosis whereas white cells are unremarkable. The cause of transient erythroblastopenia of childhood is not proven but has been reported to follow toxic, allergic or infectious episodes. However, a study in 10 children failed to show any definite proof of a viral etiology.⁴⁸ Most patients recover within 1–2 months from diagnosis and many begin to recover by the time they present. Transient erythroblastopenia of childhood can be confused with Diamond–Blackfan anemia, and differentiating features are discussed in Chapter 2.

Leukemoid reaction

Leukemoid reactions may be myeloid or lymphoid and are secondary to some other, underlying disease, most commonly infection. Such a reaction reverses on treatment of the underlying condition but may be confused with leukemia. In Down syndrome, transient abnormal myelopoiesis may be seen but this is distinct from a leukemoid reaction.

Causes of myeloid leukemoid reactions include any strong stimulus to the bone marrow, particularly severe bacterial infection, malignant disease and tuberculosis. Toxic changes, such as toxic granulation in the neutrophils and relatively few myelocytes and myeloblasts compared with the total neutrophil count, favor a reactive etiology. Lymphoid leukemoid reactions are classically seen in whooping cough, where the lymphocyte count may reach $100 \times 10^9/L$, or in the self-limiting condition acute infectious lymphocytosis, which is probably due to coxsackievirus⁴⁹ and results in lymphocyte counts of $\leq 50 \times 10^9/L$. Because chronic lymphocytic leukemia is so rare in children, these diseases are rarely confused with each other.

Hemolysis

Infection can precipitate most forms of hemolysis including cold immune hemolysis, fragmentation syndromes, oxidant hemolysis and that secondary to parasitized red cells or toxin production.

Cold autoimmune hemolytic anemia

In this syndrome, the autoantibody attaches to the red cell mainly in the peripheral circulation where the blood temperature is cooler. The antibody, usually IgM, binds to the red cells best at 4°C and the severity of the hemolysis and consequent anemia depend upon the antibody titer, the affinity of the antibody for red cells, its ability to bind complement and its thermal amplitude. The antibody is nearly always directed at the I or i antigen on the red-cell surface. Both mycoplasma and Epstein–Barr virus infections have been associated with cold autoimmune hemolytic anemia (AIHA), which is usually transient. Clinical features, when present, are mainly due to hemolysis rather than to red cell agglutination in peripheral vessels. Agglutination is seen on the blood film, even in the absence of clinical features, and with varying numbers of spherocytes and a degree of polychromasia dependent on the severity of the hemolysis. The mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH) and mean corpuscular hemoglobin concentration (MCHC) are raised due to the presence of the agglutinates.

Paroxysmal cold hemoglobinuria

This rare syndrome can occur after viral infections, including

measles, or less commonly as a late manifestation of syphilis, and results in acute intravascular hemolysis. The antibody, named the Donath–Landsteiner antibody, is an IgG and directed against the P blood group antigens. It binds to red cells in the cold but causes lysis with complement in the warm. Variable numbers of spherocytes and polychromasia are seen on the blood film.

Bacterial and parasitic infections

Clostridium welchii and *Cl. perfringens* septicemia can result in severe intravascular hemolysis characterized by the presence of microspherocytes on the blood film. The bacteria produce several hemolytic toxins, one of which exposes the Thomsen–Friedenreich cryptoantigen (or T-antigen).⁵⁰ Infection can follow penetrating wounds or peritonitis from a perforated viscus, or occur in immunosuppressed patients.^{51,52}

Bartonellosis, malaria and babesiosis can all cause a hemolytic anemia. *Bartonella* organisms coat the red cells and result in their rapid removal from the blood, whereas malaria and *Babesia* colonize the red blood cells and cause their destruction. In addition, malaria also induces antibodies resulting in autoimmune hemolysis and increased destruction of the parasite-damaged red cells by the spleen. All of the organisms can be identified on correctly prepared and stained blood films, although in the later stages of bartonellosis the organisms leave the bloodstream. Heavy infestation with *Plasmodium falciparum* malaria parasites can cause severe acute intravascular hemolysis and acute tubular necrosis described as “blackwater fever.” It can also cause cerebral malaria. In both conditions, small vessels are occluded with parasitized cells, with associated intravascular fibrin and perivascular hemorrhage. Immune-mediated thrombocytopenia without DIC is also common in malaria.

Specific infections

Visceral leishmaniasis (kala-azar)

Visceral leishmaniasis is transmitted by sandflies and can cause fever, pancytopenia, hepatosplenomegaly and, to a lesser extent, lymphadenopathy up to several years after exposure. It may be mistaken for a lymphoma. Bone marrow or splenic aspirates may show the parasites, so called Leishman–Donovan bodies, in and around the macrophages. Hemophagocytosis may also be seen.

Tuberculosis

Childhood tuberculosis is an increasing problem with the emergence of multidrug resistance and human immunodeficiency virus (HIV) coinfection. Tuberculosis produces several hematologic features including monocytosis, anemia of chronic disease or a myeloid leukemoid reaction (see

above). Thrombocytopenia and pancytopenia have also been reported. Bone marrow involvement is rare, except in immunosuppressed patients, but when it does occur may result in a leukoerythroblastic film and granulomas in the bone-marrow biopsy.

Epstein–Barr virus

Primary infection by Epstein–Barr virus (EBV) causes infectious mononucleosis (IM), which is predominantly a disease of adolescents and young adults. Infection can occur in young children, where its presentation and clinical features may be mild so that EBV is not recognized as the cause. IM, commonly known as “glandular fever,” presents with pharyngitis, fever, lymphadenopathy and hepatosplenomegaly. Rarely, there may be a generalized rash. The incidence of rash approaches 100% in patients given ampicillin, a strange, induced allergy that is almost pathognomonic for the disease. The same applies to the now more commonly used analogous antibiotic, amoxicillin.

EBV infects B lymphocytes but the characteristic atypical mononuclear cells seen on the blood film are mainly activated CD8⁺ T lymphocytes. These cells contribute to the lymphocytosis and leukocytosis seen in IM and are highly pleomorphic. They are large, with blue cytoplasm, and may have nucleoli. Where they abut other cells, their edges are typically “scalloped.” They usually comprise > 25% of the total lymphocytes (commonly > 50%) in contrast to the “EBV-negative” IM-like syndromes. There may be accompanying neutropenia, which can be severe, and mild thrombocytopenia in about one-third of patients. Severe thrombocytopenia occurs in < 1% of patients and is probably of immune etiology; cold AIHA can occur (see above) with accompanying red-cell agglutination but often not overt hemolysis; spherocytes and polychromasia may be seen on the blood film to varying degrees.^{53,54} Hemophagocytosis can occur, and rarely aplastic anemia some weeks after the primary infection.

The diagnosis is made by the typical hematology together with specific EBV serology. A widely used and reliable screening test detects heterophile red cell agglutinins, a feature of classical “glandular fever” noted by Paul and Bunnell in the 1930s. Unlike naturally occurring heterophile antibodies, the agglutinins seen in IM are not absorbed by guinea pig kidney. They are absorbed by ox red cells, and agglutinate sheep and horse red cells. These features are exploited in the popular “monospot” test of Lee and Davidshon, where sera are exposed to either guinea pig kidney or beef red cell stroma before being assessed for their potential to agglutinate horse red cells. Heterophile antibodies appear around the same time as the atypical lymphocytosis, or shortly thereafter, and peak around 2 weeks. They can persist for several months. They are not specific, and can occasionally arise in disorders other than IM, including acute leukemia and lymphoma.

There is no treatment of proven benefit in uncomplicated IM. The benefit of steroids, often used for symptomatic thrombocytopenia or severe hemolysis, is difficult to assess as both problems normally recover quickly with or without therapy. High-dose immunoglobulin has also been used.⁵⁵

EBV infection in immunosuppressed patients

EBV infection in some individuals with cellular immune deficiency states can give rise to uncontrolled lymphoproliferative disorders. X-linked lymphoproliferative disease (Purtilo or Duncan syndrome) is a rare inherited inability to combat EBV infection where patients may die of progressive disease, occasionally associated with a virus-induced hemophagocytic syndrome.⁵⁶ They also suffer from marrow aplasia, hypogammaglobulinemia and lymphomas. Those on aggressive immunosuppressive therapy following solid organ transplants, recipients of allogeneic marrow grafts and patients with HIV infection can all develop polyclonal proliferation of B lymphocytes that carry the EBV genome and which in some instances progresses to a fatal clonal lymphoma. In marrow transplant patients, the problem usually involves donor-derived lymphocytes and occurs in recipients of mismatched T-cell-depleted marrow after treatment with T-cell antibodies for graft-versus-host disease. A later form of the disease may arise from host cells.⁵⁷

Burkitt lymphoma

This is endemic in Africa, where it is the commonest cancer in children. It commonly presents with jaw lesions, extranodal abdominal involvement and ovarian tumors in girls. EBV has been identified in Burkitt cell culture but there is some evidence that *Plasmodium falciparum* malaria might interact with EBV in the etiology of this disease.^{58,59}

Human immunodeficiency virus

HIV infection in children is covered in detail in Chapter 19. The direct hematologic (as opposed to the immunologic) effects of the virus can briefly be summarized as cytopenias due either to a direct effect on marrow stem cells resulting in decreased production or as a consequence of autoantibodies to blood cellular elements.^{60,61} Hemostatic abnormalities that predispose patients to thromboembolism have also been recognized.⁶²

Anemia in HIV-infected children is commonly due to many factors other than the virus. A study in Abidjan, where the prevalence of HIV infection in unselected children admitted to hospital was 8.2%, showed that the most frequent reason for admission in such patients was malnutrition; malaria can also coexist.⁶³ The virus can, however, result in an autoimmune hemolytic state in which the direct antiglobulin test is positive, although overt hemolysis is rare.^{60,62} It can also cause reticulocytopenia.⁶⁰

ITP is a common manifestation of HIV infection and can be the first sign of infection in otherwise apparently well children.⁶⁴ It can therefore be mistaken for simple ITP (see Chapter 23), although careful examination of the child with HIV will usually identify lymphadenopathy or hepatosplenomegaly. HIV testing of selected thrombocytopenic children, such as those in high-risk groups or those with ITP that does not resolve, should be considered. Neutropenia is not uncommon and may be immune mediated, but may also be compounded by reduced production due to antiretroviral therapy or co-trimoxazole. Highly active antiretroviral therapy (HAART) is being used successfully in children and allowing discontinuation of prophylactic medication for *Pneumocystis pneumonia* or opportunistic infections.⁶⁵

Lymphomas and other HIV-associated malignancies arise less frequently in children than adults, although the number of children developing malignancies is increasing as they live longer and the number with HIV infection increases.⁶⁶

Parvovirus B19

In normal individuals, acute infection by B19 parvovirus produces fifth disease (erythema infectiosum), which is characterized by facial erythema, giving a “slapped cheek” appearance and sometimes arthralgia/arthritis. It often goes unnoticed, and a study in Scotland has shown that by 20 years of age, 65% of people have antibodies to the virus.⁶⁷ The virus itself has a predilection for the P antigen on red cells and binds to erythroid precursors in the bone marrow, preventing their replication, and to a lesser extent, replication of the other cell lineages. In people whose red cells have a normal lifespan this has little clinical impact, but in those whose red cells have a shortened cell lifespan, such as a patient with sickle-cell disease or hereditary spherocytosis, this can result in an acute aplastic crisis characterized by a rapidly falling hemoglobin and the absence of a reticulocyte response. In immunocompromised individuals, infection can result in a pure red cell aplasia or prolonged pancytopenia,⁶⁸ which is also not infrequently seen in children on chemotherapy for leukemia,⁶⁹ suggesting that normal immunity is necessary for virus control. Because viral infection is prevalent in the population, therapeutic immune globulin preparations are a good source of anti-B19 antibodies, and IgG administration can lead to cure of anemia in the congenitally immunodeficient patient and to its amelioration in AIDS patients with persistent parvovirus infection.⁷⁰ Fetal infection with parvovirus B19 can lead to hydrops fetalis. It can also occasionally cause symptomatic pancytopenia in otherwise healthy children.⁷¹

TORCH infections

This is a miscellaneous group of congenital infections including *Toxoplasma*, rubella, cytomegalovirus (CMV), herpes simplex (HSV), HIV and syphilis. Although they are all very

different diseases, the collective acronym is justified by certain common features: they can all cause neonatal anemia, thrombocytopenia (see also Chapter 22) and hepatosplenomegaly.

Kawasaki disease

Kawasaki disease is an acute multisystem vasculitic condition that occurs in children and is self-limiting. It is characterized by fever, bilateral nonexudative conjunctivitis, erythema of the lips and oral mucosa, rash and cervical lymphadenopathy. Coronary artery aneurysms or ectasia develop in approximately 15–25% of untreated children and may lead to ischemic heart disease or sudden death through coronary artery occlusion or rupture.⁷² Treatment is based on the use of aspirin and intravenous immunoglobulin.⁷³ The most striking hematologic feature, apart from the marked neutrophilia and acute-phase response seen during the acute stage of the disease (up to 4 weeks), is a secondary thrombocytosis. This commonly arises during the second week of the illness and may persist into the subacute and convalescent phase, with counts commonly well in excess of $1000 \times 10^9/L$. There is some evidence that it is mediated through production of the acute-phase cytokine IL-6.⁷⁴

Nutritional disorders

Hematinic deficiencies are described in Chapters 5 and 6, but brief consideration is given here to protein-calorie malnutrition, scurvy and anorexia nervosa, all of which can produce hematologic abnormalities.

Protein-calorie malnutrition

This all-embracing term covers malnutrition due to protein deficiency in the presence of adequate carbohydrate calorie intake (kwashiorkor); simple calorie deficiency (marasmus) and, as commonly occurs, a combination of the two. While primarily a problem of underdeveloped countries, malnutrition can also arise in children of strict vegetarians and can complicate some chronic diseases such as renal failure, malignancy and serious intestinal disorders.

Anemia is usual in children with severe protein deficiency. Uncomplicated, it is usually mild, normochromic and normocytic and appears to be due to reduced cell production despite adequate erythropoietin drive.⁷⁵ Frequently, concomitant iron or folate deficiency will complicate the picture. Protein-calorie malnutrition also predisposes children to infection, which is in part due to impaired leukocyte function.⁷⁶

Scurvy

Scurvy (vitamin C deficiency) is rare, but is occasionally seen in children between the ages of 6 months and 2 years due to

poor dietary intake and where fruit juices are boiled. Those affected become irritable and dislike being handled. The legs become tender and this can result in pseudoparalysis, where the child lies in a froglike pose. Purple spongy swellings appear around erupted teeth. Petechial, subperiosteal, orbital or subdural hemorrhages may arise, together with hematuria or melena. Mild anemia is common, probably due to extravasation of blood. The bleeding tendency is due to loss of vascular integrity with collagen deficiency.

Anorexia nervosa

Anorexia nervosa produces hematologic changes in its more advanced stages. As might be expected, these are similar to those seen in severe malnutrition and include macrocytosis,⁷⁷ mild anemia, neutropenia and thrombocytopenia. There is a predisposition to infection associated with neutropenia and the lower ranges of body mass index.⁷⁸ The marrow undergoes gelatinous change and occasionally can become severely hypoplastic.⁷⁹ Small numbers of irregularly contracted erythrocytes are seen, similar to those of hypothyroidism, possibly reflecting a disturbance in the composition of membrane lipids.⁸⁰

Drugs

The list of candidate drugs causing hematologic side-effects is long. Certain drugs are associated with specific side-effects that may not be predictable but are well described; others occur in a dose-dependent fashion or are unpredictable. It should be assumed that any drug can cause a hematologic side-effect, particularly perhaps an immune-mediated thrombocytopenia, when such an effect occurs in a child for no other obvious reason. Myelosuppression affecting all cell lines is a dose-dependent side-effect of many antineoplastic agents (see Chapters 16, 20 and 21). Idiosyncratic marrow failure (aplasia) can also occur as an aberrant response to noncytotoxic drugs such as chloramphenicol and butazone (see Chapter 4), and can affect one cell line preferentially, such as the myeloid line with carbimazole. Drugs can also reduce the numbers of circulating blood cells by shortening their survival, either via an immune-mediated effect or through direct damage. Neutropenia is covered in Chapter 14. Drug-induced immune hemolytic anemia is discussed in Chapter 8, and red cell damage from oxidant drugs in Chapter 9. Two specific drug effects are mentioned below.

Sodium valproate, used in epilepsy, has a high incidence of drug-induced thrombocytopenia. In an early prospective study of 45 children, one-third had a measurable fall in their platelet count, one child reaching a nadir of $35 \times 10^9/L$.⁸¹ Subsequent studies have confirmed this phenomenon, with several showing the occurrence of thrombocytopenia in 12–18%

of patients, with the platelet count inversely correlated with age and dose of sodium valproate but not duration of treatment.^{82–84} It is not clear whether the thrombocytopenia is always or wholly immune-mediated; there is some evidence of defective platelet production.^{85,86}

Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is of two types: HIT type I, which occurs soon after starting heparin and is a mild, transient, nonimmune disorder; and HIT type II, which is an immune-mediated thrombocytopenia that is severe and arises after 8–10 days of heparin.^{87,88} HIT type II affects up to 3% of patients treated with unfractionated heparin; it is less frequent when low-molecular-weight heparins are used.⁸⁹ It is characterized by a fall in platelet count, not necessarily outside the normal range, platelet activation and consequent arteriovenous thromboembolism. Platelet activation is due to an antibody against a neoantigen formed by the heparin–platelet factor 4 complex.⁸⁸

Heparin is not as frequently used in pediatrics as in adult medicine due to the lower incidence of thromboembolic disease. It is used, however, and all patients on intensive care invariably receive small but significant amounts from indwelling catheters and arterial lines. A study by Risch *et al.*⁹⁰ reports on 70 pediatric patients with HIT, the majority of whom were on intensive care. The diagnostic features and outcomes were similar to those seen in adults.

Patients receiving any form of heparin for longer than 5 days should have their platelet count measured. Any who develop a decreasing platelet count, unexplained thrombosis, or resistance to heparin anticoagulation should be tested for heparin-associated antibodies. Heparin should be withdrawn immediately and alternative anticoagulation instituted, even if thrombocytopenic. Danaparoid, lepirudin and argatroban appear to improve outcomes.⁹⁰

Hematologic effects of nonhematopoietic tumors

The effects of cancer on peripheral blood and bone marrow are legion; some are characteristic but few are diagnostic by themselves. Even larger centers will see only perhaps 50 cases per year and these will be a mix of different tumors, with only a small number in even the most common diagnostic categories. Therefore, to build up a picture of typical findings requires collaboration, and this area is not well documented in the literature, except as incidental details in incidental case reports. This section concentrates on the common abnormalities of blood and bone marrow that are not directly caused by treatment, and also highlights some characteristic and other, less common, features of infiltrated bone marrow.

Peripheral blood abnormalities

Anemia, erythrocytosis, leukopenia, leukocytosis, thrombocytopenia, thrombocytosis, microangiopathic hemolysis and rouleaux have all been seen at presentation in children with cancer. No single pattern is restricted to any particular form of cancer but it is worth highlighting some of the typical findings in the peripheral blood.

Anemia of chronic disease

The anemia may be mild or severe and is often a concern to the treating physician. Characteristically it is normochromic and microcytic with normal or raised serum ferritin, low serum iron and rouleaux formation. The anemia is probably caused by the complex interaction of a variety of cytokines (see above) produced in response to the presence of a tumor; it may be associated with some degree of reactive thrombocytosis. In most children with cancer, anemia is not primarily due to marrow infiltration or bleeding. Even in those with disseminated disease, bone marrow infiltration is not the sole (or even, necessarily, the prime) cause of anemia. Concomitant iron deficiency is difficult to exclude by laboratory tests, and assessment of response to oral iron therapy is impractical in most children with cancer. If bone marrow aspirates are performed, iron stains will be helpful in showing whether stainable iron is present. In anemia of chronic disease, iron is present but there is poor incorporation into red blood cells, reflected by decreased numbers of sideroblasts; absent stainable iron is seen in the deficient state.

It is easier to appreciate the importance of anemia of chronic disorders if cancers that have not infiltrated the marrow are considered. Wilms tumor and hepatoblastoma stand out in this regard. Although both erythrocytosis and anemia are said to be features, albeit rare ones, of Wilms tumor,⁹¹ the typical pattern is of mild or moderate anemia. In the last 55 consecutive children with Wilms tumor seen in three UK Children's Cancer Study Group (UKCCSG) centers (Newcastle, Edinburgh and Glasgow), the average hemoglobin was 10.7 g/dL (range 5.8–15.7 g/dL). The average MCV was 75.3 fL (range 64–91 fL). This excludes a single case of mesoblastic nephroma where the hemoglobin was 20.1 g/dL and MCV was 103.8 fL. Ferritin levels were measured in only six children, five of whom had an MCV of ≤ 70 fL, and were normal or raised in all six cases. It was not possible to estimate what contribution bleeding from the renal tract may have made to the usually mild anemia. Ferritin levels are rarely informative in determining the cause of microcytosis in children presenting with cancer; an iron stain of a bone marrow is more helpful. In 12 children with hepatoblastoma from the same UKCCSG centers (age range 3 weeks to 7 years), the average hemoglobin was 10.3 g/dL (range 5.5–15.6 g/dL) and MCV was 74 fL (range 61–89 fL). These two diseases are associated with lower MCVs than

other neoplastic diseases. Hodgkin lymphoma is classically described as having a microcytic anemia at presentation. However, blood counts at presentation from 74 consecutive patients with Hodgkin lymphoma had an average MCV of 79.6 fL. Twenty patients were 17 years or older and, if excluded, the average MCV was 79.8 fL. Of the 46 children (age range 4–15 years) only 12 had an MCV below the normal range for age, and average hemoglobin for 45 children was 11.8 g/dL. Although anemia of chronic disorder does occur in neuroblastoma, frequent or marked microcytosis is less common. The only child with marked microcytosis (MCV < 70 fL) of 49 with widely disseminated neuroblastoma from two centers (Newcastle and Edinburgh) was found to have concomitant β -thalassemia trait. These examples of discrepancy between textbook descriptions of classical features and routine experience suggest that the "classical" picture may have been inordinately influenced by individual cases with "exciting" hematologic features; erythrocytosis, occasionally seen in Wilms tumor or mesoblastic nephroma (see above), is a rare condition in childhood and thus worthy of reporting while microcytosis is commonplace and of less interest.

Reactive thrombocytosis

A variety of stimuli and diseases can sometimes produce dramatically high platelet counts in children,⁹² in some of whom elevated IL-6 levels may be a contributory factor.^{93,94} Rebound during cancer treatment is one of the common causes, but thrombocytosis is not thought to be particularly common at presentation.⁹² To some extent the frequency of thrombocytosis depends on its definition (see Chapter 24). Patients with Wilms tumor and hepatoblastoma provide a useful source of information about platelet counts. In the groups of patients from the three UKCCSG centers described above, the average platelet count in those with Wilms tumor was $383 \times 10^9/L$ (range $91\text{--}885 \times 10^9/L$, including eight children with counts $> 500 \times 10^9/L$) and in those with hepatoblastoma it was $865 \times 10^9/L$ (range $502\text{--}1674 \times 10^9/L$). Similar platelet counts may be found in some children with localized neuroblastoma, rhabdomyosarcoma, Ewing tumor and other cancers. Perhaps more surprising is the average platelet count of $244 \times 10^9/L$ (range $44\text{--}839 \times 10^9/L$) for the last 49 cases of neuroblastoma with infiltrated bone marrow seen in two centers (as above), of whom eight had counts $> 400 \times 10^9/L$. Both sets of observations, in Wilms tumor, hepatoblastoma and disseminated neuroblastoma, suggest that other factors may influence the platelet count rather more than the presence (or absence) of marrow infiltration.

Neutrophilia and neutropenia

There is an even less consistent pattern in neutrophil counts at presentation. Moderate reactive neutrophilia seems to be as common as mild neutropenia, even in children with

infiltrated marrows. Beyond awareness of potential infective risks, there is little of practical importance in the neutrophil count in most cases.

Microangiopathic hemolysis

Microangiopathic hemolytic anemia, manifest by red cell fragmentation with perhaps a degree of thrombocytopenia and either with or without derangements in coagulation, has been seen in a wide range of cancers. Acute promyelocytic leukemia is the most-recognized cause of DIC in childhood cancer. However, among the nonhematopoietic tumors no single type stands out. Minor red cell fragmentation or poikilocytosis is so common and nonspecific that it is of little value as a diagnostic pointer or in alerting hematologists (or clinicians) to a clinically important coagulopathy. However, fragments and thrombocytopenia may alert a hematologist to the presence of an otherwise unsuspected hemangioma.

Leukoerythroblastic blood film

The presence of circulating nucleated red blood cells and myelocytes immediately raises the possibility of bone marrow infiltration but this peripheral blood picture is not generally as striking in children as in adults with disseminated cancer. Leukoerythroblastic pictures may be associated with pancytopenia, isolated cytopenias and normal or raised white cell counts. A case can be made for examining the bone marrow in any child with such a picture at diagnosis, even if this is not one of the recommended initial investigations for the tumor, whatever the rest of the blood count indicates. However, a leukoerythroblastic picture is a poor diagnostic aid and should not be used to help discriminate between leukemia and nonhematopoietic cancer in cases where the initial differential diagnosis is broad; it is the bone marrow appearances that matter. Striking leukoerythroblastosis may occur in nonmalignant conditions such as infection or hemolytic anemia.

Circulating tumor cells

Circulating tumor cells are rarely seen in the peripheral blood of children with cancer. However, primitive cells that cannot be positively identified as either hematopoietic or nonhematopoietic cells are seen from time to time. Neuroblastoma,⁹⁵ medulloblastoma⁹⁶ and rhabdomyosarcoma⁹⁷ have all been mistaken for acute leukemia because of peripheral blood abnormalities and, in the case of the cited example of rhabdomyosarcoma, cerebrospinal fluid (CSF) and pleural fluid involvement. Such reports are sometimes used as examples of circulating tumor cells. Highlighting these rare cases may give an unrealistic impression of the typical child with cancer for at least two reasons. Firstly, such cells are extremely rare. Secondly, closer inspection of these three

published cases shows that very small numbers of circulating “blasts” ($0.03\text{--}0.12 \times 10^9/\text{L}$) were found, there were no distinctive features that could help distinguish between non-hematopoietic cells and normal or malignant hematopoietic precursors, and the striking blood abnormality was simply a leukoerythroblastic reaction. In none of these cases did the authors claim that the circulating blasts were necessarily tumor cells. The syndrome of carcinocythemia, in which clumps of tumor cells may be found in the blood, seems to be more common in adults and may reflect tumor emboli rather than circulating tumor cells.

Newer techniques, with sensitivities in the range of one malignant cell per $10^4\text{--}10^6$ normal cells, have identified circulating tumor cells in peripheral blood, for instance in neuroblastoma and Ewing sarcoma, and correlations with bone marrow findings and clinical outcome have been made.^{98–101} Techniques include immunocytochemistry to detect disialoganglioside (GD2) and reverse transcription-PCR (RT-PCR) to detect tyrosine hydroxylase (TH) or GD2 synthase mRNA in neuroblastoma.^{99,100} RT-PCR is used to detect the chimeric transcripts *EWS-FLI1* and *EWS-ERG* found in Ewing sarcoma and primitive neuroectodermal tumors (PNET).^{101,102} The specificity of these markers has not been fully validated; false positives have been found using anti-GD2 by some workers,¹⁰³ and it might be important to combine information from both immunologic and molecular cytogenetic techniques. It is not perhaps surprising that these cells can be detected given the metastatic nature of these tumors and widespread disease at presentation or relapse. However, it is more important to determine the significance of these cells and whether quantitative analysis can help either to direct therapy or predict outcome. These techniques are being used to determine the level of residual disease in bone marrow specimens, peripheral blood and peripheral blood stem cell harvests, but it is important that this is correlated with clinical staging and outcome in rigorous well-designed clinical trials so that the importance of detecting such tumor cells can be ascertained.

Bone marrow abnormalities

Bone marrow specimens have been part of the staging procedure in certain children's cancers from the 1960s. From early studies^{104,105} experience of the pattern of metastases and relapse has grown and has indicated those tumors in which there is a sufficiently high incidence of dissemination to warrant routine examination of the bone marrow at diagnosis. In most centers attention has focused on the small round-cell tumors: neuroblastoma, Ewing tumor, PNET and rhabdomyosarcoma. Accuracy of the primary diagnosis has steadily improved over the past 35 years but the adequacy of material gained from bone marrow specimens to determine disease involvement had not been clearly specified. It is only within the last 20 years that the routine practice of obtaining

marrow from more than one site, and by both aspirate and trephine biopsy, has gained wider acceptance.¹⁰⁶ Apart from unique clinical circumstances, routine monitoring of bone marrow is virtually restricted to neuroblastoma, for which internationally agreed criteria for staging and assessment of response have been developed.^{107,108} It is important that adequate specimens are obtained because crucial treatment decisions are made on the basis of the results.

The following section deals mainly with the appearances of infiltrated bone marrow and draws on both the scanty published data and collective personal experience.

Neuroblastoma

Neuroblastoma is the commonest malignant infiltrate of bone marrow of children after leukemia. In most cases its detection and correct identification present few problems; there is usually a strong clinical suspicion of the correct diagnosis, and a simple diagnostic test allows the detection of high levels of catecholamine metabolites in > 90% of patients with neuroblastoma. The simplicity of this test and its general reliability have probably contributed to the lack of vigor with which hematologists have studied the tumor cells because the diagnosis is often known at the time of examining the bone marrow. Despite the frequency with which neuroblastoma is seen by hematologists, only sporadic descriptions, as opposed to studies of frequency of infiltration, existed until Mills and Bird¹⁰⁹ described the "variability of the microscopic pattern of marrow infiltration," having studied both bone marrow aspirate smears and trephine biopsies from 48 new cases.

Cytology

In the current HR-NBL-1/ESIOP trial it is recommended that bone marrow smears are made at the bedside from freshly aspirated bone marrow. Unless the operator is very experienced, or has a "spreader" to help, the aspirated bone marrow is often put into ethylenediamine tetraacetate (EDTA) and cytologic preparations made later. This may introduce other artifacts and should not, if possible, be relied on as the sole or routine method of handling aspirated bone marrow. It can be difficult for the operator, however, as increasing numbers of aspirate specimens are needed for the different biologic and cytogenetic studies.

Superficially, individual neuroblasts often resemble lymphoblasts, and occasionally they may also have a few vacuoles. To help differentiate them from leukemic cells, it is important that the marrow smear is carefully examined under low power, when different and distinct patterns of infiltration are best seen. Mills and Bird describe three patterns: "clumps," "clumps and rosettes" and a "pseudoleukemic" pattern.¹⁰⁹ On examination of a marrow smear, different patterns may be found; none is mutually exclusive within an individual case, particularly if marrow aspirates

are obtained from more than one site. Neuroblasts have a tendency to adhere so strongly to each other that in the process of aspirating the marrow, which is often difficult to achieve, cells are often ripped apart from each other and from the tumor stroma and/or the reactive marrow fibrous tissue. This leaves numerous bare nuclei and often large amounts of cytoplasmic or stromal debris over the surface of the smear, as well as producing the more familiar clumps, doublets and intact single cells. However, it is important not to assume that bare nuclei on a smear are from neuroblastoma cells because they may be from other, nonmalignant, necrotic cells present in the marrow.

Mills and Bird¹⁰⁹ often found ball-like clumps, some with a central lumen, resembling rosettes. Others failed to find significant numbers of rosettes,¹⁰⁶ but one study showed that, provided the smears were examined carefully, rosettes were present in the majority of cases,¹¹⁰ and large numbers of these structures were virtually diagnostic of neuroblastoma.

The partially fibrillar nature of the center of the rosettes strongly resembles earlier descriptions of neuroblastoma cytoplasm,¹¹¹ and the centers also stain strongly with UJ13A,¹¹² a monoclonal antibody to the neural cell adhesion molecule (NCAM), which reacts strongly with most neuroblastomas.¹¹³ However, this antibody is not specific, and false positive reactions have been reported.^{112,114} Although syncytia have often been described, it remains possible that they too are artifacts. Careful examination of rosettes on smears suggests that filamentous extensions of neuroblast cytoplasm extend into the centers of the rosettes, which may also contain secreted substances; together they may give the impression of multinucleate cells.

Bone marrow histology

Mills and Bird¹⁰⁹ also provided the first satisfactory descriptions and illustrations of the histologic features of neuroblastoma in the bone marrow, highlighting the prominent reticulin fibrosis. The range of appearances they described was confirmed shortly after in a larger study.¹¹⁵

From these two studies it is clear that the term "small round-cell tumor," when used to describe neuroblastoma within the bone marrow, can be very misleading. Tumor cells ranging in size from that of a lymphoblast to that of a megakaryocyte can be found, with variable amounts of fibrotic stroma. In some biopsies, fibrosis with few easily identifiable tumor cells predominates. In others, almost monomorphous sheets of tumor cells can be found. Both extremes can occur in different biopsies taken at the same time from the same patient. Occasionally, clear-cut differentiation to ganglion cells is obvious. The classic rosettes in histologic sections of the primary tumor in neuroblastoma are less often found in sections of the marrow than apparently similar structures on aspirate smears. This may reflect some degree of crush artifact in relatively small pieces of tissue or some effect of the tissue (i.e., bone marrow) in which the metastases

have developed. It is also possible that the rosettes in aspirated bone marrow represent a cytologic manifestation of the classic rosette found in histologic preparations.

The extent of infiltration may vary between two simultaneous biopsies from different sites; in one there may be complete replacement of hematopoietic tissue, and in the other no evidence of tumor or a single, small, well-circumscribed cellular nodule. There is often marked discrepancy between the apparent tumor load inferred from the aspirate and biopsy appearances. Such variations highlight the patchy, nonuniform distribution of metastases within bone marrow and the futility of attempting to quantify infiltration of marrow as a simple percentage of aspirated cells. Despite studies carried out nearly 30 years ago,^{106,116} it is only more recently that pediatric oncologists and hematologists have come to accept that single aspirates are inadequate for staging.^{117,118} This growing appreciation has culminated in internationally agreed criteria for both staging and assessing response to treatment;^{107,108} these recommend at least two aspirates and two trephine biopsies from two separate sites as part of the initial staging and also on each occasion that full reassessment of response is carried out. The exception to this general advice is that trephine biopsy, as opposed to aspirate, is recognized as being technically difficult in infants aged < 6 months; it could then remain an optional investigation. The current international high-risk neuroblastoma trial, HR-NBL-1/ESIOP of the Société Internationale d'Oncologie Pédiatrique (SIOP), specifies adequacy of trephine – at least 0.5-cm bone marrow core and preferably 1-cm cores from each posterior iliac crest – because treatment decisions with regard to failure of protocol and proceeding to peripheral blood stem cell rescue depend on the results. A study of adequacy of bone marrow biopsy in neuroblastoma has shown that central review of 605 specimens from 25 centers of the European Neuroblastoma Study Group assessed 25% as being inadequate,¹¹⁹ a deterioration in performance from a study 3 years earlier, when 17% were assessed as inadequate. Despite the documented frequency of “inadequate” samples, one recent estimate of marrow involvement within some European centers showed that only 10% of children with stage 4 disease at presentation have no “conventionally” detectable tumor at presentation.¹²⁰ In the HR-NBL-1/ESIOP trial, biologic, immunocytochemical and molecular data on bone marrow aspirates taken at the same time as the trephines are being collected and hopefully will help to clarify the significance of minimal disease and the sensitivity of the standard bone marrow investigations.

Monitoring effects of treatment: restaging

The role of monitoring progress in treatment by attempting to measure the response of bone marrow metastases is still evolving. Once treatment has started it is difficult to find tumor cells in aspirated marrow, even from children with previously heavy infiltration. The trephine biopsy assumes

even greater importance. There has only been one attempt to describe the range of histologic abnormalities in bone marrow of treated children.¹¹⁵ Four main patterns emerged, which were graded 1 to 4.

- Grade 1: marrow without abnormal architecture, infiltrate or fibrous stroma, albeit often very hypocellular.
- Grade 2: marrow with similar features but with a pathologic increase in reticulin.
- Grade 3: marrow with distorted architecture, increased fibrous stroma and abnormal although not frankly malignant mononuclear cells.
- Grade 4: marrow with an obvious infiltrate of malignant cells.

This grading of bone marrow histology was offered as an alternative to the simple “yes or no” response to the question asked of the hematologist: is the marrow clear of disease? Apparent clearance of malignant cells does not equate with a normal marrow appearance. Whether such a grading system will prove to be clinically important remains to be seen. However, it was clear from the material examined in this study that histologic patterns identical to the posttreatment fibrotic picture could be found in children with infiltrated bone marrow who had not yet received any treatment. One small study¹²¹ showed that the massive reticulin fibrosis and distorted architecture (grade 3 appearances), which often persisted after treatment, were most unlikely to be caused by the trauma of earlier biopsies. It also contrasted the persistence of abnormal fibrous tissue in treated neuroblastoma with the speed of resolution of fibrosis in B-precursor acute lymphoblastic leukemia. The hypothesis that such persisting fibrosis implies failure to eradicate all tumor from the bone marrow has not yet been effectively tested. The combination of fibrosis, unidentifiable mononuclear cells and, occasionally, ganglion-like cells also raises the possibility that differentiation may be taking place. Whether some of these cells can revert to aggressive neuroblastoma also remains unknown.

Immunocytochemical and molecular techniques

Accurate staging is most problematic in apparently limited stage disease (stages 1–3) and those rare children with stage 4 disease but without obvious marrow involvement. There have been many studies looking at the potential ability of immunologic tests to increase the sensitivity of detection of metastatic disease.^{122–124} Unfortunately, there have been problems with specificity because one of the early monoclonal antibodies used, NCAM, was positive in osteoblasts and other tumors such as Ewing tumor, PNET, rhabdomyosarcoma, medulloblastoma, retinoblastoma and pinealblastoma. In addition, antibodies used in immunophenotyping leukemic cells, CD10, CD19 and terminal deoxynucleotidyl transferase (TdT) can be positive in other malignant or reactive conditions.¹²⁵ More recently, other monoclonal antibodies have been used, and a study by Swerts and colleagues¹²⁶ has compared flow cytometry and immunocytochemistry in detecting

residual neuroblastoma cells in material found negative by cytomorphologic examination. CD9, CD81, CD56, CD45 and GD2 antibodies were used, and 28 bone marrow (BM) samples, 12 biopsies and three peripheral blood stem cell (PBSC) preparations from 22 patients with neuroblastoma were assessed. Flow cytometric and immunocytochemical analyses showed residual neuroblastoma cells in 4 of the 28 BM samples. One PBSC and 20 BM samples were negative for both assays. Four BM and two PBSC were positive with immunocytochemistry but negative with flow analysis. There was a strong correlation between the two techniques, with immunocytochemistry being more sensitive. However, there are no clinical outcome data available and so the significance of the findings has not been determined.

Molecular tests have been developed targeting the TH gene. TH is the first enzyme in the pathway of catecholamine synthesis and is expressed by neuroblastoma cells. RT-PCR and real-time PCR have been used to examine the expression of TH mRNA in neuroblastoma. A study by Tchirkov and colleagues⁹⁸ looked at the significance of molecular quantification of minimal residual disease in metastatic neuroblastoma. Real-time PCR that allowed quantification of TH mRNA was performed on 165 BM, peripheral blood (PB) and PBSC samples from 30 children, and results correlated with disease status and patient survival. The levels of TH mRNA agreed well with clinical status and were significantly different across the groups, which included samples obtained from patients at diagnosis, after three cycles of chemotherapy, in complete or very good partial remission, and at relapse. Overall survival was significantly worse for patients with >1000 TH copies in BM after initial chemotherapy ($P=0.0075$).

Combinations of techniques may improve accuracy of minimal residual disease detection but will obviously increase expense and complexity. A study by Corrias and colleagues¹⁰⁰ has compared immunocytochemistry with routine cytomorphologic techniques and molecular tests using TH RT-PCR and also has data on outcome. The accuracy of different techniques was studied in 2247 evaluations from 247 patients with neuroblastoma; 561 BMs, 265 PB samples and 69 PBSC were analyzed, and immunocytochemistry using an anti-GD2 antibody gave the most accurate results. Positive results obtained by immunocytochemistry in BM and PB samples taken from stage 1, 2 and 3 patients at diagnosis correlated with an unfavorable outcome. No correlation was found between positive results obtained by immunocytochemistry or TH RT-PCR in BM, PB or PBSC samples from stage 4 patients. Patients who have a negative TH RT-PCR may still have localized deposits in bone marrow, shown using magnetic resonance imaging.¹²⁷

Finally, TH RT-PCR has also been used to determine if PBSC preparations have been contaminated by neuroblastoma cells,^{98,100,128} and to estimate tumor depletion in contaminated autografts using CD34 selection.⁹⁸ Positive results have correlated with a less favorable outcome in several

studies,^{98,128} with Tchirkov and colleagues,⁹⁸ showing that in 57% of cases PBSC harvests were contaminated by neuroblastoma cells, and at the level of > 500 TH copies survival was significantly decreased ($P=0.003$).

Molecular and immunocytochemical tests are not yet routine, nor do they replace careful, expert scrutiny of bone marrow aspirates and trephines. However, they may find a place in conjunction with conventional techniques, for instance in those with apparently localized disease and for detecting disease in PBSC preparations.

Soft tissue sarcomas

Soft tissue sarcomas account for approximately 7% of malignant neoplasms in children, and include rhabdomyosarcoma, which is the commonest, and the Ewing family of tumors, namely Ewing sarcoma, primary neuroectodermal tumor of bone (PNET), soft tissue Ewing, and Askin tumor of the chest wall. Major progress in the accuracy of diagnosis and classification has been made by the identification of specific, recurring genetic alterations t(2;13)(q35;q14) and t(1;13)(p36;q14) in alveolar rhabdomyosarcomas, and t(11;22)(q24;q12) or t(21;22)(q22;q12) for the Ewing tumor family.¹²⁹

Rhabdomyosarcoma

Marrow infiltration at presentation is thought to occur in 25–30% of cases.^{105,130} Many have been thought to be embryonal rhabdomyosarcoma but more recent reports have been predominantly of alveolar rhabdomyosarcoma.

There may have been some difficulty with inaccurate diagnosis, but this has improved over the past 30 years with the addition of molecular techniques (see above). Disseminated alveolar rhabdomyosarcoma has in the past often been misdiagnosed as a hematologic or other form of cancer,^{131–133} particularly those cases with occult primary tumors.

Rhabdomyosarcoma may be the commonest cause of disseminated nonhematopoietic cancer of children and adolescents in whom the primary tumor is hard to find, and although occasionally neuroblastoma can present in this way, there are the biochemical markers of elevated urinary catecholamine metabolites to help make the diagnosis.

Cytology

The cytologic features of alveolar rhabdomyosarcoma in the marrow are characteristic,^{131,134} and along with the bone marrow histology are virtually diagnostic.¹³⁴ The study by Reid *et al.*¹³⁴ described features of alveolar rhabdomyosarcoma, and reported no cases of bone marrow invasion by embryonal rhabdomyosarcoma. In my experience, only one case of infiltration was due to embryonal rhabdomyosarcoma, and this was seen in the bone marrow trephine only. Appearances of marrow infiltration echo those described elsewhere,^{131,134} including extensive invasion accompanied by bone marrow failure, and as noted can resemble leukemia. However, there

is a tendency for the cells to clump, particularly noted in the trails of the bone marrow smears, but the clumping is not as prominent as in neuroblastoma, Ewing tumor or PNET. Vacuolation of cytoplasm is prominent, often peripherally placed in a rim of cytoplasm that stains darker than the main body of cytoplasm. The vacuoles may coalesce into elongated lakes, and on staining with periodic acid–Schiff (PAS) there is a striking positivity often corresponding to the position of the vacuoles. Multinucleate cells are commonly seen, including giant cells with up to 10 nuclei per cell, and these may be the result of tumor cells having ingested other tumor cells. The tumor cells may also ingest red cells or erythroblasts. However, this is not unique and has been seen in some cases of Ewing tumor as well as in histiocytic malignancy, monocytic leukemia and breast cancer, and therefore it is not specific for rhabdomyosarcoma. Nonetheless, this combination of cytologic features is characteristic of rhabdomyosarcoma and should suggest the correct diagnosis. Bone marrow aspirates can also be analyzed for the molecular markers t(2;13)(q35;q14) and t(1;13)(p36;q14) specific to this tumor. There is some recent work indicating that rhabdomyosarcoma cells express chemokine and tyrosine kinase receptors that respond to stromal-derived factor and hepatocyte growth factor, modulating the metastatic behavior of the cells by directing them to the bone marrow and lymph nodes.¹³⁵

Bone marrow histology

Reid and colleagues¹³⁴ give a thorough description of the bone marrow histologic features of metastatic rhabdomyosarcoma. This is important for two reasons: the first is that bone marrow may provide the only tissue for diagnosis if the site of the primary is unknown; the second is the prognostic importance, several studies having shown that bone marrow infiltration by rhabdomyosarcoma is associated with a significantly worse outcome.¹³⁶ Alveolar patterns of infiltration were found that are so characteristic that, once recognized, the correct diagnosis may be made even in children in whom no primary tumor can be found. Supportive evidence may also be found in the almost universal expression of desmin by the tumor cells and by detecting the translocation t(2;13). The overall rate of marrow infiltration in this study was similar to those reported elsewhere but all cases had alveolar patterns of bone marrow histology. This is different from other centers, in which embryonal rhabdomyosarcoma features strongly; for example, Ruymann *et al.*¹³⁰ reported that 12 of 30 cases with bone marrow infiltration had the embryonal subtype. This discrepancy may reflect the relatively small number of published cases investigated by both aspirates and trephine biopsies and the small number of cases reported from individual centers. Further experience of trephine biopsies and more uniform diagnostic criteria, with the help of other discriminators such as molecular markers, within the entire field of small round-cell cancers are needed to build up an

accurate picture of the frequency of bone marrow dissemination in rhabdomyosarcoma.¹³⁷

Ewing tumor and primitive neuroectodermal tumor

The bone marrow is infiltrated in approximately 22–38% of cases of Ewing tumor and PNET.^{138,139} Over half of those with bone marrow infiltration have evidence of metastases elsewhere. Studies emphasize the focal nature of bone marrow metastases and, as in neuroblastoma, highlight the need for examination of more than one site with both aspirates and biopsies as results from each investigation are often not concordant. Immunocytochemical stains have thus far been disappointing as an aid to diagnosis, apart from detecting the apparent lack of desmin positivity. However, molecular studies to detect the translocation t(11;22) or its rarer variant t(21;22), expressing the transcripts *EWS-FLI1* and *EWS-ERG* respectively, have shown that in apparently localized disease, bone marrow micrometastases and circulating malignant cells can be detected, and predict poor outcome and systemic relapse.^{101,140} Outcome of stem cell transplants may also be predicted by detection of malignant cells, both in the harvest and in the patient posttransplant.¹⁴¹

In general, tumor infiltration is less extensive than in neuroblastoma. The cells are approximately twice the size of small lymphocytes, can occur in clumps or smaller aggregates, and occasional rosettes are seen.¹¹⁰ Cells may be vacuolated with a Burkitt lymphoma-like pattern and distinct from rhabdomyosarcoma. The PAS reaction is often positive, being finely dispersed or showing block positivity. Phagocytosis of other cells is occasionally seen. Histology shows patchy infiltration with irregular groups of cells in a fibrous stroma; desmin stains are negative.

PNET is even rarer than Ewing sarcoma and hematologists/pathologists in any single center will rarely see this tumor infiltrating bone marrow. There are few descriptions of such cells but it appears that they may form clumps readily and have striking vacuolation, sometimes even more so than in Ewing tumor.¹³⁹

Other tumors

There can scarcely be a cancer of childhood that has not been found to infiltrate bone marrow at some stage of the disease. No single center will ever see enough cases to obtain a comprehensive and reliable in-house background of experience. Instead, occasional examples in atlases of hematology, the handing down of knowledge from hematologist to hematologist, and the opinions of other experienced microscopists must be relied upon. Involvement of the bone marrow by osteosarcoma, retinoblastoma, malignant germ-cell tumor and medulloblastoma has been reported. Disseminated osteosarcoma may present a virtually diagnostic picture of a marrow that is very difficult to aspirate and a trephine showing tumor

cells embedded in a matrix of osteoid. The few aspirated cells should stain strongly positive for alkaline phosphatase.

Other tissues

Samples of tissue in fluids other than blood or bone marrow are often examined in hematology laboratories, due to the expertise in preparation of these fluids. Techniques include cell counting, cytospin preparation, special stains and flow cytometry. CSF, pleural effusions, ascites fluid and joint fluid may all be examined by a hematologist. Cytospin preparations can result in significant artifact, including a "flattening" effect and the displacement of granules to one side of the cell. In addition, normal nonhematopoietic cells present in, for example, pleural fluid or ascites can look malignant. Such cells are usually mesothelial lining cells or reactive macrophages. Where the fluid is infiltrated with malignant hematopoietic cells, the diagnosis is not usually too difficult as the mesothelial cells will be in the minority and supplementary immunophenotypic and cytogenetic analysis can be performed. However, problems in correctly identifying mesothelial cells may arise if nonhematopoietic malignant infiltration is suspected, not least because the number of malignant cells in effusions or ascites in such cases is often much lower than in cases of lymphoblastic or Burkitt lymphoma, and mesothelial cells are thus relatively more prominent; there may also be a scattering of lymphoid cells. Immunophenotypic analysis of these lymphoid cells is unhelpful and, at worst, confusing. Most will be T cells and as immunophenotyping does not discriminate between monoclonal or polyclonal proliferation, this might mislead the unwary into diagnosing a lymphoid malignancy. Molecular studies to show polyclonal T-cell infiltrates may not be readily available in many centers and may take too long to be immediately helpful to clinicians. Nonhematopoietic tumor cells have a tendency to clump but otherwise have no characteristic cytologic features. The pattern of vacuolation may be helpful in rhabdomyosarcoma but collective experience of such infiltration is not reported. Morphologic expertise is of great importance. Just as consultation with a histopathologist can be very helpful with interpretation of trephine specimens, so can discussion with an experienced cytopathologist in such cases.

Brain tumors and retinoblastoma are well known to involve the CSF although rarely at presentation (<1% of low-stage cases).¹⁴² If extraglobular progression is found after enucleation, or other signs or symptoms of central nervous system involvement are present, both bone marrow and CSF examination should be carried out.

Conclusions

There are few descriptions of peripheral blood, bone marrow

and other body fluid abnormalities in children with non-hematopoietic cancer. Reports of results with immunocytochemical and molecular techniques are much more common, but comparison with morphologic and histologic findings is not always made. It is tempting to equate positive results using the newer, possibly more sensitive techniques with clinical significance but more studies are needed to evaluate specificity, sensitivity and prognostic potential. These techniques are complex and expensive and are only available in a few specialized centers. It is therefore essential that they do not replace the conventional diagnostic and staging assessment of nonhematopoietic tumors. However, it is also incumbent upon hematologists to set diagnostic and investigative standards through collaboration with other centers and networks and to be rigorous in their description and recording of findings in this rare set of tumors.

Acknowledgments

I would like to thank Annette Weddell, data manager at the Royal Hospital for Sick Children, Edinburgh, and Jennifer Ferguson at the Royal Hospital for Sick Children, Glasgow, for retrieving the peripheral blood and bone marrow data on patients with nonhematopoietic tumors.

Lysosomal storage disorders

Brad T. Tinkle and Gregory A. Grabowski

Introduction

The lysosomal storage disorders (LSDs) are a group of more than 40 different diseases, the majority of which are caused by a deficiency of a lysosomal enzyme (Table 36.1). Most result from single gene mutations that alter an enzyme's amino acid sequence. However, several LSDs result from gene deficits that alter posttranslational modification of lysosomal enzymes with consequent defects in multiple enzymes. The pathogenesis of the LSDs derives from an inability to adequately degrade normal metabolites within lysosomes. The particular metabolites accumulate to abnormal levels (i.e., stores) within a variety of tissues or cell types giving rise to the clinical heterogeneity.

The incidence of LSDs, as a group, is roughly 1 in 7000 to 1 in 9000.^{1,2} All but two LSDs are autosomal recessive. Thus, family histories are usually not informative. Fabry disease and mucopolysaccharidosis type II are X-linked, and familial recurrence is likely. The rarity and clinical variability of the LSDs makes recognition challenging and underdiagnosis likely. Moreover, essentially all LSDs manifest in childhood, thereby placing the pediatrician and/or pediatric hematologist at the cutting edge of their medical care. For many LSDs, an abnormal peripheral blood smear and/or characteristic bone marrow findings can be the first clue to diagnosis.

The significant morbidity and/or mortality associated with each LSD and the development of effective cell and enzyme replacement therapies have made recognition and accurate diagnosis essential. The marked clinical variability and, in some, phenotypic similarity to other LSDs makes differentiation among the LSDs challenging even for experienced physicians. For example, the mucopolysaccharidoses have significant clinical similarities including characteristic bony abnormalities (dysostosis multiplex), hepatosplenomegaly, neurologic impairment and coarse facial features. Although most of the LSDs have been characterized at the biochemical

and genetic levels, selecting the specific biochemical or genetic test can be daunting. Clinical insight can guide the selection of the proper tests to expedite the diagnosis. Fortunately, detailed history, physical examination, and a few simple tests can significantly focus the differential diagnosis.

Many patients afflicted by an LSD will present to the pediatric hematologist with hypersplenism, thrombophilia, anemia, and/or unusual bony abnormalities on radiography. Inclusion bodies within white blood cells or their precursors are observed in several of the LSDs, making a peripheral blood smear examination highly useful (Table 36.1). The cells of interest are best observed in the tail of the smear. Using standard staining methods, vacuolation may be present in lymphocytes or monocytes, and careful examination of the neutrophils and eosinophils can reveal typical inclusion bodies (e.g., Alder-Reilly bodies). Lymphocytic vacuolations are typically clear and well demarcated and can occur as small or large vacuoles of variable number. Monocyte vacuolation is best appreciated in smears from anticoagulated blood. Examination under polarized light may also be helpful and can reveal birefringent storage material. Additional stains or ultrastructural examination are not very useful in narrowing the diagnostic list but can be used as a supplement if initial testing does not define the LSD.

Bone marrow aspirates can be equally revealing and, indeed, may be essential in guiding further work-up. In the absence of a diagnostic peripheral smear (e.g., hereditary spherocytosis), children presenting with cytopenias or asymptomatic splenomegaly require a bone marrow biopsy with marrow aspiration to exclude infection, malignancy, or a LSD. Bone marrow aspirates for LSDs are best prepared from anticoagulated marrow samples as they are easy to spread, provide excellent cell type recognition, and cellular contents of lipids, carbohydrates and enzymes are preserved. Several stains to characterize storage materials should be considered including periodic acid-Schiff (PAS) for carbohydrates, lipid stains such as luxol fast blue and Sudan black, alcoholic basic

Table 36.1 The various types of lysosomal storage disorders and the characteristic cellular attributes.

Disease	Eponym/synonym	Enzyme deficiency/protein function	Characteristic cell types
Aspartylglucosaminuria		Aspartylglucosaminidase	Small lymphocytic vacuoles
Cholesteryl ester storage disease	Wolman disease	Lysosomal acid lipase	Foamy macrophage (rare); lymphocytic lipid inclusions; sea-blue histiocytes (rare)
Cystinosis		Lysosomal cystine transport protein	Cystine crystals within foam cells
Fabry disease	Fabry disease	α -galactosidase A	Foamy macrophages
Farber lipogranulomatosis	Farber disease	Acid ceramidase	Foamy macrophages
Fucosidosis		α -L-fucosidase	Foamy macrophages with hemophagocytosis; small lymphocytic inclusions; vacuolated plasma cells
Galactosialidosis types I and II		Protective protein for β -galactosidase and neuraminidase	Foamy macrophages (rare); vacuolated lymphocytes
Gaucher disease types I, II and III	Gaucher disease	Glucocerebrosidase	Gaucher cell
Globoid cell leukodystrophy	Krabbe disease	Galactocerebrosidase	
Glycogen storage disease II	Pompe disease	Acid α -glucosidase	Lymphocyte glycogen inclusions
G _{M1} gangliosidosis types I, II and III	Landing disease	β -galactosidase	Foamy macrophages (rare); coarsely vacuolated lymphocytes; abnormal granules of the eosinophils
G _{M2} gangliosidosis type I	Tay–Sachs disease	β -hexosaminidase A	
G _{M2} gangliosidosis type II	Sandhoff disease	β -hexosaminidases A and B	Foamy macrophages; vacuolated lymphocytes
G _{M2} gangliosidosis type AB	Tay–Sachs disease, AB variant	G _{M2} -activator	
α -mannosidosis types I and II		α -mannosidase	Foamy macrophages; vacuolated lymphocytes and plasma cells
β -mannosidosis		β -mannosidase	
Metachromatic leukodystrophy	Late infantile, juvenile, and adult forms	Arylsulfatase A	
Metachromatic leukodystrophy	Adult metachromatic leukodystrophy	Saposin B	
Mucopolidosis type I	Sialidosis types I/II	Neuraminidase/sialidase 1	Foamy macrophages; vacuolated lymphocytes; finely granulated neutrophils
Mucopolidosis types II and III	I-cell disease	<i>N</i> -acetylglucosamine-1-phosphotransferase	Small lymphocytic inclusions; vacuolated plasma cells
Mucopolidosis type III	Pseudo-Hurler polydystrophy		
Mucopolidosis type IV	Pseudo-Hurler polydystrophy	Phosphotransferase γ -subunit	Foamy macrophages; vacuolated plasma cells
Mucopolysaccharidosis type I	Hurler, Hurler–Scheie and Scheie syndromes	Mitochondrial NADH dehydrogenase 5	Gasser cells (few); Alder–Reilly bodies
Mucopolysaccharidosis type II	Hunter syndrome	α -L-Iduronidase	Gasser cells
Mucopolysaccharidosis type IIIA	Sanfilippo syndrome		Gasser cells; vacuolated lymphocytes
Mucopolysaccharidosis type IIIB	Sanfilippo syndrome	Iduronate sulfatase	Gasser cells
Mucopolysaccharidosis type IIIC	Sanfilippo syndrome	Heparan <i>N</i> -sulfatase	Gasser cells
Mucopolysaccharidosis type IIID	Sanfilippo syndrome	α - <i>N</i> -acetylglucosaminidase	Gasser cells
Mucopolysaccharidosis type IVA	Morquio syndrome	Acetyl-CoA: α -glucosaminide acetyltransferase	Foamy macrophages; vacuolated lymphocytes; finely granulated neutrophils
Mucopolysaccharidosis type IVB	Morquio syndrome	<i>N</i> -acetylglucosamine 6-sulfatase	Gasser cells
Mucopolysaccharidosis type VI	Maroteaux–Lamy syndrome	Galactosamine-6-sulfatase	Gasser cells; Alder–Reilly bodies
Mucopolysaccharidosis type VII	Sly syndrome	β -Galactosidase	Gasser cells; Alder–Reilly bodies; lymphocytic vacuoles
Mucopolysaccharidosis type IX		Arylsulfatase B	Gasser cells; Alder–Reilly bodies
Multiple sulfatase deficiency	Mucosulfatidosis	β -glucuronidase	Gasser cells; Alder–Reilly bodies
Neuronal ceroid lipofuscinosis (NCL), CLN1	Santavuori disease	Hyaluronidase	Alder–Reilly bodies
Neuronal ceroid lipofuscinosis, CLN2	Jansky–Bielschowsky disease	Sulfatase modifying factor 1	Lymphocyte granular osmiophilic deposits
Neuronal ceroid lipofuscinosis, CLN3	Batten disease	Palmitoyl-protein thioesterase 1	Curvilinear lymphocyte inclusions
	Vogt–Spielmeier disease	Tripeptidyl-peptidase 1	Lymphocyte inclusions
Neuronal ceroid lipofuscinosis, CLN5	Late infantile NCL, Finnish variant	Protein function not known ¹⁵²	
Neuronal ceroid lipofuscinosis, CLN6	Late infantile NCL, early juvenile variant	Protein function not known ¹⁵³	Curvilinear lymphocyte inclusions
Neuronal ceroid lipofuscinosis, CLN8	Northern epilepsy	ER-resident protein of unknown function ¹⁵⁴	Curvilinear lymphocyte inclusions
Niemann–Pick disease types A and B	Niemann–Pick disease	ER-resident protein of unknown function ¹⁵⁵	
Niemann–Pick disease type C1	Niemann–Pick disease	Acid sphingomyelinase	Foamy macrophages; sea-blue histiocytes
	Niemann–Pick disease	Niemann–Pick C1 protein	Foamy macrophages; occasional coarsely vacuolated lymphocytes; sea-blue histiocytes
Niemann–Pick disease type C2	Niemann–Pick disease	Epididymal secretory protein	Foamy macrophages; occasional coarsely vacuolated lymphocytes; sea-blue histiocytes
Pyknodysostosis		Cathepsin K	
Schindler disease types I and II	Schindler disease/Kanzaki disease	α - <i>N</i> -acetylglactosaminidase	Small vacuoles in leukocytes
Sialic acid storage disease	Sialuria, Salla disease	Sialin	Foamy macrophages with hemophagocytosis; small lymphocytic inclusions

ER, endoplasmic reticulum.

Table 36.2 Effective therapies for the lysosomal storage disorders.

Storage disorder	HSCT ⁴	ERT	Substrate reduction ¹⁵⁶
Aspartylglucosaminuria	Not effective		
Fabry disease		+	
Farber disease	Effective (few cases reported)		
Gaucher disease type I	Restricted use	+	+
Gaucher disease type II	Not effective		
Gaucher disease type III	Somatic improvement	+	
Hurler disease (MPS I)	Somatic improvement	+	
Hunter disease (MPS II)	Somatic improvement	+*	
I-cell disease	Effective (few cases reported)		
Krabbe disease	Effective		
α -mannosidosis	Clinical improvement		
Maroteaux–Lamy syndrome (MPS VI)	Clinical improvement (few cases reported)	+*	
Metachromatic leukodystrophy	Effective in some		
Morquio disease	Visceral improvement		
Niemann–Pick type A	Not effective		
Niemann–Pick type B	Effective		
Niemann–Pick type C	Somatic improvement		
Pompe disease		+	
Sandhoff disease			+
Sanfilippo (MPS III)	Not effective		
Sly disease (MPS VII)	Effective (few cases reported)		
Tay–Sachs disease			+
Wolman disease	Effective (few cases reported)		

* In clinical trials.

HSCT, hematopoietic stem cell transplant; ERT, enzyme replacement therapy.

fuscin, acid phosphatase and ferric hematoxylin for sphingomyelin. Polarized light microscopy may enhance the characterization of the storage material.

Management of the various LSDs is disease specific and includes hematopoietic stem cell transplantation (HSCT), enzyme reconstitution and substrate depletion approaches (Table 36.2). Supportive therapies continue to have essential roles. HSCT has specific therapeutic roles in selected LSDs, but the results are disease and organ-system specific, and timing of engraftment is critical.^{3–5} The theory for use of HSCT suggests that the normal levels of lysosomal enzymes in derivatives of hematopoietic stem cells could supply the missing enzyme to deficient cells by secretion and reuptake. Thus, the lysosomal enzymes released within tissues from donor white blood cells would be taken up by the deficient host cells, and then delivered to the intracellular site of action (i.e., the lysosome). Consequently, the abnormally accumulated substrates diminish in serum, tissues and other bodily fluids. Improvement in hepatosplenomegaly and cytopenias is universal. Prevention, stabilization or improvement of neurologic function is variable and is highly dependent on the type of disease, severity, age of onset, and the timing of the HSCT as well as attendant complications.⁶ Newer

treatment modalities such as enzyme replacement therapy (ERT) and substrate inhibition are available for a limited number of LSDs but can effect substantial improvement in morbidity.⁷ Comprehensive reviews of the LSDs are available.⁸ Here, highlights of the hematologic findings in various LSDs and their therapies are presented.

Sphingolipidoses

The sphingolipidoses derive their name from the accumulation of complex lipids containing ceramide. Ceramide is composed of a sphingosine backbone covalently linked to fatty acid acyl chains of variable length, hence sphingolipid. Ceramide, an amino alcohol, can have covalent links to phosphate (sphingomyelin), glycoside (glycosphingolipids), or sulfated glycoside (sulfoglycosphingolipids) groups. The stepwise degradation of these sphingolipids occurs in the lysosomal compartment. Defective enzymatic activity at each step in this degradation pathway leads to accumulation of specific by-products and the distinctive storage material and phenotype. There are 10 well-recognized sphingolipidoses, of which only Gaucher disease and Niemann–Pick disease

variants have significant frequencies and well-characterized hematologic findings.

Gaucher disease

Gaucher disease is the most common LSD and has an incidence in the general population of 1 in 57 000 to 1 in 86 000.^{1,2} This disease is pan-ethnic, but the prevalence varies among different ethnic and demographic groups. Among Ashkenazi Jews, the prevalence is approximately 1 in 855, whereas among non-Jews in the Netherlands, a prevalence of 1 in 325 000 was found.⁹ Gaucher disease results from the defective activity of acid β -glucosidase (glucocerebrosidase) and consequent accumulation of glucosylceramide (glucocerebroside) in tissue macrophages. Storage is most evident in tissue macrophages of the liver, spleen, bone marrow and lung.

Gaucher disease has been divided into three clinical phenotypes, which are distinguished by the absence (type 1) or presence and severity (types 2 and 3) of central nervous system (CNS) disease (see below). Diagnosis and classification of Gaucher disease is based on clinical features and established by biochemical or genetic testing. Acid β -glucosidase analyses are sensitive, generally available, and usually are conducted on leukocytes or cultured fibroblasts. The enzyme deficiency is generic and is the preferred method of diagnosis of affected patients. Carrier testing by enzyme analysis is not reliable. Genetic testing by allele-specific or total gene sequencing is available. More than 200 mutations have been identified. Genotype–phenotype correlations are limited, but may be useful in differentiating among the types.^{10–14} Indeed, there is a continuum of clinical features between the phenotypes, particularly types 2 and 3, that is quantitative, namely more or less acute or progressive CNS disease. Between types 2 and 3, and type 1, the distinguishing feature is categorical, i.e., type 1 is defined as the absence of primary CNS involvement by Gaucher disease. This is not age dependent in that type 1 (previously termed adult) Gaucher disease can present at any age from early childhood to late adulthood.¹⁵ The detection of a N370S allele in an affected patient has significant clinical utility because it is prognostic of type 1, nonneuronopathic Gaucher disease, in all cases to date.

In all variants of Gaucher disease, a distinctive hematologic feature is the presence of Gaucher cells in bone marrow and other tissues (Fig. 36.1). Gaucher cells are large tissue storage cells of macrophage lineage. The cytoplasm of these cells stains pale gray-blue with Giemsa, and they have eccentrically placed nuclei due to numerous large vacuoles.¹⁶ The storage bodies are loose in appearance, stain weakly positive with PAS, are strongly acid phosphatase positive, and stain pale gray with lipophilic stains, namely Sudan black. These cells are not “foamy” in appearance. Morphologically similar “Gaucher-like” cells are observed in chronic granulomatous disease, thalassemia, multiple myeloma, Hodgkin disease,

Fig. 36.1 Gaucher cell in a bone marrow aspirate of a patient with Gaucher type 1 disease (Giemsa stained). Note the “wrinkled tissue paper” appearance and eccentrically placed nucleus.

lymphoma, AIDS, and acute lymphoblastic leukemia but can be distinguished readily.^{9,17} The Gaucher cells can be sufficiently abundant (near total replacement) in bone marrow to interfere with normal hematopoiesis in some individuals. Myelofibrosis and/or bone marrow failure occurs infrequently.^{18,19}

Gaucher disease type 1 (nonneuronopathic)

Gaucher disease type 1 is the most common variant. In the International Collaborative Gaucher Group Registry, type 1 disease accounts for 90% of all cases.²⁰ The age of onset can vary from childhood to late adulthood, and the clinical severity varies from severe to indolent. Most data derive from affected patients of European ancestry and are heavily influenced by the ascertainment bias of the Ashkenazi-Jewish phenotypes. However, the clinical spectrum of type 1 variants is becoming increasingly broad with descriptions of patients from other demographic regions.

The most common presenting finding in affected patients is asymptomatic splenomegaly.^{15,20,21} Derivative findings can include bleeding due to thrombocytopenia as a result of splenic sequestration, low-grade chronic consumptive coagulopathy secondary to intrasplenic activation,²² bone marrow infiltration, and factor XI deficiency among Ashkenazi Jews.²³ In the pediatric population, anemia and thrombocytopenia are the most common hematologic findings.^{24,25} Anemia is usually mild and due to splenic sequestration and bone marrow involvement. Also, many patients have an unexplained macrocytosis.

The skeletal manifestations include bone marrow infiltration with Erlenmeyer flask deformity from bone marrow expansion (50–61%), generalized bone mineral loss (universal), infarction (16–35%), and bone pain (20–66%).^{25–29} The resultant osteopenia/osteoporosis and infarction can lead to pathologic and/or osteoporotic fractures accounting for

some bone pain. About 50% of affected patients experience one or more episodes of bone crises characterized by fever, an increased sedimentation rate, and excruciating localized pain. Such episodes are more frequent among adolescents and young adults. The most frequently involved sites are along the femurs. These bone crises mimic osteomyelitis, which may need to be excluded by biopsy and culture.³⁰ About 50% of untreated affected children have growth retardation and shorter than expected final heights.^{31,32}

Hepatosplenomegaly can be massive, with abdominal distension and pain (Fig. 36.2). The volumetric increase in these organs, particularly splenomegaly, can cause early satiety, nausea, dyspareunia and ligamentous pain. Hypersplenism develops in the majority. Splenic sizes can range from four to more than 70 times normal predicted volumes. Splenic infarction is common and occasionally presents acutely with pain, rigid abdomen, fever, metabolic acidosis and hyperuricemia. Splenic nuclide scans are helpful in differentiating old (cold) versus new (surrounding hot) infarcts in the presence of an acute abdomen. Hypersplenism with sequestration of platelets and red blood cells can lead to thrombocytopenia and anemia. Concurrent iron, folate, or vitamin B₁₂ deficiencies should be excluded. Clinically significant liver dysfunction due to Gaucher disease alone is uncommon, despite significant hepatomegaly in 79% of affected patients.¹⁵ Mild, persistent elevation of aspartate aminotransferase (also called serum glutamate oxaloacetate transaminase), alanine transaminase (also called serum glutamate pyruvate transaminase), and γ -glutamyl transferase can be found frequently.

Recommendations from expert panels are available for evaluation and monitoring of treated or untreated Gaucher disease type 1 patients.^{20,24} Symptomatic management of Gaucher disease type 1 involves addressing concurrent complications such as the portal and pulmonary hypertension, as well as the bone manifestations. The skeletal manifestations are frequent and require pain management, physical therapy and orthopedic surgery. Concomitant ERT and bisphosphonate treatment improves bone mineral density, but has minor effects on focal cortical thinning of the long bones with significant marrow involvement.^{33,34} Splenectomy, once the mainstay of treatment for the hypersplenism, now has utility limited to acute intervention for severe hypersplenism or infarction in the era of ERT.^{35–37} HSCT should cure Gaucher disease type 1, but the attendant morbidity and mortality have severely limited its use especially given the efficacy and safety of ERT.⁹

ERT for Gaucher disease has been available since 1991.³⁸ The theory of ERT is to reconstitute the lysosomal enzyme levels sufficient to degrade stored substrate and maintain normal cellular metabolism.³⁹ Regular infusions of imiglucerase (Cerezyme, Genzyme Corp, Cambridge, MA) reverses many disease signs and symptoms.^{40,41} The outcomes summary below is based on reports of treatment results from approximately 2000 affected patients.^{20,42} Anemia shows a

Fig. 36.2 Abdominal distension due to massive hepatosplenomegaly in Gaucher disease type 1. Clinical variability is evident among the siblings (aged 16 and 17 years) shown here.

rapid and sustained response within 6 months, eliminating the need for blood transfusions. Platelet counts respond more slowly, but within 12 months, normal platelet counts are achieved in splenectomized patients. This may take up to 5 years of continuous ERT in the nonsplenectomized patient. Spleen and liver sizes show major decreases within the first 1 to 3 years of ERT. Decreased bone pain and less frequent bone crises also occur in the majority of patients.⁴³ Normalization of growth rates and catch-up growth occurs in children with growth retardation.⁴⁴ Patients generally report greater

energy, less pain, reduced dyspnea and improved quality of life. Detailed therapeutic goals are available.^{20,35}

An alternative/supplementary approach to ERT is to reduce the flux of the offending substrate (e.g., glucosylceramide) through the lysosomes, by decreasing its synthesis, and therefore its delivery. This has been termed substrate depletion. Inhibitors of glucosylceramide synthase have been used and are approved for restricted use in Europe and the USA. The available agent is miglustat (*N*-butyldeoxynojirimycin, Zavesca), which has been clinically tested with promising results.^{45–49} The agent is approved in the USA for use in affected patients who have medical indications for not receiving ERT.⁵⁰

Gaucher disease type 2 (acute neuronopathic)

Gaucher disease type 2 is a rare variant comprising less than 1% of total cases.^{51,52} This severe, rapidly progressive CNS disease has infantile onset of failure to thrive, organomegaly and neurologic symptoms. Oculomotor apraxia and/or strabismus occur from birth to 3–4 months of age. Opisthotonus, bulbar signs, limb rigidity and seizures develop within 6–7 months. Most infants die within the first 2 years of life, with a mean survival of 9 months.⁵³ No therapeutic intervention has had clear clinical benefit for the CNS disease.⁵⁴

Gaucher disease type 3 (subacute neuronopathic)

The subacute neuronopathic variant, type 3, accounts for about 4–5% of total Gaucher disease in Europe and the USA.²⁰ Several variants of type 3 disease have been delineated and are distinguished clinically by the degree and progression of visceral and CNS manifestations.⁵⁵ Massive visceral disease with rapid progression and relatively static CNS disease or isolated eye findings are predominant in one variant whereas rapid progression of CNS disease with uncontrollable myoclonic seizures characterizes another variant. Additional variants with calcification of the aortic root and valves, and variable hydrocephalus have been described in Japan and the Middle East, but appear pan-ethnically.^{56–61} Neurologic findings include variable presence and progression of decreased mental capacities, oculomotor apraxia, seizures, poor coordination and hypertonicity. Type 3 disease is distinguished from the type 2 by the neurologic manifestations in children > 1 year of age. The variants cannot be differentiated by enzyme testing. L444P homozygosity is highly associated, but not exclusively so, with neuronopathic variants.⁶²

HSCT has improved the visceral disease in type 3 patients, but the effect on CNS resolution is not well established.⁶³ ERT has shown clear benefit for the visceral disease in type 3 patients, but the efficacy for CNS involvement is controversial.⁶⁴ Experimental studies in type 3 with miglustat are ongoing.⁶⁵

Niemann–Pick disease

The group of disorders termed Niemann–Pick disease involves the accumulation of unesterified cholesterol or sphingomyelin in the lysosomes of tissue macrophages and other cell types. This group of diseases has a frequency of about 1 in 130 000.² Types A and B result from deficiencies of acid sphingomyelinase and the accumulation of sphingomyelin. The type C variant was originally thought to be due to sphingomyelinase deficiency but is now known to be the result of a defect in one of two genes involved in lipid/sterol trafficking.^{66–68}

Niemann–Pick disease types A and B represent a clinical continuum due to the degree of acid sphingomyelinase deficiency. Their overall incidence is 1 in 248 000, but may be more frequent in those of Jewish ancestry.^{2,69} The diagnosis is established in suspected patients by the deficiency of acid sphingomyelinase in leukocytes or cultured fibroblasts. The enzyme does not normally occur in plasma. Typically, the enzyme activity is < 5% of normal in type A (NPA), a severe neurologic variant, compared with somewhat higher levels in Niemann–Pick type B (NPB).⁷⁰

In both variants, microcytic anemia can occur late in the clinical course. Peripheral blood smears reveal vacuolated lymphocytes, with the number of cells involved roughly correlated to clinical severity, that is, more in NPA than NPB. Use of special stains reveals a lack of demonstrable sudanophilic lipid or glycogen material. Bone marrow smears demonstrate “foamy” cells with numerous uniform vacuoles, often described as having a “honeycomb” appearance (Fig. 36.3). These “Niemann–Pick” cells are 25–75 µm in diameter, contain a single nucleus, and have a white birefringence unstained. Lipid droplets may appear yellowish under ultraviolet light. In addition, sea-blue histiocytes are often numerous. These macrophages are filled with numerous fine granulations that stain blue with Giemsa-type stains

Fig. 36.3 The honeycomb appearance of the tissue macrophage seen here in the lung of a patient with Niemann–Pick type B (×63).

Fig. 36.4 Sea-blue histiocyte in the bone marrow of a patient with Niemann–Pick type B (×63). Compared with the sea-blue histiocyte seen in Niemann–Pick type C, it has a finer granular appearance.

(Fig. 36.4). The granulations contain ceroid or lipofuscin that has autofluorescence. They exhibit stable sudanophilia and stain positive with PAS. Sea-blue histiocytes are not specific for NPB disease and can be found infrequently in lecithin–cholesterol acyltransferase deficiency,⁷¹ cholesteryl ester storage disease,⁷² myelodysplastic syndromes,^{73–75} and in people receiving total parenteral nutrition.^{76–78} Sudan black staining reveals a reddish birefringence of the lamellar inclusions. Additional staining methods such as the Schultz reaction for cholesterol and ferric hematoxylin for sphingomyelin are positive.⁷⁹ The inclusions are poorly visualized with PAS and acid phosphatase reactions. Similar “foamy” cells are seen in cholesteryl ester storage/Wolman disease, lipoprotein lipase deficiency, and G_{M1} gangliosidosis but can be differentiated on specific staining. Importantly, liver biopsy shows involvement of the Kupffer cells and hepatocytes, unlike Gaucher disease in which storage is restricted to Kupffer cells. Diagnosis of NPA or NPB is based on clinical suspicion, the presence of foamy bone marrow storage cells, and deficient acid sphingomyelinase activity. Genetic testing is available for the three most common mutations, which are present in > 90% of NPA and NPB to date.

Niemann–Pick type A (infantile, acute neuronopathic)

Infants appear normal at birth but may develop prolonged jaundice. More specific findings associated with Niemann–Pick disease present at about 4–6 months of age. These children often manifest poor feeding, failure to thrive, protuberant abdomen, hepatosplenomegaly and cherry-red macula. Psychomotor delays with muscular weakness and hypotonia are noted usually before 6 months of age and follow a progressive neurodegenerative course. Storage in tissue macrophages leads to significant lymphadenopathy and bone marrow involvement, but no bony changes are

noted except osteoporosis. Infiltration of the lung alveoli can be visualized on chest X-ray in the minority of patients. Death commonly occurs before 2–3 years of age. Management is largely supportive.

Niemann–Pick disease type B (nonneuronopathic)

NPB displays a more variable phenotype than type A and, in comparison, represents a less severe clinical variant of acid sphingomyelinase deficiency. Importantly, affected patients lack primary CNS disease, although the presence of ataxia may represent the continuous spectrum between the A and B types.⁶⁹ NPB usually presents later in childhood with a protuberant abdomen due to splenomegaly with or without hepatomegaly. The liver involvement can result in cirrhosis, portal hypertension and ascites.^{80,81} Less than 10% have cherry red macula and most live into adolescence or adulthood. Pulmonary interstitial and alveolar infiltration is extensive as seen by imaging techniques, but pulmonary function deficits are poorly documented (Fig. 36.3). In a few cases, continued infiltration can cause decreased diffusion capacity leading to respiratory compromise in late adolescence or adulthood.^{82–88}

A single NPB patient underwent allogeneic transplantation at 3 years of age with resultant reduction of liver sphingomyelin levels.⁸⁹ The patient did not have CNS involvement at 3 years, but at 16 years posttransplant, a neurodegenerative course led to severe physical and mental deficiencies.⁹⁰

Niemann–Pick disease type C

Niemann–Pick type C (NPC) variations are autosomal recessive disorders of lipid trafficking that have major CNS involvement.⁹¹ The prevalence of this disorder is 1 in 150 000 to 1 in 211 000.^{2,92} It exhibits genetic heterogeneity, with the involvement of two known genes, *NPC1* and *NPC2*. Nearly 95% of the > 100 mutations found to be associated with type C disease reside within *NPC1*.^{92–94} The actions of the *NPC1* and *NPC2* gene products and their respective substrates are not well characterized but the decrease in acid sphingomyelinase and acid β -glucosidase are secondary effects.^{95–97}

Peripheral blood lymphocytes may exhibit coarse vacuolization. Foamy macrophages and sea-blue histiocytes (Figs 36.5 and 36.6) are typically seen on bone marrow aspirate as well as in the liver, spleen, lymph nodes and lungs.⁹⁸ These storage cells have variably sized and shaped vacuoles that have a “ragged” appearance and do not have birefringence or sudanophilia.⁹⁹ The Schultz reaction for cholesterol is strongly positive, as is the acid phosphatase reaction. Diagnosis is made by the demonstration of intralysosomal accumulation of cholesterol by filipin staining or mutation analysis of the *NPC1* or *NPC2* genes; however, most affected patients have private mutations and DNA analysis is not available clinically.

Fig. 36.5 Granulations seen in the bone marrow histiocyte in a patient with Niemann-Pick type C disease are typically very coarse.

Fig. 36.6 In Niemann-Pick type C disease, the sea-blue histiocyte of the bone marrow stains very intensely and may be useful in differentiation from type B.

Clinically, the presentation is highly variable and patients may exhibit signs and symptoms at any time in life.^{92,100–105} More than half will manifest prolonged neonatal jaundice.¹⁰⁶ About 10% develop cholestatic jaundice requiring liver transplantation.^{106–109} Beyond the neonatal period, many affected patients will present with neuropsychiatric symptoms. About 90% of patients have splenomegaly with or without hepatomegaly, but the degree of splenic enlargement is less than in Niemann-Pick A/B disease. Early in the disease course, most will experience behavioral disturbances around school age. Vertical supranuclear gaze palsy, which is seen in nearly all affected individuals, may become evident at this time.⁹² The course worsens with the onset of ataxia, dementia, oromotor dysfunction, dystonia, gelastic cataplexy, violent behavior and/or seizures. The neuropsychiatric features

often worsen with the onset of puberty. Progression to loss of motor control leads to a nonambulatory state. Death commonly occurs in late adolescence or young adulthood from CNS and pulmonary complications.

Therapy is symptomatic treatment.¹¹⁰ Attempts to use liver transplantation and hydroxymethylglutaryl (HMG)-CoA reductase inhibitors failed to show clinical benefit.^{92,107,111} HSCT in an affected 3 year old led to visceral improvement, but the neurologic status continued to decline.¹¹² Because of the secondary accumulation of glucosylceramide and gangliosides, a trial is underway using substrate depletion.¹¹⁰

Mucopolysaccharidoses

The mucopolysaccharidoses (MPS) constitute a group of disorders that result in the lysosomal accumulation of glycosaminoglycans (GAGs) in cells throughout the body. Clinically, MPS patients often present with coarsened facial features, skeletal manifestations, and joint limitations. Keratan, heparan and/or dermatan sulfate in the urine in excessive amounts is highly suggestive of one of the mucopolysaccharide disorders. Distinguishing these MPS variants depends on clinical acumen and enzymatic analyses.¹¹³ The MPS variants are listed in Table 36.1, and those of significant frequency and/or hematologic importance are described in more detail.

Vacuolated lymphocytes with basophilic inclusions (Gasser cells) are observed in all types of MPS although they are more numerous in Sanfilippo syndrome (MPS III) and rare in Hurler syndrome (MPS IH). These inclusion bodies are metachromatic when stained with toluidene blue and are best visualized under oil immersion. Neutrophils can contain coarse basophilic inclusions and Alder-Reilly bodies, which are similar in appearance to toxic granules but are lilac-rose or brown colored (Fig. 36.7). Alder-Reilly bodies are seen in the absence of toxic changes. In Maroteaux-Lamy syndrome (MPS VI) and Sly syndrome (MPS VII), the majority of

Fig. 36.7 Alder-Reilly body seen in the granulocytic series is common among the mucopolysaccharidoses.

neutrophils will contain Alder–Reilly bodies. These cells are also present in multiple sulfatase deficiency, a very rare disease. Bone marrow aspiration is usually not necessary, but Gasser-type cells as single- or multi-nucleated cells may occur. Bone marrow plasma cells demonstrate basophilic inclusions.

Mucopolysaccharidosis type I (Hurler, Hurler–Scheie, and Scheie syndromes)

Mucopolysaccharidosis type I (MPS I) results from the deficiency of α -L-iduronidase and has a prevalence ranging from 1 in 76 000 to 1 in 130 000.^{1,2,114,115} The MPS I variants have a wide clinical spectrum: Hurler (MPS IH, severe), Hurler–Scheie (MPS IH/S, intermediate), and Scheie (MPS IS, attenuated) variants.

MPS IH often presents in the neonatal period with umbilical or inguinal hernias. Within the first year of life, affected patients exhibit coarsening of the facial features, macrocephaly, progressive corneal clouding, an enlarged tongue, hepatosplenomegaly, recurrent upper respiratory infections, deafness and growth deceleration. GAGs deposited in the heart valves and coronary arteries can predispose patients to myocardial infarction.^{116,117} Skeletal manifestations include dysostosis multiplex with anterior hypoplasia of the vertebrae, enlarged diaphyses, hypoplastic epiphyses, and progressive thoracolumbar kyphosis with or without a gibbus deformity.¹¹⁸ Global developmental delay is readily apparent by 12–24 months of age, with an achieved maximal functional age of 2–4 years before progressive deterioration. Life expectancy is less than 10 years of age and demise is usually related to respiratory insufficiency and/or cardiac valvular dysfunction.

Hurler–Scheie syndrome (MPS IH/S) has similar somatic involvement, but little or no neurologic signs or symptoms. MPS IH/S patients present with corneal clouding, joint stiffness, dysostosis multiplex, and deafness usually between 3 and 8 years of age. Mucopolysaccharide accumulation in the heart valve leaflets may necessitate valve replacement. Deposition of mucopolysaccharides in the meninges leads to pachymeningitis cervicalis, which may cause obstructive hydrocephalus. Those with Hurler–Scheie typically have a life expectancy of less than 25 years.

Scheie syndrome (MPS IS) is rare, and typically has onset in childhood with mild coarsening of the facial features and joint stiffness, and preservation of stature and intellect as well as a near-normal lifespan. The decreased range of motion and the development of carpal tunnel syndrome become a functional limitation later in life.¹¹⁹ Patients have corneal clouding and some develop glaucoma, either of which may cause visual impairment. Much like Hurler–Scheie, cardiac valvular deposits can lead to valvular insufficiency requiring valve replacement.¹²⁰

Treatment of MPS I involves symptomatic care as well as HSCT and ERT. These patients benefit from physical and

occupational therapies for joint mobility and adaptations. Progressive tracheal stenosis occurs secondarily to glycosaminoglycan deposition, causing dyspnea and obstructive sleep apnea with many patients benefiting from tracheostomy.

Transplanted patients achieve and maintain normal leukocytic enzyme levels.^{4,121–124} These patients experience improved cardiac function as well as decreased coronary artery and pulmonary accumulations.^{4,116,125} The bony and neuropsychiatric complications remain problematic but promising results suggest steady gains over time.^{6,126,127} Phase III clinical trials of ERT in MPS IH/S and MPS IS have shown marked reduction in urinary GAGs, decreased liver and spleen volumes, increased range of motion, and improved exercise tolerance.¹²⁸ Laronidase (Aldurazyme, Genzyme Corp.) was approved in the USA for use in MPS I in 2003.^{50,129}

Gentamicin is being explored as a potential alternative or addition to ERT for the treatment of MPS IH. The antibiotic action of gentamicin is to inhibit mRNA translation into protein. However, gentamicin can be used to block nonsense-mediated decay, a cellular process used to recognize and degrade mRNA transcripts with premature stop codons. Research trials of gentamicin have restored α -L-iduronidase levels.¹³⁰ Although promising, this type of therapy is only potentially useful for Hurler patients with specific mutations.

Mucopolysaccharidosis type II (Hunter syndrome)

MPS II is an X-linked recessive disorder that occurs in 1 in 34 000 to 1 in 111 000 males and may be more common among people from the Pacific rim as well as those of Jewish descent.^{1,2,114,115,131,132} There is significant phenotypic variation, with the majority of patients having CNS and visceral phenotypes. The deficiency of iduronidate sulfatase results in the accumulation of dermatan and heparan sulfate. The clinical features in the majority of patients are similar to MPS IH, with delayed development, short stature, macrocephaly, hydrocephalus, coarse facial features, hepatosplenomegaly, dysostosis multiplex, limited range of motion, deafness and chronic diarrhea, with the major difference being the lack of significant corneal clouding and a slower, progressive course.¹³³ Life expectancy is 10–15 years in the more severe variant. Survival into the fourth to sixth decades, with normal intellectual function, has been observed.¹³⁴

HSCT has been performed in a number of patients.^{3,6,135–140} Normal leukocytic enzyme levels are readily achieved in engrafted patients with demonstrable decrease in urinary mucopolysaccharides. Histologic clearance of stored substrate occurs in bone marrow and liver. Somatic improvement in the facial features, hepatomegaly, joint contractures and short stature has been seen in the majority with little or no improvement of the dysostosis multiplex or in sensorineural hearing loss. Improved quality of life occurs in many, but there is little neuropsychiatric benefit. Recommendations for

patients to even undergo HSCT are controversial.^{5,140,141} ERT is currently in phase III trials.¹⁴²

Mucopolysaccharidosis type VI (Maroteaux–Lamy syndrome)

Maroteaux–Lamy syndrome results from arylsulfatase B deficiency and has an incidence ranging from 1 in 100 000 to 1 in 1 300 000.^{1,2,114,115} Dermatan sulfate accumulates in most tissues throughout the body. The clinical features are very similar to MPS IH and MPS II syndromes (e.g., short stature, cloudy cornea, hepatomegaly, thickened skin, dysostosis multiplex and stiff joints) except that CNS involvement is not a feature of MPS VI. The cardiac valves can become thickened and calcified leading to pulmonary hypertension and heart failure.¹⁴³ Accumulation can occur in the meninges, as is seen in Hurler syndrome, resulting in obstructive hydrocephalus. Intelligence is usually normal. Death occurs in the second or third decade due to cardiac disease.

HSCT results in metabolic correction and somatic improvement.⁶ There is variable benefit for the musculoskeletal system probably related to the age of transplantation, but no improvement in the corneal clouding.^{3,6,144,145} Significant improvement in cardiac and pulmonary function has been observed.⁴ ERT phase I/II trials are encouraging, based on the observations of reduced urinary glycosaminoglycan levels and clinical improvement.¹⁴⁶

Wolman disease/cholesteryl ester storage disease

Wolman and cholesteryl ester storage disease (CESD) results from lysosomal acid lipase deficiency leading to abnormal fat stores in visceral organs and fat malabsorption. Wolman disease is rare, occurring in 1 in 528 000.² CESD appears less rare, and its true prevalence may be about 1 in 100 000 in some populations.¹⁴⁷ In Wolman disease, onset occurs in the neonatal period with severe failure to thrive, vomiting, diarrhea, hepatosplenomegaly and calcifications of the adrenal glands.¹⁴⁸ Anemia is usually seen in the first 1–2 months of life. Peripheral lymphocytes may contain intranuclear as well as intracytoplasmic vacuoles. Foam cells are usually evident in bone marrow aspirates after the first month of life and are also occasionally seen in the peripheral blood. Diagnosis is based on clinical concerns and confirmed by enzyme assay of lysosomal acid lipase activity in peripheral leukocytes or cultured fibroblasts. Death commonly occurs in the first year of life.

CESD represents a less severe phenotype with significant clinical variability. The most consistent findings are hepatomegaly and hypercholesterolemia.¹⁴⁹ Morbidity is related to liver function, which worsens over time and progresses to cirrhosis and fibrosis. Esophageal varices are uncommon

but have been reported.¹⁴⁹ Bone marrow aspirates are usually normal but foam cells may be seen in those with a moderate–severe phenotype.

Management is symptomatic. Hypercholesterolemia has responded to HMG-CoA reductase inhibitors, cholestyramine and a low-cholesterol diet.^{148,150} This approach has had no significant effects on hepatic progression. At least two Wolman disease patients have undergone HSCT with successful engraftment at several years follow up.^{4,151} These patients demonstrate normal levels of lysosomal acid lipase and show no signs of clinical disease.

Reference values

Paula S. Simpkin and Roderick F. Hinchliffe

The values of many hematologic variables change markedly in the first weeks and months of life and reference data are important to enable proper interpretation of laboratory results, both in infancy and until an age at which adult reference ranges can be applied.

Most reference data are affected to some degree by factors such as racial origin, diet, drug intake and the presence of subclinical illness. Other variables include the methodology and instrumentation used to obtain the data and the method of statistical analysis. Ideally, each laboratory would generate its own reference ranges from the population it serves, but this is rarely if ever practical. However, the following tables and figures (listed below) should prove useful in most circumstances.

Contents

Blood count variables: a summary (birth–18 years) Table 37.1

Hematologic variables in healthy premature infants

Red cell values Table 37.2
 Hemoglobin values Table 37.3
 Neutrophil values Tables 37.4 and Fig. 37.1
 Platelet values Figure 37.2
 Coagulation screening tests, 24–29 weeks' gestation Table 37.5
 Coagulation factor levels, 30–36 weeks' gestation Table 37.6
 Coagulation inhibitor levels, 30–36 weeks' gestation Table 37.7

Hematologic variables in term infants and older children

Red cells and associated variables

In the first year Table 37.8
 In African neonates Table 37.9
 4–18 years Table 37.10
 Reticulocytes in the first year Table 37.11
 Hemoglobins F and A₂ Tables 37.12 and 37.13
 Methemoglobin Table 37.14
 Red cell enzymes Table 37.15
 Red cell morphology in term neonates Figure 37.3
 Iron and transferrin Tables 37.16 and Fig. 37.4
 Serum ferritin Figure 37.5
 Soluble transferrin receptor Table 37.17
 Zinc protoporphyrin Table 37.18
 Vitamin B₁₂, serum and red cell folate Tables 37.19 and 37.20
 Erythropoietin Table 37.21
 Red cell and plasma volume Table 37.22

Red cell survival in term and preterm infants Table 37.23
 Bilirubin Figure 37.6
 Haptoglobin Table 37.24

Normal white cell values

Neutrophils
 At term Figure 37.7
 In the first month Figure 37.8
 Immature forms in the first month Tables 37.25 and Fig. 37.9
 In African neonates Table 37.26
 At 2, 5 and 13 months Table 37.27
 4–19 years Table 37.28

Lymphocytes
 In the first month Table 37.29
 In African neonates Table 37.26
 At 2, 5 and 13 months Table 37.27
 4–19 years Table 37.28
 Subsets Table 37.30

Monocytes and eosinophils
 In the first month Table 37.29
 At 2, 5 and 13 months Table 37.27
 4–19 years Table 37.28

Basophils
 At 2, 5 and 13 months Table 37.27
 4–19 years Table 37.28

Progenitor cells Table 37.31

Other hematologic variables

Normal values for hemostatic variables
 Coagulation factor levels in healthy term infants Table 37.32
 Coagulation inhibitor levels in healthy term infants Table 37.33
 FDP-D dimer levels at birth Table 37.34
 PIVKA-II levels at birth Figure 37.10
 Platelet count throughout childhood Table 37.35
 PFA-100 closure time in children and adults Table 37.36
 Bleeding time in and children and adults Table 37.37

Normal values for immunoglobulins
 IgG, IgA, IgM, neonate to adult Table 37.38
 IgG subclasses, neonate to adult Table 37.39
 IgD, infants and children Table 37.40
 IgE, neonate to adult Table 37.41

Normal values for the ESR in children Table 37.42

Normal isohemagglutinin titers: birth to adult Table 37.43

Table 37.1 Normal blood count values from birth to 18 years.

Age	Hemoglobin (g/dl)	RBC ($\times 10^{12}/l$)	Hematocrit	MCV (fl)	WBC ($\times 10^9/l$)	Neutrophils ($\times 10^9/l$)	Lymphocytes ($\times 10^9/l$)	Monocytes ($\times 10^9/l$)	Eosinophils ($\times 10^9/l$)	Basophils ($\times 10^9/l$)	Platelets ($\times 10^9/l$)

Counts performed on heel-prick blood. MCV, mean corpuscular volume.

Reproduced with permission from Ref. 1.

Table 37.3 Hemoglobin values (g/dl, median and 95% range) in the first 6 months of life in iron-sufficient (serum ferritin ≥ 10 μ g/l) preterm infants.

Age	Birthweight		Birthweight	
	1000–1500 g	Number tested	1501–2000 g	Number tested
2 weeks	16.3 (11.7–18.4)	17	14.8 (11.8–19.6)	39
1 month	10.9 (8.7–15.2)	15	11.5 (8.2–15.0)	42
2 months	8.8 (7.1–11.5)	17	9.4 (8.0–11.4)	47
3 months	9.8 (8.9–11.2)	16	10.2 (9.3–11.8)	41
4 months	11.3 (9.1–13.1)	13	11.3 (9.1–13.1)	37
5 months	11.6 (10.2–14.3)	8	11.8 (10.4–13.0)	21
6 months	12.0 (9.4–13.8)	9	11.8 (10.7–12.6)	21

All infants had an uncomplicated course in the first 2 weeks of life and none received exchange transfusion. Counts obtained from venous and skin-puncture blood.

Reproduced with permission from Ref. 2.

Age (hours)	Mature neutrophils ($\times 10^9/l$)		Immature neutrophils ($\times 10^9/l$)		Immature : total ratio	
	Median (range)	Mean	Median (range)	Mean	Median (range)	Mean
1 ($n = 10$)	4.64 (2.20–8.18)	4.57	0.11 (0–1.5)	0.30	0.04 (0–0.35)	0.09

All values are given as a mean (M) followed by lower and upper boundaries (B) encompassing 95% of the population. All factors except fibrinogen and plasminogen are expressed as unit/ml where pooled plasma contains 1.0 unit/ml. Plasminogen units are those recommended by the Committee on Thrombolytic Agents (CTA). Between 40 and 96 samples were assayed for each value for newborns.

* Values indistinguishable from those of adults.

† Measurements are skewed owing to a disproportionate number of high values. Lower limit, which excludes the lower 2.5% of the population, is given (B).

‡ Values different from those of full-term infants.

PT, prothrombin time; APTT, activated partial thromboplastin time; TCT, thrombin clotting time; vWF, von Willebrand factor; PK, prekallikrein; HMWK, high-molecular-weight kininogen.

Reproduced with permission from Ref 6.

All values are expressed in unit/ml, where pooled plasma contains 1.0 unit/ml. All values are given as a mean (M) followed by lower and upper boundaries (B) encompassing 95% of the population. Between 40 and 75 samples were assayed for each value for newborns.

* Values indistinguishable from those of adults.

† Measurements are skewed owing to a disproportionate number of high values. Lower limit, which excludes the lower 2.5% of the population, is given (B).

‡ Values different from those of full-term infants.

ATIII, antithrombin III; α_2 -M, α_2 -macroglobulin; α_2 -AP, α_2 -antiplasmin; C1E-INH, C1 esterase inhibitor; α_1 -AT, α_1 -antitrypsin; HCII, heparin cofactor II.

Reproduced with permission from Ref. 6.

Table 37.8 Normal hemoglobin (Hb) and red blood cell (RBC) values in the first year of life.

	0.5 months (n = 232)	1 month (n = 240)	2 months (n = 241)	4 months (n = 52)	6 months (n = 52)	9 months (n = 56)	12 months (n = 56)
Hb (g/dl)							
Mean	16.6	13.9	11.2	12.2	12.6	12.7	12.7

MCH (pg)							
Mean	33.6	32.5	30.4	28.6	26.8	27.3	26.8
-2 SD	30	29	27	25	24	25	24
MCV (fl)							
Mean	105.3	101.3	94.8	86.7	76.3	77.7	77.7
-2 SD	88	91	84	76	68	70	71
MCHC (g/dl)							
Mean	31.4	31.8	31.8	32.7	35.0	34.9	34.3
-2 SD	28.1	28.1	28.3	28.8	32.7	32.4	32.1

Values after the age of 2 months were obtained from an iron-supplemented group in whom iron deficiency was excluded. Counts performed on venous blood. MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume. Reproduced with permission from Ref. 7.

Table 37.9 Hemoglobin (Hb), hematocrit (Hct) and red blood cells (RBC) in term African neonates. Values are means \pm 1 SD.

	Number tested	Hb (g/dl)	Hct	RBC ($\times 10^{12}/l$)
Day 1	304	15.6 \pm 2.0	0.450 \pm 0.065	4.00 \pm 0.67
Day 3	261	15.5 \pm 2.1	0.442 \pm 0.062	3.91 \pm 0.61
Day 7	249	14.2 \pm 2.3	0.413 \pm 0.063	3.67 \pm 0.55
Week 2	233	13.1 \pm 1.9	0.391 \pm 0.043	3.45 \pm 0.56
Week 3	145	11.1 \pm 1.8	0.356 \pm 0.050	3.27 \pm 0.47
Week 4	117	10.6 \pm 1.6	0.325 \pm 0.044	3.01 \pm 0.48

Values are lower than those reported in neonates from Europe and North America, and may be intrinsic to this group. Other variables (RBC indices, reticulocytes) do not differ from those in other populations studied. Hb measured as oxyhemoglobin, Hct by centrifuged microhematocrit and RBC by hemocytometry using venous blood.

Summarized from Ref. 8.

Table 37.10 Red cell values (3rd to 97th centiles) derived from 2135 Irish schoolchildren.

Adults, 14–78 years	30	0.11	0.09	0–0.28	27	0.82	0.63	0–1.9

Summarized from Ref. 13.

Table 37.15 Comparison of enzyme activities and glutathione content in newborn and adult red blood cells.

Enzyme	Activity in normal adult RBC in IU/g Hb (mean \pm 1 SD at 37°C) (100%) activity	Mean activity in newborn RBC as percentage of mean in normal adult RBC
Aldolase	3.19 \pm 0.86	140
Enolase	5.39 \pm 0.83	250
Glucose phosphate isomerase	60.8 \pm 11.0	162
Glucose 6-phosphate dehydrogenase	8.34 \pm 1.59	174
WHO method	121 \pm 2.09	
Glutathione peroxidase	30.82 \pm 4.65	56
Glyceraldehyde phosphate dehydrogenase	226 \pm 41.9	170
Hexokinase	1.78 \pm 0.38	239
Lactate dehydrogenase	200 \pm 26.5	132
NADH-methemoglobin reductase	19.2 \pm 3.85 (at 30°C)	Increased
Phosphofructokinase	11.01 \pm 2.33	97
Phosphoglycerate kinase	320 \pm 36.1	165
Pyruvate kinase	15.0 \pm 1.99	160
6-Phosphogluconate dehydrogenase	8.78 \pm 0.78	150
Triose phosphate isomerase	211 \pm 39.7	101
Glutathione	6570 \pm 1040 nmol/g Hb	156

Percentage activity in newborn RBCs compared with mean adult (100%) values is presented with quantitative data from studies on adult RBCs. Newborn data from Ref. 14; quantitative data from Ref. 15.

Reproduced with permission from Ref. 16.

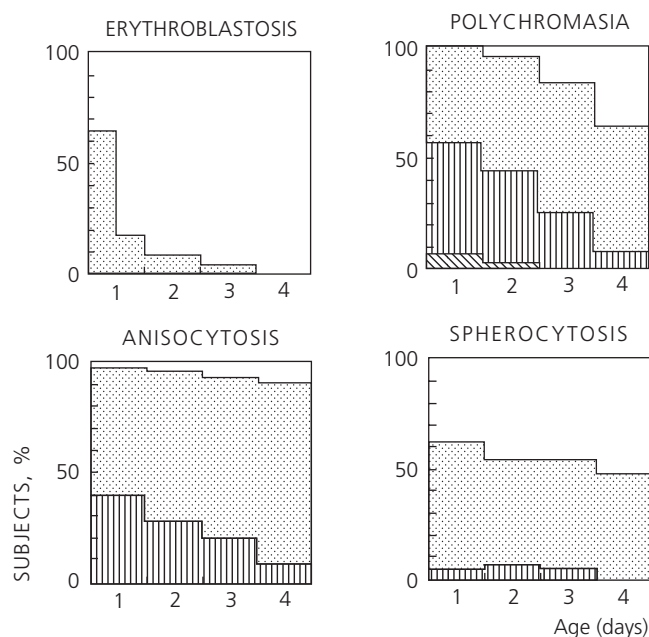

Fig. 37.3 Red blood cell morphology in the first 4 days of life in 138 healthy term infants. Findings are graded from normal (white area) to mild, moderate and marked change (the last only in the case of polychromasia). Erythroblastosis: mild, 1–2 cells/10–15 fields; moderate, 1–5 cells/100 WBC. Polychromasia: mild, 1 cell in every or every other field; moderate, 1–3 cells/field; marked, > 3 cells/field. Anisocytosis: mild, < 5 cells/field differ in size from normal; moderate, the variation is more marked. Spherocytosis: mild, 1 spherocyte in every or every other field; moderate, on average > 1 spherocyte/field. Reproduced with permission from Ref. 17.

Fig. 37.4 Normal values for serum iron and transferrin saturation in individuals with normal values of hemoglobin, mean corpuscular volume, serum ferritin and free erythrocyte protoporphyrin. The heavy horizontal lines indicate the median values, the lower lines the lower limit of the 95% range, and the stippled area an intermediate zone of overlap between iron-deficient and normal subjects. Numbers of subjects are given in parentheses. Reproduced with permission from Ref. 19.

Table 37.16 Values of serum iron, total iron-binding capacity (TIBC) and transferrin saturation from a group of 47 infants.

		Age (months)						
		0.5	1	2	4	6	9	12
Serum iron

	µg/dl	Mean ± SD	191 ± 43	199 ± 43	246 ± 55	300 ± 39	321 ± 51	341 ± 42
Transferrin saturation (%)								
	Median	68	63	34	27	23	25	23
	95% range	30–99	35–94	21–63	7–53	10–43	10–39	10–47

Not all infants were tested on each occasion, and those with Hb < 11 g/dl, MCV < 71 fL or serum ferritin < 10 µg/l were excluded. Reproduced with permission from Ref. 18.

Fig. 37.5 Serum ferritin concentration ($\mu\text{g/l}$, mean \pm 2 SD) in 3819 children aged 6 months to 12 years. Subjects with low hematocrit and evidence of increased iron absorption were excluded. Mean values for boys and girls were similar in each age group and there was no significant difference between blacks, whites and American Indians in age-matched samples. Ferritin measured by a two-site radioimmunoassay. Reproduced with permission from Ref. 20.

Table 37.17 Reference limits for soluble transferrin receptor concentration (mg/l). Values in parentheses are confidence limits.

Age group	2.5% reference limit	97.5% reference limit
6 months to 4 years	1.5 (1.4–1.5)	3.3 (3.1–3.4)
4–10 years	1.3 (1.3–1.4)	3.0 (2.9–3.2)
10–16 years	1.1 (1.1–1.2)	2.7 (2.7–2.8)
>16 years	0.9 (0.9–1.0)	2.3 (2.2–2.4)

Reproduced with permission from Ref. 21.

Table 37.18 Red cell zinc protoporphyrin values ($\mu\text{mol/mol}$ heme, 97.5th percentile) for females and males aged 0–17 years.

Age groups	Males	Females	Number studied	
			Males	Females
0–12 months	64	74	145	203
13–24 months	63	59	605	725
2–5 years	64	57	1926	1822
6–9 years	57	55	522	408
10–17 years	58	62	61	61
Total			3259	3219

Reproduced with permission from Ref. 22.

Table 37.19 Range of serum vitamin B_{12} (pmol/l) and serum folate (nmol/l) levels in childhood.

Age (years)	Vitamin B_{12}		Folate	
	Male	Female	Male	Female
0–1	216–891	168–1117	16.3–50.8	14.3–51.5
2–3	195–897	307–892	5.7–34.0	3.9–35.6
4–6	181–795	231–1038	5.1–29.4	6.1–31.9
7–9	200–863	182–866	5.2–27.0	5.4–30.4
10–12	135–803	145–752	3.4–24.5	2.3–23.1
13–18	158–638	134–605	2.7–19.9	2.7–16.3

Measured by radioimmunoassay in 1486 children (vitamin B_{12}) and 1368 children (folate).

Summarized from Ref. 23.

Table 37.20 Red cell folate levels ($\mu\text{g/l}$, mean and range) in the first year of life.

Age	Term infants ($n = 24$)	Preterm infants ($n = 20$)
Birth	315 (100–960)	689 (88–1291)
2–3 months		164 (26–394)
3–4 months	283 (110–489)	
6–8 months	247 (100–466)	299 (139–558)
1 year	277 (74–995)	

Obtained by microbiologic assay.

Summarized from Refs 24 and 25.

Table 37.21 Range of erythropoietin values (mIU/ml) in childhood.

Age (years)	Male	Female
1–3	1.7–17.9	2.1–15.9
4–6	3.5–21.9	2.9–8.5
7–9	1.0–13.5	2.1–8.2
10–12	1.0–14.0	1.1–9.1
13–15	2.2–14.4	3.8–20.5
16–18	1.5–15.2	2.0–14.2

Measured by enzyme-linked immunosorbent assay (ELISA) in 1122 children. Summarized from Ref. 26.

Table 37.22 Mean red cell, plasma and total blood volume (ml/kg) measurements in children.

Age	Red cell volume	Plasma volume	Total blood volume	Reference
Newborn	(43.4)	41.3	84.7	27
3 days	31*	51*	82*	28
	49 [†]	44 [†]	93 [†]	28
1–7 days	37.9	(39.8)	77.7	29
1 week–30 months	29.5	(48.5)	78.0	29
3–11 months	(32.7)	46.0	78.7	30
3 months–1 year	23.3	(45.4)	68.7	29
1–2 years	24.1	(43.6)	67.7	29
1–3 years	(34.9)	47.9	82.8	30
2–4 years	22.9	(40.0)	62.9	29
3–5 years	(36.0)	48.4	84.4	30
4–6 years	26.7	(42.9)	69.6	29
5–7 years	(34.9)	48.9	83.8	31
6–8 years	23.3	(42.8)	66.1	29
7–9 years	(35.9)	47.8	83.7	30
8–12 years	25.9	(40.8)	66.7	29
9–11 years	(38.0)	48.5	86.5	30
11–13 years	(37.4)	46.4	83.8	30

Data in parentheses calculated from the measured variables.

* No placental transfusion at birth.

† Placental transfusion at birth.

Table 37.23 Red blood cell survival (T_{50} measured by ^{51}Cr) in term and premature infants.

	Number	Range (days)	Mean (days)
Term infants	10	17–25	22.8
	11	21–35	28
Premature infants	6	10–18	15.8
	6	9–20	15.2

Reproduced with permission from Refs 31 and 32.

**Fig. 37.6** Total bilirubin ($\mu\text{mol/l}$) measured in 2099 children. The 3rd, 50th and 97th percentiles and the adult normal range (stippled area) are shown. Reproduced with permission from Ref. 33.**Table 37.24** Serum haptoglobin concentration in preterm and term infants and in adults.

Age	Number tested	5th to 95th percentile reference limits for serum haptoglobin concentration (g/l)
1 month		
Preterm	75	0.12–0.85
Term	96	0.11–1.08
3 months		
Preterm	59	0.21–1.19
Term	96	0.21–1.65
6 months		
Preterm	33	0.39–2.62
Term	57	0.41–3.24
Adults	250	0.35–2.78

Measurements performed by nephelometry.
Summarized from Ref. 34.

Fig. 37.7 Total neutrophil count ($\times 10^9/l$, including band cells and earlier forms) in the first 60 hours of life. Each dot represents a single value and numbers represent the number of values at the same point. Data based on automated leukocyte count and 100-cell differential. Reproduced with permission from Ref. 35.

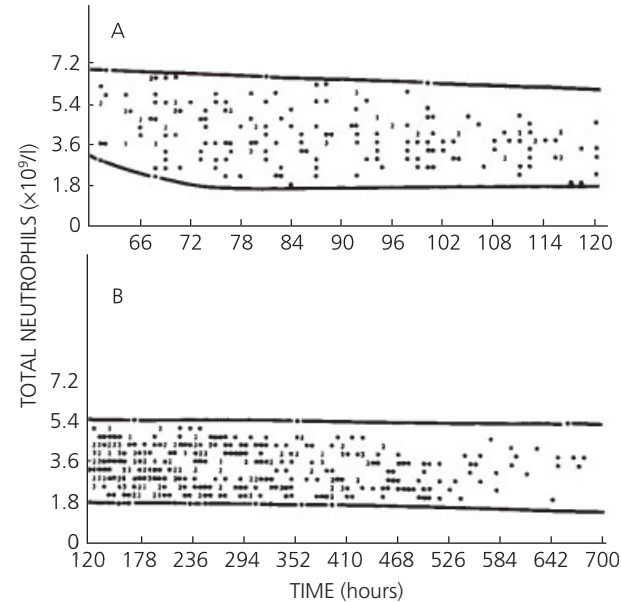

Fig. 37.8 Neutrophil count ($\times 10^9/l$) between (A) 60–120 hours and (B) 120 hours to 28 days. Data obtained and expressed as in Fig. 37.7. Reproduced with permission from Ref. 35.

Table 37.25 Normal limits of the immature : total and immature : segmented granulocyte ratios in healthy neonates.

	Day 1	Day 7	Day 28	Reference
Immature : total	0.16	0.12	0.12	35
Immature : total (African)	0.22	0.21	0.18	36
Immature : segmented	0.3 (neonatal period)			37

Table 37.26 Mean and range of values for neutrophils, band forms and lymphocytes ($\times 10^9/l$) in African neonates.

	Day 1	Day 7	Day 28
Neutrophils	5.67 (0.98–12.9)	2.01 (0.57–6.5)	1.67 (0.65–3.2)
Band forms	1.16 (0.16–2.3)	0.55 (0–1.5)	0.36 (0–0.39)
Lymphocytes	5.10 (1.4–8.0)	5.63 (2.2–15.5)	6.55 (3.2–9.9)

Data based on 100-cell differential count.
Summarized from Ref. 36.

Fig. 37.9 Reference range for immature neutrophils ($\times 10^9/l$) in the first 60 hours of life. Data obtained and expressed as in Fig. 37.7. Reproduced with permission from Ref. 35.

Table 37.27 Total and differential white cell count ($\times 10^9/l$, mean and 95% range) from a cohort of children tested at 2, 5 and 13 months of age.

	2 months (<i>n</i> = 100)	5 months (<i>n</i> = 96)	13 months (<i>n</i> = 86)
Total WBC	8.9 (5.1–15.3)	10.0 (5.9–17.0)	9.7 (5.8–16.2)
Neutrophils	1.8 (0.7–4.8)	2.5 (1.1–5.8)	2.7 (1.0–7.7)
Lymphocytes	5.8 (3.3–10.3)	6.2 (3.3–11.5)	6.0 (3.4–10.5)
Monocytes	0.7 (0.4–1.2)	0.56 (0.25–1.27)	0.5 (0.2–0.92)
Eosinophils	0.3 (0.09–0.8)	0.32 (0.1–1.1)	0.2 (0.05–0.9)
Basophils	0.05 (0.02–0.13)	0.07 (0.02–0.2)	0.06 (0.02–0.13)

Reproduced with permission from Ref. 38.

Table 37.28 Differential leukocyte counts in children.

Age (years)	Number	Mean	3rd Centile	97th Centile	Age (years)	Number	Mean	3rd Centile	97th Centile

Summarized from Ref. 9.

Table 37.29 Normal values for lymphocytes, monocytes and eosinophils ($\times 10^9/l$) from birth to 30 days of age based on a study of 393 infants.

	Percentile	Age (hours)		
		0–60	61–120	121–720
Lymphocytes	95	7.26	6.62	9.13
	50	4.19	8.66	5.62
	5	2.02	1.92	2.86
Monocytes	95	1.91	1.74	1.72
	50	0.6	0.53	0.67
	5	0	0	0.10
Eosinophils	95	0.84	0.81	0.84
	50	0.14	0.18	0.24
	5	0	0	0

Data based on 100-cell differential count.
Reproduced with permission from Ref. 39.

Table 37.30 Absolute counts ($\times 10^9/l$), median and percentiles (5th to 95th percentiles) of T-cell (CD3), helper/inducer T-cell (CD4), suppressor/cytotoxic T-cell (CD8) and B-cell (CD19) lymphocytes and natural killer (CD15–56) cells in peripheral blood.

Age	N	CD19 B cells	CD3 T cells	CD3/CD4 T helper cells	CD3/CD8 T suppressor cells	CD15-56 natural killer cells
Neonatal	20	0.6 (0.04–1.1)	2.8 (0.6–5.0)	1.9 (0.4–3.5)	1.1 (0.2–1.9)	1.0 (0.1–1.9)
1 week–2 months	13	1.0 (0.6–1.9)	4.6 (2.3–7.0)	3.5 (1.7–5.3)	1.0 (0.4–1.7)	0.5 (0.2–1.4)
2–5 months	46	1.3 (0.6–3.0)	3.6 (2.3–6.5)	2.5 (1.5–5.0)	1.0 (0.5–1.6)	0.3 (0.1–1.3)
5–9 months	105	1.3 (0.7–2.5)	3.8 (2.4–6.9)	2.8 (1.4–5.1)	1.1 (0.6–2.2)	0.3 (0.1–1.0)
9–15 months	70	1.4 (0.6–2.7)	3.4 (1.6–6.7)	2.3 (1.0–4.6)	1.1 (0.4–2.1)	0.4 (0.2–1.2)
15–24 months	33	1.3 (0.6–3.1)	3.5 (1.4–8.0)	2.2 (0.9–5.5)	1.2 (0.4–2.3)	0.4 (0.1–1.4)
2–5 years	33	0.8 (0.2–2.1)	2.3 (0.9–4.5)	1.3 (0.5–2.4)	0.8 (0.3–1.6)	0.4 (0.1–1.0)
5–10 years	35	0.5 (0.2–1.6)	1.9 (0.7–4.2)	1.0 (0.3–2.0)	0.8 (0.3–1.8)	0.3 (0.09–0.9)
10–16 years	23	0.3 (0.2–0.6)	1.5 (0.8–3.5)	0.8 (0.4–2.1)	0.4 (0.2–1.2)	0.3 (0.07–1.2)
Adults	51	0.2 (0.1–0.5)	1.2 (0.7–2.1)	0.7 (0.3–1.4)	0.4 (0.2–0.9)	0.3 (0.09–0.6)

Data obtained by flow cytometry.
Summarized from Ref. 40.

Table 37.31 Normal progenitor cell numbers during development.*

Age	PB BFU-E	BM BFU-E	BM CFU-E	PB CFU-GM	BM CFU-GM	PB CFU-Meg	BM CFU-Meg
Fetus 18–20 weeks	75–1500			20–700		1–10	
Birth, term	40–100			10–200		5–20	
Adults	5–40	10–150	25–150	5–20	15–100	2–10	1–30

* Data are approximate ranges derived from various sources, and indicate numbers of progenitor cells per 10^5 mononuclear cells plated.
PB, peripheral blood; BM, bone marrow; BFU-E, erythroid burst-forming unit; CFU-E, erythroid colony-forming unit; CFU-GM, granulocyte–macrophage colony-forming unit; CFU-Meg, megakaryocyte colony-forming unit.
Reproduced with permission from Ref. 41.

Table 37.32 Reference values for coagulation tests in the healthy full-term infant during the first 6 months of life.

	Day 1 (n)	Day 5 (n)	Day 30 (n)	Day 90 (n)	Day 180 (n)	Adult (n)

FXIIIb (unit/ml)	0.76 ± 0.23 (44)	1.06 ± 0.37 (47)*	1.11 ± 0.36 (45)*	1.16 ± 0.34 (44)*	1.10 ± 0.30 (41)*	0.97 ± 0.20 (29)
Plasminogen (CTA, unit/ml)	1.95 ± 0.35 (44)	2.17 ± 0.38 (60)	1.98 ± 0.36 (52)	2.48 ± 0.37 (44)	3.01 ± 0.40 (47)	3.36 ± 0.44 (29)

All values expressed as mean ± 1 SD. All factors except fibrinogen and plasminogen are expressed as unit/mL where pooled plasma contains 1.0 unit/mL.

Plasminogen units are those recommended by the Committee on Thrombolytic Agents (CTA). Note that longer or shorter APTT and TCT values may be obtained in newborns and infants using reagent combinations other than those used in this study.

* Values do not differ statistically from adult values.

† These measurements are skewed because of a disproportionate number of high values.

PT, prothrombin time; APTT, activated partial thromboplastin time; TCT, thrombin clotting time; vWF, von Willebrand factor; PK, prekallikrein; HMWK, high-molecular-weight kininogen.

Reproduced with permission from Ref. 42.

HCII (unit/ml)	0.43 ± 0.25 (56)	0.48 ± 0.24 (72)	0.47 ± 0.20 (58)	0.72 ± 0.37 (58)	1.20 ± 0.35 (55)	0.96 ± 0.15 (29)
Protein C (unit/ml)	0.35 ± 0.09 (41)	0.42 ± 0.11 (44)	0.43 ± 0.11 (43)	0.54 ± 0.13 (44)	0.59 ± 0.11 (52)	0.96 ± 0.16 (28)
Protein S (unit/ml)	0.36 ± 0.12 (40)	0.50 ± 0.14 (48)	0.63 ± 0.15 (41)	0.86 ± 0.16 (46)*	0.87 ± 0.16 (49)*	0.92 ± 0.16 (29)

All values expressed in unit/mL as mean ± 1 SD.

* Values indistinguishable from those of adults.

ATIII, antithrombin III; α₂-M, α₂-macroglobulin; α₂-AP, α₂-antiplasmin; C1E-INH, C1 esterase inhibitor; α₁-AT, α₁-antitrypsin; HCII, heparin cofactor II.

Reproduced with permission from Ref. 42.

Fig. 37.10 PIVKA (protein induced by vitamin K absence or antagonism)-II levels in cord blood and blood samples obtained at 3 or 5 days of age. Group I did not receive vitamin K and Group 2 did. The dotted line indicates the lower limit of sensitivity of the assay. One arbitrary unit of PIVKA-II corresponds to one μg of purified prothrombin (Factor II). Reproduced with permission from Ref. 44.

Table 37.34 Concentrations of D-dimers in blood from 15 preterm infants and 45 born at full term.

Concentration of D-dimers (mg/l)	No. (%) of patients		
	Full term (n = 45)	Preterm (n = 15)	Total (n = 60)
<0.25	24 (53%)	7 (47%)	31 (52%)
0.25–0.5	14 (31%)	2 (13%)	16 (27%)
0.5–1	6 (13%)	2 (13%)	8 (13%)
1–2	1 (2%)	2 (13%)	3 (5%)
2–4	0	2 (13%)	2 (3%)

All D-dimer concentrations in the pregnant mothers were < 0.25 mg/l. Reproduced with permission from Ref. 43.

Table 37.35 Platelet count ($\times 10^9/\text{l}$) during childhood.

Age	Both sexes	Girls	Boys
2 months	214–648 (n = 119)		
5 months	210–560 (n = 106)		
13 months	180–508 (n = 101)		
1–3 years	207–558 (n = 68)		
4–6 years		193–489 (n = 118)	205–450 (n = 159)
7–8 years		191–439 (n = 155)	194–420 (n = 202)
9–10 years		201–384 (n = 182)	174–415 (n = 258)
11–12 years		180–387 (n = 206)	178–382 (n = 274)
13–14 years		188–429 (n = 129)	183–370 (n = 157)
15–18 years		170–359 (n = 151)	189–374 (n = 116)

Data from our laboratory (2 months to 3 years, 95% range) and Ref. 11 (3rd to 97th centiles). Platelet counts are significantly lower at 5 months than at 2 months of age, and at 13 months than at 5 months ($P < 0.001$ for both). The fall in counts with age from 4 years is statistically significant, as are the overall higher values in girls than boys between 4 and 18 years ($P < 0.0001$ for both).

Table 37.36 PFA-100 closure times in healthy children and adults, and in children with hemophilia.

Subjects	Number	Age (years)	Closure times (s)	
			Col/Epi	Col/ADP
Healthy children				
21-gauge needle	30	2.5–17	82–165	70–110
23-gauge needle	27	5–17	91–142	77–112
Combined data	57	2.5–17	83–163	72–111
Healthy adults				
21-gauge needle	31	25–54	82–142	67–111
Healthy neonates	17	>37 weeks' gestational age	61–108	48–65
Hemophiliacs	11	6–18	109 \pm 20	81 \pm 13

All subjects had hemoglobin and platelets within normal reference limits for age.

Col/Epi, collagen/epinephrine membrane; Col/ADP, collagen/ADP membrane.

Reproduced with permission from Ref. 45.

Table 37.37 Bleeding time (min) in children and adults.

Subjects	Number	Mean	SD	Range
Children	36	4.6	1.4	2.5–8.5
Adults	48	4.6	12	2.5–6.5

Bleeding time performed using a template technique with incision 6 mm long and 1 mm deep and sphygmomanometer pressure 40 mmHg. Note that using this technique, bleeding times up to 11.5 min have been observed in apparently healthy children tested in our laboratory. Summarized from Ref. 46.

Table 37.38 Serum immunoglobulin levels in UK Caucasians (−2 SD, meridian, +2 SD by log-Gaussian).

Age		IgG (g/l)	IgA (g/l)	IgM (g/l)
Weeks	Cord	10.8 (5.2–18.0)	<0.02	0.1 (0.02–0.2)
	0–2	9.4 (5.0–17.0)	0.02 (0.01–0.08)	0.1 (0.05–0.2)
	2–6	7.1 (3.9–13.0)	0.05 (0.02–0.15)	0.2 (0.08–0.4)
	6–12	3.9 (2.1–7.7)	0.15 (0.05–0.4)	0.4 (0.15–0.7)
Months	3–6	4.6 (2.4–8.8)	0.2 (0.1–0.5)	0.6 (0.2–1.0)
	6–9	5.2 (3.0–9.0)	0.3 (0.15–0.7)	0.8 (0.4–1.6)
	9–12	5.8 (3.0–10.9)	0.4 (0.2–0.7)	1.2 (0.6–2.1)
Years	1–2	6.4 (3.1–13.8)	0.7 (0.3–1.2)	1.3 (0.5–2.2)
	2–3	7.0 (3.7–15.8)	0.8 (0.3–1.3)	1.3 (0.5–2.2)
	3–6	9.9 (4.9–16.1)	1.0 (0.4–2.0)	1.3 (0.5–2.0)
	6–9	9.9 (5.4–16.1)	1.3 (0.5–2.4)	1.2 (0.5–1.8)
	9–12	9.9 (5.4–16.1)	1.4 (0.7–2.5)	1.1 (0.5–1.8)
	12–15	9.9 (5.4–16.1)	1.9 (0.8–2.8)	1.2 (0.5–1.9)
	15–45	11 (6.0–16.0)	1.9 (0.8–2.8)	1.2 (0.5–1.9)
	>45	11 (6.0–16.0)	1.9 (0.8–4.0)	1.2 (0.5–2.0)

Determined in 53 males and 54 females above 15 years and in groups of at least 30 subjects for the other age groups.

Reproduced with permission from Ref. 47.

Table 37.39 Mean and 5th to 95th centile ranges (g/l) for IgG subclasses at various ages.

Age	IgG1	IgG2	IgG3	IgG4
Cord blood	4.7 (3.6–8.4)	2.1 (1.2–4.0)	0.6 (0.3–1.5)	0.2 (<0.5)
6 months	2.3 (1.5–3.0)	0.4 (0.3–0.5)	0.3 (0.1–0.6)	<0.1
2 years	3.5 (2.3–5.8)	1.1 (0.3–2.9)	0.4 (0.1–0.8)	<0.1
5 years	3.7 (2.3–6.4)	2.0 (0.7–4.5)	0.5 (0.1–1.1)	0.3 (<0.1–0.8)
10 years	5.2 (3.6–7.3)	2.6 (1.4–4.5)	0.7 (0.3–1.1)	0.4 (<0.1–1.0)
15 years	5.4 (3.8–7.7)	2.6 (1.3–4.6)	0.7 (0.2–1.2)	0.4 (<0.1–1.1)
Adult	5.9 (3.2–10.2)	3.0 (1.2–6.6)	0.7 (0.2–1.9)	0.5 (<0.1–1.3)

In adults IgG3 levels are higher in females than in males, and IgG4 higher in males than females. No sex difference is seen before the age of 15 years.

Reproduced with permission from Ref. 47.

Table 37.40 Serum IgD levels (g/l).

Number	Age	IgD
23	6 weeks to 19 months	<0.01–0.016
105	3–14 years	<0.01–0.036

Reproduced with permission from Ref. 48.

Table 37.41 Total serum IgE levels.*

Age	Median	95th centile
Newborn	0.5	5
3 months	3	11
1 year	8	29
5 years	15	52
10 years	18	63
Adult	26	120

* Data expressed in units in relation to the first British Standard for human serum IgE 75/502.

Reproduced with permission from Ref. 47.

Table 37.42 Erythrocyte sedimentation rate (mm/h) in healthy children.

Method	Number	Age (years)	Mean	Range	% > 20 mm/h
Wintrobe	245	4–11	12.0	1–41	9
	169	12–15	7.5	<1–34	7
Westergren (read at 45 min)	78	4–7	13	<1–55	
	153	8–14	10.5	1–62	

Summarized from Refs 49–51.

Table 37.43 Isohemagglutinin titers in relation to age.

Age	Mean (range)
Cord blood	0*
1–3 months	1 : 5 [†] (0 to 1 : 10)
4–6 months	1 : 10 [†] (0 to 1 : 160)
7–12 months	1 : 80 [‡] (0 to 1 : 640)
13–24 months	1 : 80 [‡] (0 to 1 : 640)
25–36 months	1 : 160 [§] (1 : 10 to 1 : 640)
3–5 years	1 : 80 (1 : 5 to 1 : 640)
6–8 years	1 : 80 (1 : 5 to 1 : 640)
9–11 years	1 : 160 (1 : 20 to 1 : 640)
12–16 years	1 : 160 (1 : 10 to 1 : 320)
Adult	1 : 160 (1 : 10 to 1 : 640)

* Isohemagglutinin (IHA) activity is rarely detectable in cord blood.

† 50% of normal infants will not have IHA at this age.

‡ 10% of normal infants will not have IHA at this age.

§ Beyond this age all normal individuals have IHA with the exception of those of blood group AB.

Summarized from Ref. 52.
