Appreciation of Richard Frederick Stevens

Richard Stevens, better known to all his friends and colleagues as Dick, died in tragic circumstances in July 2003. As John Lilleyman's appreciation in the *Journal of the Royal College of Pathology* testified, Dick radiated warmth of character and was the best of company. Those of us who travelled with him to meetings were regaled with clinical conundrums, insight into the workings of railway timetables and delays in travel, and not a little in-depth knowledge of medical and musical history. This was frequently interspersed with clinical anecdotes and discussion on pediatric hemato-oncology problems. He was a national figure both in hemophilia and in acute leukemia management, particularly myeloid leukemia.

With Ian Hann he oversaw the AML 10 study, which produced the great leap forward in survival that we had all been waiting for since the 1970s. Dick wrote extremely well in his chosen subjects and in the previous editions of this text on leukemia and in the last edition on disorders of granulopoiesis and granulocyte function. His remarkable enthusiasm led to far too many calls on his time: as Clinical

Director, Chairman of the local Trust Staff Medical Committee, Secretary to the National Childhood Leukaemia Working Party, and Secretary to the UK Haemophilia Doctors' Association and at the time of his disappearance he had just been elected President of the Manchester Paediatric Club.

His lectures always contained fascinating anecdotes on the topic in question. He became more and more respected as a historian. Those of us who knew him well and worked with him sadly miss him, his excellent company and his immensely friendly support. It can be said of very few of us that we make friends but no enemies. He fought for his patients, particularly at the difficult time which all hemophilia patients faced when recombinant factor VIII became available at a price that many in the Health Service were not willing to pay.

His death was an unpredictable tragedy. We are privileged to have known and worked with this very special man. He is truly a great loss to pediatric hematology in the UK and the world.

Appreciation of Anton H. Sutor

During the period of editing the current issue of this book, Professor Dr Anton H. Sutor, one of the leading scientists in pediatric hemostasis, passed away. We greatly appreciate his significant contributions to both clinical and laboratory research in pediatric hemostasis.

Born in Augsburg, Germany, Anton Sutor's early years studying medicine were in Freiburg, Berlin and Worcester (MA). During a fellowship at the Mayo Clinic in Rochester, Minnesota, 1967–1970, he began working in the field of pediatric hemostasis. He returned to Freiburg, and from 1977 to 1982 he held a position as an Associate Professor at the Department of Pediatric Hematology and Oncology in Münster. In 1982, he accepted the position of Professor of Pediatric Hematology and Hemostasis at the University of Freiburg.

Professor Sutor contributed significantly to pediatric hematology through his work on vitamin K, the genetics of thrombosis, the toxicity of heparin, and the pathophysiology of procoagulant and anticoagulant factors. During his last years, he focused on the pathophysiology and treatment of thrombocytosis and thrombocytopenia. He published over

100 articles in peer-reviewed journals and numerous textbook chapters, edited 16 textbooks, and organized many international meetings. He also earned various awards, including the Goedecke Research Award, the Alexander Schmidt Award of the German Society of Thrombosis and Hemostasis (GTH), and an award for excellence in teaching. He served as chair for the section on pediatric hemostasis in the GTH and as co-chairman of the International Society of Thrombosis and Haemostasis (ISTH). In 2000, Professor Sutor was president of the International Conference of this society in Freiburg, which was combined with a meeting of the Japanese Society of Pediatric Hemostasis.

Professor Sutor was very much honored by the international scientific community in pediatric hematology and oncology. He had excellent contacts with many international groups, particularly in Japan. Besides medicine, he had a passion for flying, skiing, and chamber music. His tremendous clinical and scientific work, his skills for teaching students and young fellows, and his lovely personality will be always remembered by us.

- 4 Acquired aplastic anemia, 64
Juliana Teo and Yigal Dror

Section 3: Red Cell Disorders

- 5 Disorders of iron metabolism: iron deficiency, iron overload and the sideroblastic anemias, 79
Andrew M. Will
- 6 Megaloblastic anemia and disorders of cobalamin and folate metabolism, 105
Eric J. Werner
- 7 Nonimmune neonatal anemias, 130
Brenda E.S. Gibson and Christina Halsey
- 8 Immune hemolytic anemias, 151
Bertil Glader
- 9 Disorders of erythrocyte metabolism including porphyria, 171
Lawrence Wolfe and Peter E. Manley

- 10 Sickle cell disease, 213
Corrina McMahon

- 11 Hemoglobin variants and the rarer hemoglobin disorders, 231
Andreas E. Kulozik

- 12 Red cell membrane abnormalities, 255
Patrick G. Gallagher

- 13 Thalassemias, 281
Nancy F. Olivieri and David J. Weatherall

Section 4: Granulocyte Disorders

- 14 Disorders of granulopoiesis and granulocyte function, 305
Arian Laurence, Pratima Chowdary and Philip Ancliff
- 15 Histiocytic disorders, 340
Amir H. Shahlaee and Robert J. Arceci
- 16 Acute myeloid leukemia, 360
Leslie S. Kean, Robert J. Arceci and William G. Woods
- 17 Chronic myeloid leukemia, 384
Irene A.G. Roberts and Inderjeet S. Dokal
- 18 Myelodysplastic syndromes, 405
David K.H. Webb

Section 5: Lymphocyte Disorders

- 19 Primary and acquired immunodeficiency, 425
Andrew R. Gennery, Adam H.R. Finn and Andrew J. Cant
- 20 Clinical features and therapy of lymphoblastic leukemia, 450
Owen P. Smith and Ian M. Hann
- 21 Lymphomas, 482
O.B. Eden and Ross Pinkerton

Section 6: Platelet Disorders

- 22 Inherited and congenital thrombocytopenia, 507
Owen P. Smith
- 23 Idiopathic thrombocytopenic purpura, 526
Paul Imbach
- 24 Thrombocytosis, 548
Christof Dame
- 25 Platelet function disorders, 562
Alan D. Michelson

Section 7: Coagulation Disorders

- 26 Hemophilia A and B, 585
Judith Smith and Owen P. Smith
- 27 von Willebrand disease, 598
David Lillicrap
- 28 Rare congenital hemorrhagic disorders, 608
Nigel S. Key and Margaret A. Heisel-Kurth
- 29 Acquired disorders of hemostasis, 624
Elizabeth A. Chalmers, Michael D. Williams and Angela Thomas
- 30 Bleeding in the neonate, 643
Elizabeth A. Chalmers
- 31 Thromboembolic complications in children, 672
Mary Bauman and M. Patricia Massicotte

Section 8: Supportive Therapy

- 32 Blood components and fractionated plasma products: preparation, indications and administration, 693
Nancy Robitaille and Heather A. Hume
- 33 Hazards of transfusion, 724
Naomi L.C. Luban and Edward C.C. Wong
- 34 Management of infection in children with bone marrow failure, 745
Subarna Chakravorty and Ian M. Hann

Section 9: Secondary Problems

- 35 Hematologic effects of systemic disease and nonhematopoietic tumors, 757
Angela Thomas
- 36 Lysosomal storage disorders, 778
Brad T. Tinkle and Gregory A. Grabowski
- 37 Reference values, 792
Paula S. Simpkin and Roderick F. Hinchliffe

Cancer Center and Blood Disorders Service, Children's
Healthcare of Atlanta/Emory University, 1405 Clifton
Road, Atlanta, GA 30322, USA

Foreword

It is a great honor for me to write the foreword for the Third Edition of this well established major textbook which deals with all aspects of blood diseases in infants and children. Pediatric hematology has led the world in the application of the new techniques of molecular biology to elucidate at a DNA level, the underlying defect in both inherited and acquired diseases. New discoveries have led to a better understanding of the etiology and clinical manifestations of these diseases and to substantial improvements in their prevention and management. Moreover, the study of rare genetic diseases in childhood has led to a major increase in knowledge of the normal physiological and biochemical processes of the human body. Advances in pediatric hematology have also had a major impact on treatment of many adult diseases. The use of combination chemotherapy for childhood lymphoblastic leukemia, for example, now achieves an impressive cure rate of approximately 85%, and has provided a model for chemotherapy of cancer in general.

Two of the Editors, Ian Hann, Great Ormond Street Hospital for Sick Children, London and Owen Smith, Our Lady's Hospital for Sick Children, Dublin were most impressive trainees in the Department of Haematology at the Royal Free Hospital. Together with Robert Arceci of Johns Hopkins

Oncology Center, Baltimore, USA their combined expertise covers the whole range of benign and malignant disorders of the bone marrow as well as diseases of the immune and hemostatic systems. They are to be congratulated on assembling as authors such a distinguished team of international experts. The publishers have ensured clarity of the presentation of the text and produced beautiful diagrams. In the age of the internet and easy electronic access to information, a large text book has to justify its existence by being outstanding in all respects. The Third Edition of *Pediatric Hematology* meets these criteria. The Editors have succeeded in producing a book that is authoritative and up to date, describing in a comprehensive and lucid fashion one of the most rapidly advancing areas of medicine. It will be of great value to all working in the field of hematology and related areas of medicine, especially for those dealing with neonates, infants and children.

A. Victor Hoffbrand
DM, FRCP, FRCPATH, DSc, FMedSci
Emeritus Professor of Haematology
Royal Free and University College School of Medicine
London

Preface

There is an old Chinese proverb that says “when you drink from the well, remember who dug it.” To this end, the Third Edition of *Pediatric Hematology* owes its current form and substance to an original solo text of Dr. Michael Willoughby followed by the First Edition (c. 1992), edited by Drs. Lilleyman and Hann. The Second edition (c. 1999) was edited by Drs. Lilleyman, Hann and Blanchette. In addition, we are immensely indebted to all the authors of the chapters in the current edition. These individuals represent an extraordinary breadth and depth of experience of both scientific and practical experience. The authors also represent wide geographical as well as chronological ranges. We hope that both characteristics provide a balanced and a cutting edge tone to the content. We are also thankful for the good natured persistence and expertise of Nick Morgan from Blackwell Publishing Ltd, as well as the publication prowess of Kathy Auger project manager for Graphicraft Limited. Without them, this Third Edition could not have been made a reality.

The Third Edition has not succumbed to the often immense temptation of relentless expansion. The number of authors is similar to the previous edition and the total number of chapters has been condensed from 40 to 37. This was accomplished by combining some chapters, such as those on topics concerning the hematologic effects of systemic disease and nonhematologic tumors, as well as the chapters on erythrocyte metabolism and porphyria. We have also eliminated the chapters dedicated strictly to the pathology of acute myelogenous and lymphoblastic leukemia and have instead integrated the essential aspects of biology directly into the chapters on those respective topics. Instead of expansion, we have therefore tried to retain the comprehensive yet practical aspects of the content.

The organization of the Third Edition has remained true to previous editions. This straightforward organization presents an introductory chapter on the Holy Grail of Hematopoiesis followed by sections on Marrow Failure, disorders of the Red Blood Cell, the Granulocytic lineage, Lymphocytes and Platelets. These “cell lineage” directed sections are followed by a comprehensive series of chapters covering Coagulation, Supportive Therapy and Secondary Problems. The last section includes information on standard Reference Values.

The intended audience for Pediatric Hematology includes students, subspecialty trainees, pediatricians and established subspecialists in Pediatric Hematology/Oncology or other subspecialists who will see patients with these benign and malignant disorders of the blood. In addition, nursing specialists taking care of children and young adults with hematologic disorders will find this a practical reference.

At its very essence, a textbook like this is a labor of love including the intense and time consuming process of writing and editing. It is clearly not for fame, ego or money as our subspecialty is unlikely to significantly support any of these. Instead, it is a debt to be paid to the incredible history that precedes us as well as a hope for the future that will succeed us. There is still also a remarkable satisfaction with “turning a page” on where we’ve been, where we are and where we expect to be. The study of normal and abnormal blood formation remains both a clinically important and scientifically challenging field. We hope that Pediatric Hematology will help to chronicle this discipline while providing caretakers with information that improves the lives of their patients.

Robert J. Arceci, Ian M. Hann & Owen P. Smith

SECTION

1 The Scientific Basis

1

Hematopoiesis: an introduction

Hugh J.M. Brady

All the cells of the hematopoietic system originate from pluripotent hematopoietic stem cells (HSCs). HSCs have the intrinsic capacity for self-renewal but are low in number and divide infrequently. Therefore, it is the committed progenitors that are responsible for initiating the large amount of cell proliferation required to maintain blood cell production. These multipotent progenitors, which are the immediate progeny of HSCs in bone marrow, do not have detectable self-renewal *in vivo*. The common lymphoid progenitor (CLP) develops into T and B cells (T and B lymphocytes) whereas the common myeloid progenitor (CMP) gives rise to erythrocytes, megakaryocytes, monocytes and granulocytes. Cells mature from the CMP through two intermediates, the megakaryocyte/erythrocyte progenitor (MEP) and the granulocyte/monocyte progenitor (GMP). However, recent work has suggested that the immediate progeny of HSCs may not be CLPs and CMPs exclusively.¹ An adult bone marrow population (termed LMPP, lymphoid primed multipotent progenitor) has been identified that has the potential to become both lymphoid and granulocyte/monocyte lineage cells but lacks the capacity to give rise to erythroid cells or megakaryocytes.

Lymphoid cells

T and NK cells

Mature circulating T cells are small cells with condensed chromatin in the nucleus and few cytoplasmic organelles. When T cells are activated upon exposure to antigen the volume of the T cells increases, the chromatin decondenses and the cytoplasm contains abundant mitochondria and endoplasmic reticulum. Circulating NK (natural killer) cells are large granular lymphocytes with abundant cytoplasmic granules containing molecules required for cytotoxicity. T cells are characterized by the surface expression of the T-cell

receptor (TCR) and CD3 complex, which is not found on NK cells. However, the two cell types share the expression of a large number of cell surface differentiation markers. Human NK cells are commonly defined by expression of the cell surface markers CD16 and CD56 although subpopulations of T cells also express these markers.

T cells can be divided into two subsets on the basis of their cell surface markers and function. CD4⁺ T-helper (Th) cells are required for the activation of other cells of the immune system (e.g., B cells and macrophages) and secretion of cytokines upon recognition of foreign antigens in the context of major histocompatibility complex (MHC) class II molecules. CD8⁺ cytotoxic T lymphocytes (CTL) recognize antigenic peptides in the context of MHC class I molecules and have two main functions, cytotoxicity and cytokine secretion. CTL and NK cells show great functional similarities. Both CTL and NK cells lyse their target using both perforin-based mechanisms and Fas–Fas ligand interactions. They also respond to the same cytokines both for proliferation and to increase cytotoxicity, and both produce a similar set of cytokines, namely interferon- γ (IFN- γ), granulocyte–macrophage colony-stimulating factor (GM-CSF), and tumor necrosis factor- α (TNF- α). However, the effector mechanisms of CTL and NK cells are triggered in distinct ways. Following recognition of the specific MHC class I–antigenic peptide complex, T cells proliferate. They also acquire their effector potential and are able to become memory T cells. NK cells can also interact with MHC class I molecules through specialized killer inhibitory receptors (KIR), and this recognition results in the inhibition of NK cell effector functions. The downregulation or absence of MHC class I molecules on target cells induces lysis by NK cells. Therefore, NK cells can eliminate cells that, due to lack of MHC class I molecules, evade CTL recognition. Complete or partial loss of MHC class I expression is a common consequence of viral infections and malignant transformations. NK cells are also able to participate in the adaptive immune response by expressing the CD16 receptor complex,

which allows them to perform antibody-dependent cell-mediated cell killing of antibody-coated target cells.

Hematopoietic cells seem to originate independently both in the yolk sac² and in the aorta-gonad mesonephros (AGM) region³ then migrate to the fetal liver, which is the major hematopoietic organ during fetal life. Precursors of T cells and mature NK cells can be identified in the fetal liver starting from as early as 6 weeks of gestation. A thymic rudiment of epithelial origin is formed by week 7, and by week 9 of gestation it is colonized by dendritic cells, macrophages, and thymic precursors. In the neonate, bone marrow becomes the major hematopoietic organ and is thought to be where NK cells develop, whereas the vast majority of T cells mature in the thymus. Some T cells can have an extrathymic differentiation in the gut mucosa or in the liver, but these cells differ from the thymic T cells in both phenotype and function. T-cell precursors proceed to differentiation and selection in the thymus. The immature precursors lack expression of the T-cell receptor (TCR), CD4 and CD8. The earliest thymic precursors are CD34⁺CD33⁺CD45RA⁺ and subsequently express CD7 and CD38 at the cell surface and CD3 intracellularly. These cells are still able to give rise to both T and NK cells. The T cells acquire the expression of CD1, CD2 and CD5 and the rearrangement of the TCR β chain starts. At this stage, T-cell precursors for the TCR $\gamma\delta$ T-cell lineage differentiate from TCR $\alpha\beta$ -committed thymocytes. The rearranged TCR β chain is expressed at the cell surface associated with a pre-TCR α (pT α) chain and CD3. Expression of the pre-TCR complex prevents further rearrangements at the TCR β locus, controls the initiation of rearrangement of the TCR α chain, and is required for the expression of CD4 and CD8 molecules on the thymocytes.⁴

The rearrangement of TCR genes during early stages of thymocyte maturation allows the generation of a large number of immature T cells bearing a single specificity. Each TCR locus consists of variable (V), joining (J) and constant (C) region genes; TCR β and TCR γ chain loci also contain diversity (D) segment genes.⁵ When both TCR β and TCR α loci are rearranged, thymocytes undergo selection. In positive selection, only thymocytes that recognize self MHC molecules become mature T cells: thymocytes that cannot interact with any self MHC molecule die by neglect; negative selection eliminates potentially self-reactive cells that have been generated during VDJ rearrangement. Greater than 98% of thymocytes are eliminated during selection. It is widely accepted that the strength of the interaction between TCR and peptide-MHC complexes as well as the amount of complexes are responsible for the selective events. If the signal is weak, the thymocytes can mature, but if the signal is too low, the thymocytes will die of neglect. A very strong signal leads the thymocytes to undergo programmed cell death and negative selection.

The identification of a T/NK bipotential precursor in the thymus indicates that NK cells can develop in the thymus

although the thymus is not required for normal NK cell development and the main site of NK cell development is likely to be the bone marrow.⁶

Mature but naive T cells leave the thymus and migrate through the bloodstream into peripheral lymphoid organs where, upon exposure to antigen, T cells proliferate and differentiate into effector T cells. All mature T lymphocytes express the TCR-CD3 complex on their cell surface. TCR α and TCR β chains have two immunoglobulin-like domains in the extracellular portion and a short intracellular domain. They are associated with the polypeptide chains of the CD3 complex, which contain immunoreceptor tyrosine-based activation motifs (ITAMs), which are responsible for the transduction of activating signals upon TCR engagement. The CD3 proteins are also required for the assembly and cell surface expression of TCR.

The activation of naive T cells in the lymph nodes requires two signals: cross-linking of the TCR (signal 1) and also costimulatory molecules such as CD28 (signal 2). Only professional antigen-presenting cells (APCs), such as macrophages, dendritic cells and B cells, express the CD28 ligands B7.1 (CD80) and B7.2 (CD86) on their surface together with MHC molecules.⁷ Antigen recognition by naive T cells in the absence of costimulatory signals induces a state of anergy (i.e., signal 1 only). This mechanism helps to ensure tolerance of T cells to self antigens. CD8⁺ T cells are cytotoxic effectors while CD4⁺ T cells can differentiate into inflammatory T cells (Th1) or helper cells (Th2). Following activation, Th1 lymphocytes produce cytokines (IFN- γ , GM-CSF and TNF- α) that activate macrophages to more efficiently eliminate intracellular microorganisms. Th2 cells secrete a different set of cytokines – mainly interleukin-4, -5 and -6 (IL-4, -5 and -6) – that activate B cells to allow them to differentiate and produce antibodies.

Mature NK cells migrate from the bone marrow to the blood. All mature NK cells have a significant level of cell surface expression of adhesion molecules including three β_2 integrins (CD11a/b/c) and CD56. As many as 10% of NK cells express high levels of CD56 (CD56^{high}) and these cells also express both the high- and intermediate-affinity IL-2 receptors (IL-2R). The remaining NK cells have a lower expression of CD56 (CD56^{low}) and express only the intermediate-affinity IL-2R. The activation of CD56^{high} NK cells leads to increased proliferation and an increase in the cell killing effect, whereas activation of CD56^{low} NK cells only results in an enhancement of their cell killing effect. CD56^{high} NK cells resemble immature NK cells, with poor cell killing activity but high proliferative capacity, while CD56^{low} cells are more differentiated. T cells only recognize antigens presented by self MHC molecules, while NK cells are not dependent on MHC although their function is regulated by the MHC. Mature NK cells express KIR, which act as inhibitory receptors for MHC class I molecules, engagement of which transmits a negative signal that leads to the blocking of NK cell activation.⁸

B cells

B cells undergo most of their differentiation in the bone marrow and mature B cells express immunoglobulins which interact directly with antigenic epitopes. Surface immunoglobulins are part of the B cell receptor (BCR) analogous to the TCR on T cells. B cells differentiate in the fetal liver and then in the bone marrow during embryonic development.

Following birth, B-cell differentiation starts in the bone marrow and precursors derived from the hematopoietic stem cells become immature B cells. This stage of differentiation is antigen-independent and is required to generate the basic immunoglobulin repertoire, which is the result of multiple V-D-J gene rearrangements.⁹ Immature B cells migrate to the secondary lymphoid organs, namely spleen, lymph nodes, tonsils, mucosa and gut-associated lymphoid tissue (GALT). The next stage of differentiation requires antigen encounter and a number of cell-cell interactions, principally T-B-cell cooperation. A second level of diversity is then generated from somatic mutations, and the final steps of differentiation, including isotope switching, lead to the emergence of plasma cells, which secrete antibodies, and memory B cells.

The B lineage derives from a precursor common to B, T and NK cells. The first steps of B-cell differentiation require interactions of the precursor cells with stromal cells, mediated by various cellular adhesion molecules. The VLA-4 integrin expressed on the cell surface interacts with stromal vascular cell adhesion molecule-1 (VCAM-1) and the resulting early pro-B cells express c-Kit, the receptor for the stem cell factor (SCF) produced by stromal cells. This triggers proliferation of pro-B cells. Late pro-B cells are stimulated by IL-7 produced by the stromal cells, which also activates proliferation of pre-B cells.

During differentiation the B cells are cycling and immunoglobulin gene rearrangements are taking place. CD34, expressed on hematopoietic stem cells, remains on early B-cell precursors and pro-B cells. Late pro-B cells are characterized by the coexpression of CD34 and CD19, which is a specific B-cell marker. CD10 is expressed up to the immature B-cell stage, and is expressed earlier than CD19.¹⁰

B-cell differentiation leads to the acquisition of the initial repertoire of immunoglobulins that are expressed as surface IgM (sIgM) on immature B cells. Immunoglobulins are made up of two heavy (H) chains and two light (L) chains (κ or λ). Depending upon the nature of the H chain, immunoglobulins exist as discrete isotypes, termed IgM, IgG, IgA, IgD and IgE, corresponding to the μ , γ , α , δ and ϵ heavy chains, respectively.¹¹ Each different isotype can be either cell surface or secreted immunoglobulins. When they are expressed at the surface of B cells, immunoglobulin molecules are associated with the Ig α -Ig β heterodimer, encoded by the *mb1* and *B29* genes respectively, to form the B-cell receptor (BCR). Each of the H and L chains has a variable and a constant region. The variable regions of the H and L chains interact

in the antibody-combining site leading to specific antigen recognition.

Immature B cells that express surface IgM are exposed to self antigen before leaving the bone marrow. Cross-linking of surface immunoglobulins by multivalent antigens results in clonal deletion by apoptosis. However, self antigens do not induce cell death of immature B cells but will induce an anergic state in which the cells still migrate to the peripheral lymphoid organs. At this point, cells that have encountered self antigen may also escape cell death or anergy by changing their specificity. This is achieved by "receptor editing", which allows the cells to replace one light chain by another one, or induces secondary rearrangement of both heavy and light chain loci. Negative selection of B cells has a threshold that still leaves a fraction of self-reactive cells entering the periphery.

When the immature B cells enter the periphery they colonize the secondary lymphoid organs and then recirculate. The final steps of B-cell differentiation then happen in the periphery and are antigen-dependent. Immature B cells emigrate from the bone marrow to the spleen to the bone marrow, as transitional T1 and T2 B cells. Transitional T2 cells will move on either to mature follicular or marginal zone B cells. Following antigen stimulation and T-cell help the activated B cells may differentiate into plasma cells and B memory cells, which are the final stages of B-cell differentiation.

Plasma cells are large cells that contain large amounts of endoplasmic reticulum and secrete immunoglobulins. After a primary stimulation, the first antibodies produced have the IgM isotype. However, some stimulated B cells can generate a germinal center where they interact with follicular dendritic cells. B cells divide rapidly, giving rise to clonal amplification in situ. They have blast-like morphology and are termed centroblasts, which form the dark zone of the germinal center. When centroblasts divide, they accumulate somatic mutations at a very high rate ($\sim 10^{-3}$).¹² These mutations are mostly localized in the variable regions of the heavy (V_H) and light (V_L) chains that interact with the antigen. The mechanism, known as somatic hypermutation and found only in B cells, considerably amplifies antibody diversity. Following these mutations, the range of affinities is much greater, and the germinal center permits the antigen to positively select the B cells that express the immunoglobulins with the highest affinities. The centroblasts then cease to divide and become small non-dividing centrocytes that accumulate in the light zone of the germinal center, where they interact with follicular dendritic cells.

Following antigenic stimulation, circulating antibodies belonging to the IgM isotype are produced initially, before being replaced by immunoglobulins of another isotype, usually IgG. This is known as isotype switching and is the consequence of a new type of gene rearrangement, which takes place in the germinal center. The light chain genes are not affected by isotype switching so the antigen recognition site

remains unaffected. Isotype switching changes the Ig isotype without modifying the specificity of the antibody but gives an antibody a distinct biological function, which can alter its physiological role, for instance, to enable a more effective attack against certain pathogens, to ensure fetal protection through transplacental transfer, or to be present in certain secretions. Isotype switching requires interaction between T and B cells and dual molecular signals. One signal involves CD40 ligand (CD40L) found on Th cells and CD40 on B cells. The second signal is provided by the Th cell and is release of cytokine to act on the B cell. Depending upon the cytokine released, the switch mechanism will give rise to a certain isotype. For example, IL-4 favors a switch toward the IgE isotype, whereas transforming growth factor- β 1 (TGF- β 1) favors a switch to IgA.

Myeloid lineage

Phagocytic leukocytes

The inflammatory response requires the recruitment of a large number of phagocytic leukocytes, which are cells of the myeloid lineage, to sites of tissue damage or infection. The cells of the myeloid lineage originate in the bone marrow. Mature myeloid cells have a short lifespan and are incapable of cell division. Hence, large numbers of cells have to be produced each day. Monocytes, macrophages and neutrophils protect against microbial invasion. Usually, neutrophils are the more efficient phagocytic cells compared with monocytes and macrophages. However, in response to a large load of pathogens, mononuclear phagocytes are more effective. The antimicrobial capacity of macrophages can be enhanced upon activation by substances such as bacterial endotoxin. Activated cells can kill ingested microorganisms by generating toxic metabolites.

Both mononuclear phagocytes and neutrophils are able to phagocytose and kill bacteria in sites of infection. They move toward the sites of infection by chemotaxis in response to stimuli, which include complement and substances derived from bacteria, cells and connective tissue proteins.

Chemokines form a novel class of small (92–99 amino acids) chemotactic cytokines that have the ability to activate phagocytes as mediators of inflammation. There are two sub-families, which are distinguished by the arrangement of the first two cysteine residues, resulting in the family of so-called C-X-C chemokines, in which either cysteine is separated by one amino acid, or the C-C chemokines, where they are adjacent. A third group, the C chemokines, have only one cysteine residue at this location. The C-C chemokines, which include the monocyte chemotactic proteins (MCP-1, -2 and -3) predominantly stimulate monocytes, while the C-X-C chemokine family, consisting of interleukin-8 (IL-8) and a number of

related molecules (e.g., macrophage inflammatory protein-1 α , MIP-1 α), is mainly active on neutrophils. C chemokines include lymphotactin and eotaxin, which acts on eosinophils.¹³

Neutrophil production in the adult only occurs in the bone marrow. The polymorphonuclear neutrophils in the blood are fully differentiated cells that remain in circulation for only a few hours before migrating into the tissues. During infection, the numbers of neutrophils may increase 10–30-fold within hours, requiring the rapid release of mature cells into circulation from the bone marrow. Mature neutrophils remain for several days in the bone marrow and act as a store, but during infection as well as in response to treatment with granulocyte colony-stimulating factor (G-CSF), the marrow transit time can be significantly reduced. This allows rapid increase in circulating neutrophil numbers during infection.

Polymorphonuclear neutrophils play a crucial role in combating bacterial infections, their primary function being phagocytosis. Impaired neutrophil function or a reduction in their number are directly associated with an increased risk of infections, for example, bacterial sepsis in newborn infants and chronic bacterial infections in older children. The lack of function can result from congenital syndromes or from neutropenia induced by chemotherapy or following conditioning from stem cell transplantation. Neutrophils, eosinophils and basophils differentiate in the bone marrow and are then released into the peripheral circulation. The major function of eosinophils relates to hypersensitivity reactions and to mechanisms acting against the larval states of parasitic infections. Basophils and mast cells are capable of phagocytosis, but their major function stems from their high content of histamine, present in basophilic granules. Histamine is released from the granules in response to a variety of stimuli, including antigen exposure (IgE) in sensitized subjects, and certain cytokines (e.g., IL-3 and GM-CSF).

The mononuclear phagocyte system comprises monocytes, macrophages and their precursor cells, all derived from bone marrow.¹⁴ The monocyte-macrophage lineage and neutrophils are derived from a common progenitor cell, the so-called colony-forming unit granulocyte-monocyte (CFU-GM). Monocytes derived from CFU-GM remain in the blood for approximately 12 hours before they migrate into the tissues, to become macrophages. The macrophages do not re-enter the circulation and have various roles in different tissues, for example as Kupffer cells in the liver or as alveolar macrophages in the lung.

In addition to their phagocytic functions, mononuclear phagocytes are required for the cellular and humoral immune responses. The presentation of antigen on MHC to T cells is preceded by phagocytosis and antigen processing by macrophages.¹⁵ Mononuclear phagocytes act as antigen-presenting cells and, in particular, dendritic cells (which are a distinct cell type from macrophages) act as professional

antigen-presenting cells. These cells also secrete IL-1, which enhances both T- and B-cell proliferation. Mononuclear phagocytes secrete a number of other soluble factors that promote the proliferation of other cell types. In addition to IL-1, macrophages are able to produce TNF- α as well as a number of myeloid colony-stimulating factors (i.e., G-CSF, GM-CSF) and macrophage colony-stimulating factor (M-CSF). They also produce factors that inhibit hematopoiesis (e.g., IFN- α and MIP-1 α). Activated macrophages can recognize tumor cells in a manner independent of antigen recognition and subsequent cytotoxic activity requires cell-to-cell contact and a number of intracellular mediators, including nitric oxide (NO). Alternatively, mononuclear phagocytes may also recognize and kill antibody-coated tumor cells.

Dendritic cells (DC) are a subset of phagocytic leukocytes that are found at the sites of potential pathogen entry such as epithelial and mucosal surfaces.¹⁶ Sentinel DC normally have an immature phenotype sampling the local environment for evidence of pathogens, tissue damage or inflammation. These immature DC are particularly effective at antigen capture, uptake and processing, but less efficient at antigen presentation. DC are rapidly activated in response to environmental stimuli that signal danger, such as microbial products and cytokines found at inflammatory sites. Activation initiates a coordinated sequence of processes that causes the DC to differentiate. Mature DC switch off their capacity to capture antigen, and increase the expression of antigen-presenting molecules (MHC molecule-peptide complexes and costimulatory molecules) on their cell surface.

At least two definable types of dendritic cells are found in the peripheral blood, where they account for less than 1% of mononuclear cells. These cells express CD4 and high levels of MHC II molecules, but most lack lineage markers. When isolated from blood, DC have an immature appearance and lack dendrites but after culture *in vitro* can stimulate T cells. One type of DC expresses myeloid markers such as CD11b, CD11c, CD13, CD33 and GM-CSFR α (CD116), as well as the MHC-like molecules CD1b/c/d, but shows little or no expression of IL-3R α (CD123w), and such cells are often referred to as CD11c⁺ DCs. The other type of DC is referred to as myeloid or CD11c⁺ PBDC (Peripheral Blood Dendritic Cell) also known as plasmacytoid DC, and these express high levels of IL-3R α , low levels of GM-CSFR α and low levels of the myeloid markers indicated above. The FLT3 ligand (FLT3L) has been shown to be the main cytokine responsible for the development of plasmacytoid DCs although G-CSF is required for mobilization from the bone marrow. The plasmacytoid DCs seem distinct from other DCs in that they do not act as sentinels but circulate in a manner driven mainly by inflammatory stimuli. They are likely not to be required for initiating immune responses but for modulating them. *In vitro* evidence has suggested that DCs are primarily lymphoid in origin. Bone marrow CD34⁺CD10⁺ Lin-precursors

with T-, B- and NK-cell potential can generate DC after culture with IL-1 β , IL-7, GM-CSF, SCF and FLT3L. Putative lymphoid-derived DC may also be generated from CD34⁺CD1a⁻ lymphoid-committed thymic precursors after culture with IL-7, TNF- α , SCF and FLT3L.

Erythroid cells

Erythropoiesis is the pathway that produces mature red blood cells from the hematopoietic stem cell.¹⁷ During mammalian development, erythropoiesis takes place in the yolk sac, the fetal liver and finally the bone marrow. The earliest forms of committed erythroid progenitors have been detected by the formation of erythroid colonies after *in vitro* culture in methylcellulose, and are called burst-forming unit erythroid (BFU-E) and the colony-forming unit erythroid (CFU-E). BFU-E are the most immature hematopoietic cells committed to the erythroid lineage. These cells represent less than 0.2% of bone marrow hematopoietic cells, and only about one in three CFU-E make up about the same proportion of bone marrow hematopoietic cells, although most of them are cycling. CFU-E differentiate into the first readily morphologically identifiable cell of the erythroid lineage, the erythroblast, which is the last nucleated cell of the mammalian erythrocyte lineage. Enucleation of the late erythroblast gives rise to reticulocytes and finally red blood cells.

The formation of BFU-E in cell culture is regulated by erythropoietin (EPO) and other growth factors, including SCF, while the formation of CFU-E is highly dependent on low concentrations of EPO alone. EPO is necessary for erythroid differentiation until the late basophilic erythroblast stage, and then the erythroid cells are no longer dependent on EPO for final maturation. The development of the erythroid lineage is characterized by a precise pattern of erythroid gene expression, mainly regulated at the transcriptional level.

Functional analysis of erythroid-specific genes, such as the globin genes, the porphobilinogen deaminase gene, the glycophorin A and B genes and EPO receptor gene have shown the importance of a sequence 5' A/T GATA A/G 3', now called the GATA motif, in the regulated expression of these genes. The sequence is recognized by a family of transcription factors whose members are structurally defined by the presence of two highly conserved zinc fingers. The range of genes regulated by members of the GATA family extends well beyond hematopoietic cells, but two members of this family, GATA-1 and GATA-2, are expressed during erythropoiesis and play a major role in this hematopoietic lineage. GATA-1 expression is restricted to the erythroid, megakaryocyte and mast cell lineages. Deletion of the GATA-1 gene in mouse embryonic stem cells blocks differentiation at the proerythroblast stage of development, where the cells die

by apoptosis,¹⁸ and highlights the absolute requirement of GATA-1 transcription factor for red blood cell production. In addition to GATA-1, other transcription factors required for erythroid development have been identified of which the most significant is probably EKLF (erythroid Krüppel-like factor). The DNA-binding site for this factor is mutated in some patients with β -thalassemia and these mutations impair EKLF binding.¹⁹ In addition, mice with the EKLF gene deleted die early in fetal development with a major thalassemia syndrome due to defective β -globin production.²⁰

Megakaryocyte lineage cells

Platelets are enucleated cells that play an important role in hemostasis by their adhesion to the endothelium and by the release of the contents of their storage organelles following activation. Platelets are produced by the cytoplasmic fragmentation of their polyploid bone marrow precursors, the megakaryocytes, which are rare, accounting for less than 0.1% of cells in bone marrow.²¹

The megakaryocyte and erythroid lineages have many similarities in their differentiation pathways and in the regulation of their specific genes, and there is evidence for a bipotent progenitor common to the erythroid and megakaryocyte lineages. In the early stages of megakaryopoiesis, megakaryocyte progenitors are capable of proliferation and have the potential to give rise to megakaryocyte colonies *in vitro*. These cells undergo a variable number of cell divisions to differentiate into promegakaryoblasts, which begin to synthesize numerous platelet proteins and enter an endomitotic process (DNA replication without cytokinesis). This process induces a parallel increase in both nuclear and cytoplasmic volumes and gives rise to a cell containing a single multilobule nucleus. After three or so DNA replication cycles the volume of cytoplasm within the cell increases substantially and terminal cytoplasmic maturation occurs, leading to proplatelet formation and platelet production. Platelet production occurs through a highly regulated process of cytoplasmic fragmentation, with each successive stage having increased platelet production, and depends on the number of megakaryocytes, their sizes and the efficiency of platelet release. However, platelet shedding following cytoplasmic maturation does appear to be independent of polyploidization as platelet shedding can occur even in diploid cells. The majority of platelet shedding occurs directly in the circulation not in the bone marrow; mature megakaryocytes are detected in the circulation. When platelets are first released into the blood, they have a characteristic elongated shape and thereafter acquire their definitive shape in the circulation.

SECTION

2 Marrow Failure Syndromes

2

Failure of red cell production

Sarah E. Ball

This chapter encompasses isolated red cell aplasia, and the congenital dyserythropoietic anemias, in which ineffective erythropoiesis is the predominant cause of anemia. Impaired red cell production in association with syndromes of global marrow failure is covered in Chapters 3 and 4. Thalassemia, in which ineffective erythropoiesis is also prominent, is discussed in Chapter 13.

Red cell aplasia

The three most important causes of pure red cell aplasia in childhood are:

- Diamond–Blackfan anemia (DBA; congenital red cell aplasia);
- transient erythroblastopenia of childhood (TEC);
- parvovirus B19-induced aplastic crisis on the background of chronic hemolysis.

Of these disorders, the chronic red cell aplasia of DBA and the self-limiting red cell aplasia of TEC are unique to early childhood, while an aplastic crisis may occur at any age. Acquired chronic pure red cell aplasia is much less common in children than in adults, but should be considered, especially in an older age group.

Diamond–Blackfan anemia

DBA, a congenital pure red cell aplasia presenting early in infancy, was first described in the 1930s.^{1,2} The results of national registries have put the incidence of typical DBA at 4–7/million live births.^{3–5} There is no apparent ethnic predominance, and both sexes are equally affected.

Clinical features

Age at presentation

Affected babies most commonly present at 2–3 months of age with symptoms of anemia, such as pallor or poor feeding.

Anemia is evident at birth in 25% of cases,^{4,6} but fetal anemia leading to hydrops has only rarely been reported.^{7–9} In the absence of associated physical anomalies or an unequivocal family history, the diagnosis of DBA should be accepted with caution in children over the age of 1 year. However, mildly affected individuals may be diagnosed as adults, for example, through family studies, or when anemia is exacerbated during pregnancy.^{10–12}

Associated physical anomalies

These are present in up to 50% of children with DBA (Table 2.1), with a wide range of severity.^{13–16} Craniofacial abnormalities are the commonest, with cleft or high arched palate, hypertelorism, and flat nasal bridge contributing to the typical DBA facies described by Cathie¹⁷ (Fig. 2.1). Thumb abnormalities are present in 10–20% of affected children, ranging in severity from a flat thenar eminence to absent radii, including the classic triphalangeal thumb described by Aase and Smith.¹⁸ Deafness is a relatively common feature, and other musculoskeletal, renal and cardiac abnormalities may also occur. Learning difficulties are relatively rare in DBA.

Table 2.1 Prevalence and pattern of physical anomalies in 65 children with Diamond–Blackfan anemia born in the UK over the 20-year period 1975–1994⁴

	Number (%)
<i>Physical anomalies</i>	
Any abnormality	38 (58)
Craniofacial (including cleft palate, typical facies, ophthalmic)	34 (52)
Thumb (including hypoplastic, bifid, triphalangeal)	12 (18)
<i>Growth retardation</i>	
Height below 3rd percentile for age	18 (28)
With associated physical anomalies	11 (17)
Isolated growth retardation	7 (10)

Fig. 2.1 Diamond–Blackfan anemia (DBA) facies: similarity in appearance between unrelated children with DBA. Reproduced with permission from Ref. 17.

Growth retardation

Over 60% of children reported in the UK DBA registry were below the 25th centile for height at the time of study, 28% being below the 3rd centile⁴ (Table 2.1). Of affected children, 10–30% have low birthweight prior to the onset of anemia or starting steroid therapy,^{4,5,19} and short stature is then likely to persist.⁴ Short stature can therefore be considered to be part of the spectrum of physical anomalies, although the final height achieved by each affected individual will be influenced by other factors, notably steroids and iron overload. Growth hormone therapy has been reported to be of benefit in the management of impaired pubertal growth in DBA.^{20–22}

Laboratory investigation of DBA

Red cell indices

The anemia at presentation may be normocytic or macrocytic. The mean corpuscular volume (MCV) is usually within the normal range for neonates,¹⁵ while children presenting after the first few months are more likely to have macrocytosis. The anemia is, by definition, associated with reticulocytopenia. The white blood cell count is usually normal at presentation, and platelets are normal or raised. However, trilineage marrow failure may become evident with increasing age.^{23–25} Fetal characteristics of red cells frequently persist after re-

sponse to therapy, in the form of raised MCV, high levels of fetal hemoglobin (HbF) and increased expression of i antigen.²⁶ These may be useful in the diagnosis of difficult cases, but are relatively nonspecific, and notably can occur during the recovery phase of TEC,²⁷ as discussed below.

Bone marrow findings

Bone marrow aspirate reveals a cellular marrow, with an isolated reduction in erythroid precursors, with normal myeloid and megakaryocytic differentiation.

Erythrocyte adenosine deaminase (eADA)

High eADA activity is present in a high proportion of patients with DBA.^{28–34} eADA activity is not raised in normal cord blood,³¹ nor in juvenile chronic myeloid leukaemia²⁸ despite the fetal pattern of erythropoiesis characteristic of that disorder.³⁵ However, eADA activity may also be high in other disorders, including leukemia and myelodysplastic syndromes,^{36,37} and so cannot be considered a specific marker for DBA. Its measurement, however, may be useful in establishing family phenotypes for genetic studies as discussed further below.

Inheritance and genetics

There is a positive family history in 10–20% of babies presenting with DBA.^{3–6} The pattern of inheritance is typically autosomal dominant,^{33,34,38–41} although recessive inheritance has been inferred in families with parental consanguinity. There has been an increasing recognition that the phenotypic spectrum of DBA is broader than that of the classical presentation of severe red cell aplasia presenting in early infancy. It is now recognized that an isolated increase in eADA activity may be the only manifestation of DBA.^{33,34} As a result, detailed family studies have revealed a higher proportion of cases of familial DBA than previously appreciated. For example, in a UK DBA Registry study, hematologic abnormalities, including raised eADA activity, were found in first-degree relatives of 31% of patients not previously considered to have familial DBA.³⁴ Inheritance was most consistent with an autosomal dominant pattern, with incomplete penetrance.

While there is no specific karyotypic abnormality associated with DBA, a *de novo* balanced t(X;19) translocation was described in a sporadic case of DBA.⁴² Linkage was established to 19q in familial DBA,⁴³ although with evidence of genetic heterogeneity.^{44,45} Analysis of the 19q breakpoint led to the identification of the gene encoding ribosomal protein S19 (*RPS19*) as the first DBA gene.⁴⁶ *RPS19* mutations have subsequently been identified in up to 25% of patients with DBA, both sporadic and familial.^{34,47–51} Linkage studies have identified a possible second DBA locus on chromosome 8 in families without *RPS19* mutations, but there are also multiplex families in which DBA cosegregates with neither 8p nor 19q, showing that there must be at least three genes

responsible for DBA.⁵² Several studies have found that it is not possible to distinguish between patients with and without *RPS19* mutations on the basis of clinical phenotype.^{34,47–51}

Pathogenesis

The typical clinical response to steroids in DBA was initially interpreted as reflecting an immune-mediated suppression of erythropoiesis, despite the general lack of efficacy of other immunosuppressive agents. However, there is no consistent *in vitro* evidence to support the existence of a humoral inhibitory agent,⁵³ nor of cell-mediated inhibition of erythropoiesis.⁵⁴ Observations interpreted as showing immune suppression of erythropoiesis in DBA^{55–57} may in fact be attributable to transfusion-related alloimmunization.

The primary pathophysiology of DBA is now generally accepted to be due to an intrinsic defect in erythropoiesis. Strong support for this comes from the demonstration of impaired erythroid differentiation *in vitro* of enriched erythroid progenitor cells⁵⁸ and of purified CD34⁺ cells⁵⁹ from patients with DBA. The success of stem cell transplantation in DBA⁶⁰ provides additional *in vivo* evidence for an intrinsic defect. Further important supportive evidence comes from the partial correction of the *in vitro* abnormality in erythroid maturation and proliferation by the induced expression of the wild-type *RPS19* gene in CD34⁺ cells carrying an *RPS19* mutation.^{61,62}

The timing and molecular basis of the erythroid defect have not yet been fully defined. Short-term erythroid colony assays have revealed a variable deficiency in burst-forming unit erythroid (BFU-E) and colony-forming unit erythroid (CFU-E)⁶³ in DBA,^{53,64–66} with partial correction *in vitro* in response to IL-3 and to stem cell factor (kit ligand; SCF).^{67–71} However, the *in vitro* response to IL-3 did not correlate with clinical efficacy in subsequent trials of recombinant IL-3.^{72–75} In a two-phase liquid erythroid culture system,⁷⁶ it was observed that the pre-erythropoietin stage of erythroid commitment was intact,⁷⁷ while the erythropoietin-dependent phase of erythroid expansion and maturation was defective.

This could be partially corrected by steroids, although again with poor *in vivo–in vitro* correlation.⁷⁷

RPS19 mutations might cause DBA by an effect on ribosomal function, whether by a global effect on translation, or by a more selective influence on the translation of a critical protein.⁷⁸ However, there is also increasing evidence that ribosomal proteins may also have extraribosomal functions.⁷⁹ The future identification of the gene responsible for linkage to 8p⁵² will be an important step in the elucidation of the role of *RPS19* mutations in the as yet elusive pathogenesis of DBA.

Treatment

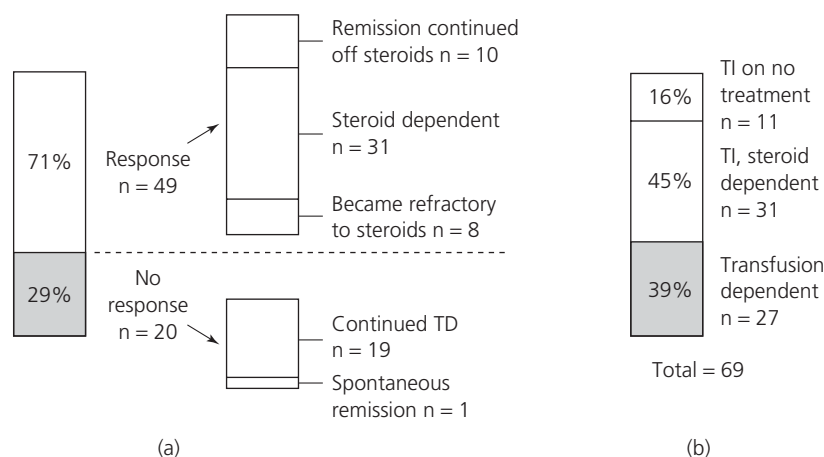

Steroids

Steroids remain the mainstay of treatment in DBA more than half a century after the original report of their efficacy.⁸⁰ Prednisolone is usually started at a dose of 2 mg/kg, to which up to 70% of patients show a good initial response in that they achieve transfusion-independence (Fig. 2.2).^{4–6,13,19} An increase in reticulocytes is usually seen within 2 weeks, but a rise in hemoglobin may take up to 1 month. In some other cases, a transient reticulocytosis is seen, but transfusion-independence is not achieved.

In responders, the dose may then be gradually tapered to determine the minimum alternate-day dosage required for continuing transfusion independence. Hemoglobin levels of 8–9 g/dL are often the highest that can be achieved, but may be acceptable provided that growth and normal activity are not compromised. Macrocytosis and markers of fetal erythropoiesis generally persist during response to treatment.^{4,19} The maintenance dose of prednisolone in steroid responders is highly variable, some children requiring extremely small doses. Steroids may be stopped completely in some cases, although there is usually a persistent mild macrocytic anemia with raised eADA activity. Steroid-independent remission with completely normal hematologic parameters including normal eADA suggests the original diagnosis may have been TEC rather than DBA.

Steroid therapy may have to be discontinued in responders

Fig. 2.2 Initial response to steroids (a) and subsequent treatment status (b) of 69 children with Diamond–Blackfan anemia born in the UK over the 20-year period 1975–1994.⁴ TI, transfusion independent; TD, transfusion dependent.

in the presence of unacceptable side-effects, including growth suppression. Growth curves should be closely monitored, especially during periods of high growth velocity in infants and at puberty. A growth plateau may indicate that steroids should be interrupted and substituted with a short-term transfusion program. In babies, the need for relatively high doses and prolonged duration of steroid therapy should be balanced against the possible detrimental effect on growth and motor developmental milestones. It may be preferable to wait until the patient has reached the age of one year before initiating steroids. Delaying steroid therapy has the additional advantage of allowing immunization against chicken pox, which otherwise carries a risk of serious and potentially fatal complications as a consequence of long-term steroid therapy started before natural immunity has developed. Active immunization with attenuated varicella vaccine may be considered,⁸¹ although varicella vaccine is not currently licensed in the UK. If the child is not immune, families should be advised to seek urgent medical attention following exposure to chickenpox, for treatment with aciclovir and/or varicella-zoster immunoglobulin.

Transfusion program

Of children and adults with DBA, 40–50% are dependent on long-term transfusion programs (Fig. 2.2), having failed to respond to steroids, having become refractory, or because of unacceptable steroid side-effects.^{4–6,13,19} An immunization program against hepatitis B should therefore be initiated as soon as possible after diagnosis. Chelation therapy forms an essential part of a long-term transfusion program as iron overload contributes significantly to morbidity and mortality in this patient group (see Chapter 13).^{5,15} Transfusion programs may also be associated with problems of venous access; two deaths reported by the French registry,⁵ and one in the UK,⁴ have been attributed to sepsis of indwelling central venous lines.

Megadose methylprednisolone

There have been anecdotal reports of response to extremely high doses of methylprednisolone in DBA.^{82,83} However, a prospective study of oral megadose (100 mg/kg) methylprednisolone failed to demonstrate a clinically significant benefit.⁸⁴ The low chance of response and the significant risk of side-effects, including serious infection, preclude the routine use of megadose steroids in children who fail to respond to conventional doses.

Interleukin-3

Clinical trials of interleukin-3 (IL-3)^{72–75} were prompted by the finding that IL-3 can enhance *in vitro* erythropoiesis. Combined results from 77 patients reported in the literature revealed a disappointingly low response rate of only 11%,⁷⁵ although IL-3 and steroid-independent remission persisted for longer than 3 years in at least two patients.^{72,75} Further trials of IL-3 have not been attempted in view of the low chance

of response, difficulties in obtaining recombinant IL-3 for clinical use, and increasing recognition of the long-term risk of acute myeloid leukemia (AML) in DBA.^{15,85,86} Treatment with stem cell factor has not been attempted, despite an often striking *in vitro* response,^{67–71} for similar reasons.

Prolactin

Pregnancy or the oral contraceptive pill may exacerbate the anemia of DBA,^{10,11} and transfusions may be required during pregnancy in women who are normally steroid responsive. However, the anemia in one woman was found to remit during late pregnancy and for the duration of breastfeeding, a pattern suggestive of a prolactin effect.⁸⁷ She subsequently responded to metoclopramide, which had been selected because of its known side-effect of hyperprolactinemia. A pilot study suggested potential benefit of metoclopramide in a proportion of patients with DBA,⁸⁷ a finding which is being further tested in larger scale clinical trials.

Other therapies

Ciclosporin (cyclosporin),⁸⁸ erythropoietin,^{89,90} intravenous immunoglobulin,⁹¹ androgens or splenectomy have been used with some reports of success in anecdotal cases, but without consistent evidence of benefit. Prior splenectomy or androgen therapy were in fact associated with significantly worse survival in a follow-up study of patients treated at a single center over a 60-year period.¹⁵ Splenectomy may still be indicated in the event of an increased transfusion requirement secondary to hypersplenism.

Spontaneous remission

The 20–30% incidence of “spontaneous remission” described in the literature includes individuals who require no therapy following an initial response to steroids,⁴ and who probably represent the milder end of the phenotypic spectrum of DBA.^{33,34} However, true spontaneous remission may occur in severe cases of DBA, even following several years of transfusion-dependence, albeit with persistent macrocytosis and high eADA. The true incidence is not known, but the UK Registry includes only one unequivocal example.

Bone marrow transplantation

Bone marrow transplantation (BMT) is potentially curative in DBA,^{60,92–96} with 75–85% long-term survival reported following matched sibling donor BMT,^{60,95,96} including successful outcome from cord-blood transplant.⁹⁷ BMT can therefore be considered an option for transfusion-dependent patients where there is a suitable donor, although BMT from other than matched sib donors carries a worse prognosis, and is not currently recommended.⁶⁰ The chance that a spontaneous remission may occur in DBA often influences the decision to undertake BMT in an individual case, but against this must be balanced the increased long-term risk of AML,^{15,85,86} which is still apparent after spontaneous

remission.¹⁵ Risk stratification for BMT in thalassemia, which is significantly influenced by the degree of iron overload,⁹⁸ is probably equally applicable to DBA.

The existence of a mild or clinically silent DBA carrier phenotype^{33,34} in the donor presents a particular hazard in sibling donor transplants,^{99,100} unless the proband has an *RPS19* mutation, for which the donor can be tested. As a minimum, a potential family donor should be confirmed to have normal hemoglobin and MCV, and normal eADA activity, including the new baby in the case of sibling cord-blood transplantation.

Prognosis

Many adults with DBA who are stable on small doses of steroids or who achieve spontaneous remission are often lost to follow-up, and representative data on long-term prognosis are hard to collate. Prospective data derived from national registries will be particularly valuable in this context.

Janov *et al.*¹⁵ analyzed 76 patients with DBA seen at Boston Children's Hospital over a 60-year period. The median survival for the entire group was 38 years, with a significantly worse prognosis for those treated before the routine use of steroids in 1960. Many deaths were directly or indirectly attributable to iron overload, a finding echoed in the data from the French DBA registry,⁵ underscoring the need for adequate chelation in this group. AML developed in 4 of 76 of the Boston patients, 1 of whom had previously received radiotherapy, and a further patient developed aplastic anemia.¹⁵ Aplastic anemia has also been reported in 2 of 132 French patients,⁵ and neutropenia and thrombocytopenia are relatively common after the first decade.²⁵ There is thus evidence for progressive hemopoietic stem cell dysfunction, which is also reflected in the reduced *in vitro* cloning efficiency of myeloid progenitors in DBA with increasing patient age.²⁴ These long-term marrow complications further endorse the use of stem cell transplantation in this patient group.

Patients with DBA are probably also at increased risk of developing nonhemopoietic malignancies.^{6,101–104} In particular, there have been reports of osteogenic sarcoma occurring at an unusually young age,^{6,104} although determination of the actuarial risk will depend on representative population-based data generated by DBA registries.⁶

Transient erythroblastopenia of childhood

Transient erythroblastopenia of childhood (TEC) is an acquired, self-limiting red cell aplasia unique to childhood, which was recognized as a clinical entity in 1970.^{105,106} One regional study in the UK of red cell aplasia in childhood over a 7-year period suggests an incidence of 5 per million per year.¹⁰⁷

Clinical features

The usual presentation is a previously fit child up to the age

of 5 years, with gradual onset of symptoms of anemia. The commonest age at presentation is 2 years, but TEC has also been described in infants under the age of 6 months.^{108,109} TEC thus tends to present in an older age group than DBA, although there is some overlap. Boys and girls are equally affected, and there is no ethnic predominance. Unlike DBA, there are no associated physical anomalies, and affected children are generally of normal stature.¹¹⁰ Transient neurologic abnormalities, including seizures and hemiparesis, have occasionally been described in association with otherwise typical TEC.^{111–113}

Hematologic findings

The anemia of TEC is normochromic and normocytic and is characterized by reticulocytopenia, although macrocytosis may occur during recovery, and reticulocytosis may be noted if recovery has already started by the time of presentation. In one study, more than 25% of children with TEC were already in the recovery phase at the time of presentation.¹¹⁴ Raised levels of HbF and expression of i antigen have been reported during recovery,²⁷ but eADA levels should be normal.¹¹⁵

There is a high incidence of neutropenia in TEC. In one study of 50 patients, 64% had a neutrophil count below $1.5 \times 10^9/L$, and in 28% this was below $1.0 \times 10^9/L$.¹¹⁴ The platelet count is usually normal, although thrombocytopenia has been documented in some cases of TEC following parvovirus infection.^{116,117}

Bone marrow examination reveals a normocellular marrow with erythroid hypoplasia; the presence of left-shifted erythropoiesis with apparent maturation arrest suggests early recovery. Myeloid maturation appears normal, despite the frequent association with neutropenia.

Serum lactate dehydrogenase, bilirubin and serum haptoglobin levels are normal in TEC. If there is evidence of hemolysis, the alternative diagnosis of an acute aplastic crisis on the background of a previously unrecognized hemolytic anemia should be considered.

Red cell enzyme activities tend to be low at the nadir of TEC,^{118,119} consistent with an older red cell population in the absence of new red cell production. Similarly, glycosylated hemoglobin (HbA_{1c}) is likely to be raised.¹²⁰ It should be remarked that HbA_{1c} levels will be influenced by recent transfusions. Although these tests might theoretically aid discrimination between acute erythroblastopenia and chronic hypoplastic anemia, in practice it is seldom necessary to do more than the basic investigations.

Etiology and pathophysiology

Many children give a history of an antecedent viral infection, and there have been varying reports of seasonality in TEC,^{121,122} but no consistent pattern has emerged. Although viral serology may reveal evidence of recent infection, for

example echovirus,¹²³ adenovirus or parainfluenza,¹⁰⁷ no specific candidate agent has been implicated. These findings do not suggest a direct viral etiology for TEC and are more consistent with a postviral process, presumably immune-mediated, analogous to childhood idiopathic thrombocytopenic purpura (ITP).¹²⁴ This is supported by *in vitro* culture results. Erythroid colony numbers may be normal or reduced, and serum inhibitors of erythroid colony formation have been detected in a high proportion of cases of TEC.^{125–127} Cell-mediated suppression of erythroid colony formation has also been reported.^{127,128}

Treatment and prognosis

Spontaneous, complete recovery of TEC usually occurs within 4–8 weeks of presentation and recurrence is rare.¹²⁹ A peak reticulocyte response is usually seen within a month of presentation, and some children will already have entered the recovery phase at the time of diagnosis.¹¹⁴ A raised MCV and increased red cell distribution width (RDW) accompany the reticulocytosis, but after recovery the steady-state hemoglobin and red cell indices are normal. Any associated neutropenia also resolves and no complications due to infection have been reported. All reported cases with neurologic abnormalities recovered fully, with no neurologic sequelae.

Transfusion may be necessary at the nadir of TEC, but the decision to transfuse should be made on clinical grounds, rather than the hemoglobin level, given the gradual onset of anemia and predicted early recovery. There is no indication to treat TEC with steroids or intravenous immunoglobulin.

Differential diagnosis of TEC

Parvovirus infection

There is usually no serologic evidence of recent infection with parvovirus B19.¹¹⁴ However, occasional cases of a TEC-like hypoplastic anemia have been reported following parvovirus infection. These tend to differ a little from typical TEC in that both thrombocytopenia and neutropenia may occur and the marrow may be hypocellular.^{116,117} The pathogenesis of parvovirus-associated TEC might reflect direct marrow suppression, equivalent to the acute aplastic crisis of chronic hemolytic anemias, rather than sharing the probable immune-mediated process underlying TEC that follows other viral infections. Certainly, parvoviral infection of hematologically normal volunteers causes neutropenia and thrombocytopenia as well as reticulocytopenia.¹³⁰

DBA spectrum

Transient anemia in childhood may be the only clinical manifestation of DBA in some individuals, as observed in families with incomplete penetrance and variable phenotype,^{33,34} although eADA activity is usually persistently raised. This

may provide one explanation for the occurrence of TEC in more than one sibling,^{131–133} which may otherwise be the effect of clustering.

Parvovirus-associated acute acquired red cell aplasia (aplastic crisis)

Transient erythroid hypoplasia caused by parvovirus infection underlies the aplastic crisis that may occur in hemolytic anemias, first recognized in association with hereditary spherocytosis (HS).¹³⁴ The presentation is usually that of an acute onset of symptoms of anemia in a child with a pre-existing hemolytic anemia, often with a febrile illness during the preceding week, but without exacerbation of jaundice. The duration of reticulocytopenia is generally 7–10 days, and this resolves with the emergence of an antibody response. Children are infectious during this time and therefore represent a risk to other children with hematologic or immunologic abnormalities. The risk to staff, especially early in pregnancy, should also be considered.¹³⁵

Etiology and pathogenesis

An infectious etiology for the aplastic crisis in patients with an underlying hemolytic process was inferred from clustering of cases. The realization that the illness has a relatively well-defined pattern and usually occurs only once in each individual, suggested that a single infectious agent was largely responsible. Parvovirus B19 was first discovered in the serum of normal blood donors,¹³⁶ and was subsequently linked to aplastic crisis in sickle-cell anemia.^{137,138} Although the majority of aplastic crises are attributable to parvovirus, in a small percentage of cases there is no evidence of B19 infection¹³⁹ and other infections may be responsible.

The red cell aplasia associated with parvovirus is the result of direct viral infection of the erythroid progenitor cell. The tropism of parvovirus B19 for erythroid cells, at all stages of maturation,¹⁴⁰ is explained by the identification of the erythrocyte P antigen (globoside) as the parvovirus receptor.¹⁴¹ The virus inhibits erythroid colony formation,¹⁴² and is cytotoxic for erythroid progenitor cells at the colony-forming unit erythroid (CFU-E) stage *in vitro*.¹⁴³

Any event leading to an interruption of erythropoiesis, however short, is likely to cause profound anemia in the presence of a shortened red cell lifespan. Thus a precipitous, potentially fatal fall in hemoglobin may be sustained by children with a severe underlying hemolytic process, such as homozygous sickle-cell disease, in which the steady-state hemoglobin may be as low as 6–7 g/dL despite massive erythroid expansion. Alternatively, a period of erythroid hypoplasia may induce anemia on a background of otherwise well-compensated hemolysis, as in mild HS, and can be the event leading to the diagnosis of the hematologic disorder. The transient anemia is usually clinically inapparent

when the red cell lifespan is normal.¹⁴⁴ However, parvovirus-induced acute exacerbation of anemia may also occur in nonhemolytic anemias, including iron deficiency,¹⁴⁵ and has been described in a patient with DBA.¹⁴⁶

Hematologic features

The aplastic crisis is characterized by a decrease in hemoglobin in association with reticulocytopenia, but neutropenia and thrombocytopenia may also occur. Bone marrow aspirate, although rarely required for diagnosis, shows erythroid hypoplasia, often with characteristic giant basophilic proerythroblasts, which are up to 100 μm in diameter with prominent nucleoli.

Chronic parvovirus B19 infection

Parvovirus B19 infection in the absence of an effective antiviral immune response may cause prolonged rather than transient red cell aplasia.^{147–152} This has been described in association with AIDS,¹⁵⁰ as well as in children with congenital immune deficiency disorders.¹⁵¹ Hemophiliacs who are HIV-positive may be particularly vulnerable as parvovirus can persist in factor concentrates despite solvent-detergent treatment.¹⁵³ Severe chronic anemia may also result from parvovirus infection in children receiving chronic immunosuppressive therapy, including chemotherapy for acute lymphoblastic leukemia (ALL).¹⁵² Chronic parvovirus infection may occur in the absence of other evidence for an immunocompromised state,¹⁵⁴ and should be considered as a cause of chronic acquired red cell aplasia even in the absence of other evidence for immune deficiency. Bone marrow aspirate may reveal the giant typical pronormoblasts. Viral serology is unreliable in the diagnosis of parvovirus-induced chronic red cell aplasia, as affected patients often fail to mount an antibody response.¹⁴⁹ The diagnosis may be confirmed by direct detection of parvovirus DNA in serum or bone marrow.¹⁵⁵

Intravenous immunoglobulin can be effective in decreasing parvoviremia and restoring bone marrow erythroid activity,¹⁵⁶ although repeated courses may be necessary.

Chronic acquired red cell aplasia

Chronic acquired pure red cell aplasia (PRCA) is rare in children; in a regional study of 33 children with red cell aplasia, none had “adult-type” PRCA.¹⁰⁷ However, it should be considered, especially in older children without features of DBA, and in whom chronic parvoviremia has been excluded. When a diagnosis of PRCA is considered, appropriate investigations should be undertaken to exclude any underlying cause.

Chronic PRCA may be idiopathic in both children and adults, or associated with autoimmune, viral and neoplastic

disorders, including acute lymphoblastic leukemia¹⁵⁷ and juvenile chronic arthritis.¹⁵⁸ Despite the classical association,¹⁵⁹ thymoma is relatively rare.¹⁶⁰ Many drugs have been associated with PRCA;¹⁶¹ among those with particular relevance to pediatric practice are carbamazepine,^{162,163} phenytoin,¹⁶⁴ and sodium valproate.¹⁶⁵ Resolution of the anemia usually follows withdrawal of the relevant drug.

The pathogenesis of chronic acquired PRCA is likely to be autoimmune. Both antibody-mediated^{166,167} and cell-mediated^{168–170} mechanisms of erythroid suppression have been demonstrated.¹⁷¹ Red cell aplasia has been reported in some patients treated with recombinant human erythropoietin (epoetin), secondary to the development of anti-epoetin antibodies, which cross-react with and thus neutralize endogenous erythropoietin.^{172–175} This should be considered as a possible cause of PRCA, especially in children with chronic renal failure. Withdrawal of epoetin is not sufficient in this context, and immunosuppressive therapy is usually necessary.

Treatment of chronic PRCA is thus directed at the underlying cause, with the use of immunosuppression where appropriate. In idiopathic chronic PRCA the remission rate with steroids is of the order of 40%.¹⁶⁰ Ciclosporin and other forms of immunosuppressive therapy may be effective in patients who fail to respond to steroids.^{160,176} The demonstration of normal colonies in clonogenic assays *in vitro* may be predictive of clinical response.^{177,178} Plasmapheresis has been found to be effective in some cases,¹⁷⁹ providing further evidence for humoral-mediated suppression of erythropoiesis.

Differential diagnosis of red cell aplasia in childhood

DBA vs. TEC

Despite the difference in their typical age of onset of anemia, TEC may occur in the first year of life,^{108,109} and DBA may present later than infancy.^{4,33,34} The distinction between TEC and sporadic DBA is straightforward in the presence of a positive family history or characteristic physical anomalies, or if there is an *RPS19* mutation. Neutropenia at presentation is more consistent with a diagnosis of TEC.¹¹⁴ Measurement of red cell ADA levels may be helpful, and persistence of anemia and macrocytosis in remission also favor the diagnosis of DBA,¹¹⁸ although fetal characteristics of erythropoiesis in the form of raised MCV, high HbF and i antigen expression may also occur during the recovery phase of TEC.²⁷ When there is doubt it may be appropriate simply to observe the patient for a few months, rather than starting steroids immediately, as a response to steroids may be coincidental with the recovery of TEC, or reflect the likely immune-mediated red cell aplasia in TEC. A firm diagnosis of TEC is often only made retrospectively, after recovery of a normal blood count and normal red cell indices.

DBA vs. parvovirus B19

Parvovirus infection during pregnancy is associated with hydrops fetalis at all gestational ages,¹⁸⁰ while hydrops is a very rare presentation of DBA.⁷⁻⁹ In addition, physical anomalies are an unlikely consequence of intrauterine parvovirus infection.¹⁸¹ However, parvovirus infection should be excluded in a new case of presumed DBA by viral serology (IgM and IgG) in both mother and infant. As chronic red cell aplasia is more likely in the absence of an effective immune response to parvovirus,¹⁴⁹ polymerase chain reaction (PCR) amplification of viral nucleic acid from presentation bone marrow should also be performed.

DBA vs. chronic acquired PRCA

The distinction between late-presenting DBA and chronic acquired PRCA may be difficult in the absence of physical anomalies or a positive family history. Both may be associated with macrocytosis, but raised eADA activity would favor a diagnosis of DBA.

DBA vs. alloimmune erythroid hypoplasia

Maternal anti-Kell alloimmunization may result in profound fetal anemia, but with relative reticulocytopenia,¹⁸² consistent with erythroid progenitor suppression.^{183,184} This is analogous to the pure red cell aplasia that may occur after ABO-incompatible bone marrow transplantation, and which is probably mediated by residual recipient isohemagglutinins.^{171,185} Maternal and infant blood group serology should therefore be included in the investigation of babies with presumed DBA who are anemic at birth.

DBA vs. other congenital syndromes of marrow failure (see Chapter 3)

DBA and Fanconi anemia have an overlapping spectrum of physical anomalies,¹⁸⁶ and macrocytic anemia may be an early hematologic manifestation of Fanconi anemia.¹⁸⁷ In practice, the distinction is rarely difficult and is resolved by the demonstration of increased chromosome breakages in response to clastogenic agents in Fanconi anemia.¹⁸⁸ Neutropenia is a more consistent hematologic finding than anemia in children with Shwachman–Diamond syndrome, who will also have evidence of exocrine pancreatic dysfunction. The majority of patients with Shwachman–Diamond syndrome have mutations affecting the *SBDS* gene.^{189,190} *SBDS* mutation analysis may therefore be useful in cases of uncertainty.

Congenital dyserythropoietic anemias

The congenital dyserythropoietic anemias (CDAs) are

uncommon hereditary disorders of erythropoiesis in which there is chronic mild-to-moderate anemia on a background of erythroid hyperplasia and ineffective erythropoiesis,¹⁹¹ associated with characteristic morphologic changes in the bone marrow.^{192,193} The CDAs have been classified into three main types based on morphologic and serologic findings,^{194,195} but there is clearly heterogeneity within the types, and many individual cases of CDA have been reported that do not fit into this classification.^{193,195}

The ineffective erythropoiesis in CDAs is associated with intramedullary destruction of red cell precursors, with elevation of the serum bilirubin and lactic dehydrogenase (LDH). The serum haptoglobin is usually reduced. There is a marked tendency to increased iron absorption,¹⁹⁶ the consequence of expanded erythropoiesis, which can lead to iron overload and organ damage. Soluble transferrin receptor levels are likely to be raised, in the absence of iron deficiency, reflecting the degree of erythroid expansion in the presence of ineffective erythropoiesis.^{197,198}

The management of an individual patient depends on the CDA subtype, the degree of anemia and the extent of iron loading. The majority of cases of CDA have a benign course, but severe variants may present as hydrops fetalis or neonatal jaundice and require exchange transfusion. In common with other disorders of red cell production, patients with even relatively mild CDA are susceptible to parvovirus-induced aplastic crisis.

The clinical and laboratory findings characterizing the three main types of CDA are described below and are summarized in Table 2.2.

Congenital dyserythropoietic anemia type I (CDA I)

Clinical features

There is usually mild anemia with slight icterus and a palpable spleen,^{199,200} which may slowly enlarge with increasing age. Physical anomalies may be present, most typically in the form of skeletal abnormalities affecting the hands or feet, with syndactyly and absence of distal phalanges and nails.^{201,202} Neurologic abnormalities have also been described.²⁰³ Significant iron loading may occur, even in the presence of only mild anemia, and there is an increased risk of gallstones.

Laboratory findings

The hemoglobin is usually between 8 and 11 g/dL, but milder or more anemic cases may be seen. There is macrocytosis (MCV 95–120 fL), with striking anisocytosis and poikilocytosis on the blood film. Reticulocytes are reduced in number for the degree of anemia. Cabot rings, a thin circle of nuclear remnant within the circulating red cells that stains purple with Romanowsky stains, may be seen in CDA I, most conspicuously in splenectomized patients.^{204,205} White cells

Table 2.2 Comparison of the three main types of congenital dyserythropoietic anemia

	CDA I	CDA II (HEMPAS)	CDA III
Inheritance	Autosomal recessive	Autosomal recessive	Autosomal dominant
Gene	<i>CDAN1</i> (15q)	Linkage to 20q, but genetic heterogeneity	Linkage to 15q in Swedish kindred
Associated anomalies	Syndactyly, absent distal phalanges, neurologic abnormalities	Uncommon, variable learning difficulties	Monoclonal gammopathies, retinal abnormalities
Anemia	Mild to moderate	Mild to moderate	Mild
Iron loading	High risk	High risk	Unusual
MCV	Increased	Slight increase	Normal or mild increase
Bilirubin	Increased	Increased	Normal or mild increase
Bone marrow morphology	Megaloblastic changes affecting early and late erythroblasts Internuclear bridging	Multinuclearity of intermediate and late erythroblasts	Gigantoblasts
Electron microscopy	Spongy chromatin ("Swiss cheese" appearance) Invagination of cytoplasm into nuclear region	Cisternae and "double membrane"	Nuclear clefts Autolytic areas in cytoplasm
Acidified serum lysis	Negative	Positive (selected sera)	Negative
Anti-i reaction	Negative	++	Variable
Treatment	α -Interferon, prevention of iron overload	Splenectomy, prevention of iron overload	Screen for monoclonal gammopathy, ophthalmic review

and platelets are normal in number, morphology and function. Unconjugated bilirubin is elevated, usually 2–3 times normal, and serum LDH is raised.²⁰⁰ The acidified serum lysis test is negative and the expression of i and I antigens on the red cell surface is within the normal adult range. HbF levels are usually within the normal range or only slightly raised (0.5–2.0%), although occasional individuals with higher levels (up to 6.0%) may be found.

The characteristic features of CDA I are apparent on the bone marrow aspirate, which is generally hypercellular with erythroid hyperplasia. Both early and late erythroblasts are characterized by anomalies of nuclear division with, most characteristically, incompletely separated normoblasts connected by an internuclear bridge.²⁰⁶ Abnormalities of nuclear chromatin condensation may make the erythropoietic changes appear megaloblastic, but giant myeloid cells and hyperlobulated megakaryocytes are absent. Iron staining may show increased storage iron and sideroblasts, but ringed sideroblasts are not a usual feature of CDA I.¹⁹⁶

Electron microscopy

Electron microscopy of erythroblasts in CDA I typically shows a spongy appearance of heterochromatin (so-called "Swiss cheese" appearance), increased nuclear pore size and invaginations of the nucleus resulting in cytoplasm with some hemoglobin intruding into the nuclear region. These changes are not apparent in very early erythroblasts.^{206,207}

Inheritance and genetics

CDA I is inherited as an autosomal recessive disorder.^{199,208} The gene responsible for CDA I in a large Bedouin kindred was localized to chromosome 15,²⁰⁸ 20 and subsequently identified as *CDAN1*.²⁰⁹ Mutations affecting *CDAN1* have also been identified in unrelated CDA I patients. *CDAN1* encodes codanin-1, but its function and role in normal erythropoiesis and in the pathogenesis of CDA I have yet to be elucidated.

Management of CDA I

The majority of patients with CDA I have a mild anemia, which requires no specific treatment. However, progressive iron loading can occur, even in patients who are transfusion-independent, and regular monitoring is essential. Chelation therapy may be indicated.

Occasionally, patients may become more anemic as they get older, possibly because of progressive enlargement of the spleen and pooling of red cells. Splenectomy has been successful in ameliorating the anemia in some of these patients, but it is not generally recommended in CDA I.

Interferon- α (IFN- α) was found by chance to improve the anemia in a patient with CDA I being treated for transfusion-acquired hepatitis C infection. Erythrokinetic studies demonstrated a reduction of the ineffective erythropoiesis, and there was an improvement in the morphologic abnormalities

seen on electron microscopy.²¹⁰ IFN- α has subsequently been used with beneficial effect in other cases of CDA I,²¹¹ with no apparent loss of effect on prolonged treatment.²¹² It is not clear whether IFN- α therapy might also prevent iron loading in nonanemic patients with CDA I. While IFN- α has been used successfully to treat severe CDA I presenting in infancy,²¹³ there remain concerns about neurologic side-effects, especially in very young children.^{214,219} The mechanism of action of IFN- α in this context is not known, although lymphoblastoid cell lines generated from patients with CDA I, but not other types of CDA, have been shown to produce low levels of IFN- α .²²⁰

Congenital dyserythropoietic anemia type II

Clinical features

CDA II, or hereditary erythroblastic multinuclearity with positive acidified serum test (HEMPAS),²²¹ is commoner than CDA I, and has been described in most ethnic groups. Associated physical abnormalities may be present, although less common than in CDA I. Learning difficulties probably represent the most consistently reported nonhematologic manifestations.²²² There is a broad spectrum in the clinical presentation of CDA II. The majority of patients have mild-to-moderate anemia with jaundice and splenomegaly.

Like hereditary spherocytosis,^{223,224} the anemia of CDA II is more severe in infancy. Anemia is present from birth in 23% of affected babies, and neonatal jaundice to the extent of requiring treatment is common. Over 30% of patients reported to the International CDA II Registry required transfusions during the first year of life, although only 5 of 88 remained transfusion dependent.²²⁵ Severely affected children may have considerable medullary hyperplasia leading to facial deformities, analogous to those seen in β -thalassemia. Extramedullary hemopoiesis may occasionally occur.²²² In less severely affected individuals, jaundice may be the only clinical finding. Gallstones are common, presenting at a young age.²²² Of the different types of CDA, CDA II carries the highest risk of iron overload, with liver cirrhosis, diabetes and cardiac failure in later life.^{226,227}

Inheritance and genetics

CDA II is also inherited as an autosomal recessive disorder,^{208,221,228} but the gene or genes responsible have not yet been identified. Linkage analysis identified a putative locus on chromosome 20 in families from southern Italy,²²⁹ but there is likely to be genetic heterogeneity.²³⁰

Laboratory findings

There is wide variation in the degree of anemia, both between different families and between siblings. The MCV is

normal or slightly increased. The reticulocyte count is usually normal, or may be modestly raised. The blood film usually shows red cell anisocytosis, acanthocytes and basophilic stippling, and there may be occasional circulating binucleate normoblasts.

Unconjugated bilirubin is raised, and serum haptoglobin levels are low or undetectable. Impaired liver function tests may be secondary to cholelithiasis, or to hepatic iron loading. Serum ferritin levels increase with age, although with considerable individual variation. In a longitudinal study of 48 patients, the mean age at initiation of chelation therapy was 20 years (range 7 to 35 years).²²²

The characteristic feature of the red cells in CDA II, which gives the syndrome its acronym HEMPAS, is their lysis by acidified serum from some but not all normal individuals. The patient's own serum will not cause lysis, which helps to distinguish the syndrome from paroxysmal nocturnal hemoglobinuria. The test is also negative with sera from obligate heterozygotes.^{231,232} It is thought that CDA II cells express an abnormal antigen to which approximately 40% of normal sera contain a complement-fixing IgM antibody, but the nature of this antigen has not been determined. CDA II red cells may also have abnormal complement activation control.²³³

CDA II red cells are strongly agglutinated by anti-i sera, even in adult life; I antigen is expressed normally.^{221,232}

There are characteristic morphologic features of CDA II on bone marrow aspirate. There is erythroid hyperplasia, with binuclearity or multinuclearity affecting intermediate and late erythroblasts, the nuclei being equal in size and DNA content. Pseudo-Gaucher macrophages may be observed.²²²

Electron microscopy

Electron microscopy reveals a characteristic double membrane effect, caused by a linear structure running parallel to the plasma membrane, caused by residual endoplasmic reticulum.^{234,235} Such changes are not unique to CDA type II, and may be seen to a lesser extent in other hemoglobinopathies.²³⁶

Pathogenesis

The underlying defect in CDA II is a failure of normal glycosylation of membrane proteins,²³⁷ particularly band 3, the anion channel of the red cell. Polyacrylamide gel electrophoresis (PAGE) has shown that band 3 protein from CDA II red cells migrates faster than normal,^{238,239} the reduction in molecular weight being the result of loss of glycosyl residues rather than an abnormal protein.²³⁷ In CDA II there is a clustering of band 3 compared with the normal even distribution of the fully glycosylated protein.²⁴⁰ Other membrane proteins, including band 4.5, and some plasma proteins, such as transferrin, are also underglycosylated. The primary molecular defect in CDA II is unknown.²⁴¹ There is no linkage with genes encoding common glycosylation

enzymes.^{242,243} Heterozygotes may also show evidence of abnormal glycosylation.²⁴⁴

Treatment

The management of CDA II depends upon the severity of anemia and the degree of iron overload. Splenectomy increases the hemoglobin in CDA II,^{222,225} by reducing peripheral hemolysis.¹⁹¹ However, splenectomy does not modulate the ineffective erythropoiesis of CDA II,¹⁹¹ and consequently does not prevent iron loading.^{222,225} The major indication for splenectomy is therefore to prevent transfusion dependence in severely anemic patients. Splenectomy has also been used to increase the hematocrit to a level that allows regular phlebotomy to facilitate the management of iron overload.

Ferritin levels should be monitored regularly, and iron chelation therapy or phlebotomy should be initiated in patients who demonstrate increasing ferritin levels.

Congenital dyserythropoietic anemia type III

CDA type III²⁴⁵ is the rarest of the classified syndromes, although the striking bone marrow abnormalities meant that it was the first to be recognized, initially known as familial erythroid multinuclearity.²⁴⁶ It is mainly inherited as an autosomal dominant disorder although there may be families with apparently recessive inheritance.²⁰⁸ The abnormal gene has been located to 15q21-q25 in a Swedish family with dominant inheritance.²⁴⁷

Clinical features

Anemia is usually mild and is accompanied by slight icterus. Splenomegaly may occur but is absent in a substantial proportion of reported cases. The condition is usually discovered in young adult life unless there is a known family history. An increased incidence of monoclonal gammopathy²⁴⁸ and retinal abnormalities, including angioid streaks and macular degeneration,²⁴⁹ has been reported in a large Swedish kindred with CDA III.

Hematologic findings

There is mild macrocytic anemia with red cell anisocytosis and poikilocytosis. There may be evidence of intravascular hemolysis with hemosiderinuria and absent serum haptoglobin.²⁴⁸ The acidified serum lysis test is negative²⁴⁸ and there is variable expression of I and i antigens.^{250,251}

The bone marrow shows erythroid hyperplasia with striking multinuclearity of the erythroblasts (up to 12 nuclei) in a single cell producing so-called "gigantoblasts".¹⁹⁵ The nuclei may be of the same or different maturity, with differing DNA content.^{248,250,251} Similar appearances may occur in erythroleukemia, from which CDA type III should be differentiated.

Electron microscopy

Electron microscopy reveals nuclear clefts and autolytic areas within the cytoplasm with multiple nuclei within the cell.²⁵² There may be duplication of parts of the nuclear membrane.²⁴⁸

Management

The anemia in CDA III is usually mild, requiring no treatment.²⁴⁵ Iron overload is unusual, despite the occurrence of ineffective erythropoiesis, probably as a consequence of intravascular hemolysis and hemosiderinuria.²⁴⁸ Adult patients with CDA III should be screened for monoclonal gammopathy, and undergo regular ophthalmologic review to allow early detection and treatment²⁵³ of neovascular changes in the retina.

Unclassified congenital dyserythropoietic anemias

A number of cases of CDA have been reported that do not fit the above classification.¹⁹³ In one family, a proband with mild anemia and multinucleated cells at all stages of erythroid differentiation had an affected child who died with hydrops fetalis.²⁵⁴ There have been other reports of infants with hydrops fetalis and unusual types of CDA,^{255,256} in most cases there was a history of previous neonatal deaths with hydrops or multiple abortions.²⁵⁵ Possible explanations for such severe cases include double heterozygosity or homozygosity for autosomal dominant forms of CDA, new subtypes of CDA, or the coinheritance of other genetic modifiers of severity. Identification of the genes responsible for CDA II and CDA III will help to elucidate such cases, and facilitate further subclassification. The management of unclassified CDAs includes treatment of anemia, iron loading and gallstones, as for the main CDA types. In addition, bone marrow transplantation may be considered for severely affected children.^{257,258}

Modifiers of severity in congenital dyserythropoietic anemia

Unbalanced globin chain synthesis with the formation of inclusion bodies containing precipitated globin chains may variably occur in the different types of CDA.²⁵⁹⁻²⁶² This provides a possible explanation for the finding that the coexistence of thalassemia trait may exacerbate the ineffective erythropoiesis of CDA II.²⁵⁸ Gilbert syndrome has been identified as another potential genetic modifier of the severity of CDA II, the degree of hyperbilirubinemia being influenced by differences in the expression of uridine diphosphate glucuronosyl transferase.²⁶³ It is not yet clear whether mutations associated with excess iron absorption in heredit-

ary hemochromatosis influence the extent of iron loading in CDAs, as has been suggested in β -thalassemia trait.^{264–266} Conversely, the severity of CDA may be ameliorated in other cases by as yet unidentified factors.²⁶⁷

Differential diagnosis of congenital dyserythropoietic anemia

It is important to make the diagnosis of CDA because of the risk of significant iron loading even in the presence of only mild anemia. CDA should be considered in any patient with evidence of a congenital anemia with raised bilirubin and reduced serum haptoglobin, especially in the presence of an inadequate reticulocytosis and abnormal red cell morphology on the blood film. Hereditary spherocytosis is the likeliest misdiagnosis in patients with CDA II,^{225,268} based on clinical and laboratory similarities between the two disorders, including improvement in anemia after splenectomy. This carries the risk that evolving iron loading remains undetected until significant hemochromatosis has developed.^{269,270}

The CDAs need to be distinguished from other congenital hemolytic anemias associated with ineffective erythropoiesis, notably β -thalassemia intermedia, especially if there is a reduced MCV, an uncommon finding in the CDAs.¹⁹³ Folate and vitamin B₁₂ deficiency should be excluded in all age groups.

Key points

Differential diagnosis of chronic red cell aplasia in children

- Congenital red cell aplasia (Diamond–Blackfan anemia)
- Chronic parvovirus B19 viremia
- Immune-mediated pure red cell aplasia
- Other congenital syndromes of bone marrow failure

Differential diagnosis of red cell aplasia in infancy

- Congenital red cell aplasia (Diamond–Blackfan anemia)
- Early presentation of transient erythroblastopenia of childhood
- Congenital parvovirus B19 infection
- Alloimmune erythroid hypoplasia (maternal anti-Kell)

Practice point

Bone marrow transplant in Diamond–Blackfan anemia:

- It is essential to exclude subclinical or mild DBA in sibling donors

Practice point

Iron loading in congenital dyserythropoietic anemias:

- Iron overload caused by ineffective erythropoiesis can occur even in mild anemia
- Splenectomy improves anemia in CDA II, but does not reduce iron loading

The mildness of the anemia in CDA may delay diagnosis until adolescence or adulthood when additional demands on hemopoiesis may produce symptomatic anemia, in which case the differential diagnosis will also include megaloblastic anemia, myelodysplasia and erythroleukemia (FAB M6).

Inherited bone marrow failure syndromes

Yigal Dror

Introduction

Bone marrow failure can either be acquired throughout life (e.g., idiopathic aplastic anemia) or can occur as part of several inherited syndromes. Inherited marrow failure syndromes (IMFSs) are rare genetic diseases characterized by varying degrees of defective production of mature erythrocytes, granulocytes, and platelets in the bone marrow, leading to anemia, thrombocytopenia, and neutropenia. The designation “congenital” has a looser connotation and refers to conditions that manifest early in life, often at birth, regardless of causation. Thus, congenital marrow failure is not necessarily inherited, and may be due to acquired factors such as viruses and environmental toxins.

Although in all IMFSs the bone marrow is hypoproliferative causing peripheral cytopenia, they constitute a heterogeneous group of disorders (Table 3.1), and are traditionally classified according to the lineage affected. In some IMFSs (e.g., Fanconi anemia) pancytopenia (two or more lineages affected) usually evolves. In others, one lineage is predominantly involved. Among the latter category are disorders with predominantly neutropenia (e.g., Kostmann neutropenia), anemia (e.g., Diamond–Blackfan anemia), or thrombocytopenia (e.g., thrombocytopenia absent radii).

A wide range of physical anomalies have been described in many IMFSs, with significant overlap among the various disorders. These include craniofacial, skeletal, cardiovascular, pulmonary, gastrointestinal, immunologic, renal, and neurologic anomalies as well as those of the skin, eyes, and ears.

All patterns of inheritance are associated with marrow failure disorders. Many IMFS cases are sporadic and could be either recessive or dominant traits with variable expression. Genes for many of the IMFSs have been identified and cloned, and can be used for diagnostic purposes (Table 3.1). A significant portion of the patients with IMFSs do not have known gene defects and cannot be accurately diagnosed by clinical and standard laboratory tests.¹

Presentation with symptoms of marrow failure in IMFSs can be triggered or hastened by environmental exposures such as viruses, drugs, chemicals, or toxins. For example, there are reports of patients with IMFSs who developed hematologic symptoms following treatment with chloramphenicol,² or following a viral illness.³

The true incidence of the acquired vs inherited marrow failure syndromes is unknown. Older studies showed that about two-thirds of the patients with marrow failure had an acquired condition and one third inherited.⁴ However, since most of these cases were diagnosed only on clinical findings, these figures are probably inaccurate. For example, recently a portion of patients with apparently “acquired” aplastic anemia or acute myeloblastic leukemia (AML) have been found to have IMFSs.⁵

Historically, the IMFSs were classified as “benign” hematology, which contrasted sharply with the malignant myeloid disorders. For example, patients with Kostmann syndrome often died early in life from complications of their disorders. However, in the current era of advanced supportive care and availability of recombinant cytokines and other therapeutics, patients with these conditions usually survive the early years of life and beyond. With the extended lifespan of patients, a new natural history for some of these disorders is evident. One of the most sobering observations is that most of these “benign” disorders confer an inordinately high predisposition to malignant transformation into myelodysplastic syndrome (MDS) and leukemia (particularly acute myeloblastic) as well as solid tumors.^{6–11}

The true risk of cancer in the various IMFSs is unknown, but might be as high as 50% in certain IMFSs. Further, some patients with an apparently acquired MDS or AML are found to have a pre-existing marrow failure condition when investigated.¹² As the IMFSs are rare and no prospective studies with a consistent approach to diagnostic criteria for malignancy are available, there are major problems when trying to estimate the risk of malignancy based on the available data.

Inherited marrow failure syndromes with predominantly pancytopenia

Fanconi anemia

This classical marrow failure disorder is typically inherited in an autosomal recessive manner with a heterozygote frequency of about 1 in 200, and occurs in all racial and ethnic groups. The original report by Professor Fanconi described pancytopenia combined with physical anomalies in three brothers.¹³ A summary of the large body of published information on hundreds of patients with Fanconi anemia (FA) over the ensuing 80 years has underscored the clinical variability of the condition.^{12,14} At presentation patients may have either a classic phenotype comprising physical anomalies and abnormal hematology, or typical physical anomalies but normal hematology, or normal physical features but abnormal hematology.

Clinical manifestations

Hematologic features

A cardinal feature is the gradual onset of bone marrow failure involving one or more hematopoietic cell lineages. Thrombocytopenia usually develops initially, with the subsequent onset of granulocytopenia and anemia. Severe aplasia eventually develops in most cases but the full expression of pancytopenia is variable and occurs over a period of months to years. The development of aplastic anemia can be accelerated by intercurrent infections or by drugs such as chloramphenicol. Data from the International FA Registry showed that 86% of the patients developed hematologic abnormalities at a median of 7 years (range: birth to 31 years).⁸ The actuarial risk of developing hematologic abnormalities increases with age, reaching 90–98% by 40 years.¹⁴ Rosenberg and colleagues studied clinical risk factors for bone marrow failure in a cohort of 144 North American patients with FA.¹⁵ They found that abnormal radii are the strongest predictor of early marrow failure. The cumulative incidence of marrow failure by age 10 years varied from 18% in the lowest risk group to 83% in the highest.¹⁵

Red blood cells are macrocytic with mean cell volumes often > 100 fL even before the onset of significant anemia. Erythropoiesis is characterized by increased fetal hemoglobin F and increased expression of i antigen, but not necessarily both features in individual cells. Increased hemoglobin F production is not clonal and has a heterogeneous distribution. Ferrokinetic studies indicate that most patients have an element of ineffective erythropoiesis as part of the marrow failure. Red blood cell lifespan may be slightly shortened but this is a minor component of the anemia.

In the early stages of the disease, the bone marrow can show erythroid hyperplasia, sometimes with dyserythro-

Fig. 3.1 Classical phenotype of Fanconi anemia. Patient has pigmentary changes around the neck, shoulders, and trunk, short stature, absent radii and thumbs bilaterally, microcephaly, and low-set ears.

poiesis and even megaloblastic-appearing cells. As the disease progresses, the marrow becomes hypocellular and fatty, and shows a relative increase in lymphocytes, plasma cells, reticulum cells and mast cells. With full-blown marrow failure, the morphology on biopsy is identical to that seen in severe acquired aplastic anemia.

Nonhematologic manifestations

The presence of one or more characteristic congenital physical anomalies in the setting of bone marrow failure should strongly suggest a diagnosis of FA (Fig. 3.1). However, a portion of patients with FA may lack anomalies, and have been historically diagnosed with “Estren–Dameshek aplastic anemia”.¹⁶ With the introduction of clastogenic stress-induced chromosomal breakage analysis as a confirmatory test for FA, data from the International FA Registry showed that of 202 patients tested, 39% had aplastic anemia and anomalies, 30% had aplastic anemia without anomalies and 24% had anomalies only.¹⁴ Seven percent had classical FA phenotype with negative chromosomal fragility testing.

The commonest physical anomaly is skin hyperpigmentation, a generalized brown melanin-like splattering, which is most prominent on the trunk, neck, and intertriginous areas and which becomes more obvious with age. Café-au-lait spots are common alone or combined with the generalized hyperpigmentation, and sometimes with vitiligo or hypopigmentation. The skin pigmentation should not be confused with hemosiderosis-induced bronzing in transfusion-dependent patients who have not been adequately chelated.

The majority of patients have short stature. Superimposed endocrinopathies might contribute to the growth defect. According to data from the International FA Registry, all 13 patients tested had abnormal spontaneous overnight growth hormone secretion; 21 of 48 (44%) patients tested had a subnormal response to growth hormone stimulation; 19 of

53 (36%) had overt or compensated hypothyroidism; 8 of 40 (25%) had impaired glucose tolerance; 28 of 39 (72%) had hyperinsulinemia.¹⁷ Improvement in stature has been reported in patients with FA treated with growth hormone; however, it is unclear whether the use of growth hormone in this patient population increases the risk of malignancy.

Malformations involving the upper limbs are common, especially hypoplastic, supernumerary, bifid, or absent thumbs. Hypoplastic or absent radii in FA are always associated with hypoplastic or absent thumbs in contrast to the thrombocytopenia with thrombocytopenia absent radii syndrome, in which thumbs are always present. Less often, anomalies of the feet are seen, including toe syndactyly, short toes, a supernumerary toe, clubfoot, and flat feet. Congenital hip dislocation and leg abnormalities are occasionally seen.

Males often have gonadal and genitalia abnormalities, including an underdeveloped or micropenis, undescended, atrophic, or absent testes, hypospadias, phimosis, and an abnormal urethra. Female patients occasionally have malformations or atresia of the vagina, uterus, and ovary.

Many patients have a characteristic “facies” and unrelated patients can resemble each other almost as closely as siblings. The head and facial changes vary but commonly consist of microcephaly, small eyes, epicanthal folds, and abnormal shape, size, or positioning of the ears. About 10% of FA patients are mentally retarded. Renal anomalies occur but require imaging for documentation. Ectopic, pelvic, or horseshoe kidneys are often detected as well as duplicated, hypoplastic, dysplastic, or absent organs. Occasionally, hydronephrosis or hydroureter is present.

Cancer predisposition

The karyotype data, the defects in DNA repair, and the cellular damage that occur in FA patients translate into an enormous predisposition for malignancy. Two recent studies described the risk of malignancy in FA. Data from the International FA Registry study¹⁴ demonstrated a crude rate of cancer of 23%; 179 patients developed 199 neoplasms. Of these neoplasms, 60% were hematologic and 40% were nonhematologic. The hematologic malignancies included AML (36%), MDS (31%), and acute lymphoblastic leukemia (3%). The authors suggested that the risk of hematologic and nonhematologic neoplasms increased with advancing age with a 33% and 28% cumulative incidence, respectively, by 40 years of age.

The second study is a survey of the literature from 1927 to 2001.¹⁸ Two hundred patients (crude rate of 17%) had developed cancer at the median age of 16 years. In approximately 25% of patients with cancer, the malignancy preceded the diagnosis of FA. The author calculated that if the competing risks of aplastic anemia and leukemia could be removed, the estimated cumulative probability of development of a solid tumor is 76% by the age of 45 years.

The risk of advanced MDS/AML is higher for patients in whom a prior clonal marrow cytogenetic abnormality (MCA) had been detected.⁸ Monosomy 7 or partial loss of 7q, rearrangements of 1p36 and 1q24–34, and rearrangements of 11q22–25 are the most frequently recurring cytogenetic changes. MCAs consisting of partial trisomies or tetrasomies of chromosome 3q conferred a high risk of transformation into advanced MDS or leukemia.¹⁹

Most of the solid tumors described in FA were squamous cell carcinomas involving the gastrointestinal tract at any site from the oropharynx to the anorectal-colonic area.^{14,18} Less frequently, patients can develop carcinomas of the vulva, cervix, and breast or unusual combinations such as Wilms tumor with medulloblastoma, cancer of the vulva and tongue, hepatic carcinoma and cancer of the tongue, and hepatic carcinoma and esophageal carcinoma.^{14,18}

Liver tumors, benign and malignant, as well as peliosis hepatis occur at increased frequency in FA.^{14,18} The commonest tumors reported were adenomas and hepatocellular carcinoma. Since almost all patients were taking androgen therapy at the time the liver disease presented, androgens have been implicated as having a direct relationship in pathogenesis. Indeed, peliosis hepatis is reversible when androgens are stopped, and in three patients with tumors, discontinuation of androgens alone or coupled with hematopoietic stem cell transplantation (HSCT) effected a regression of the tumors.

Genetic aspects

FA has been reported in all ethnic groups, and is mostly inherited as an autosomal recessive condition. This was confirmed with the identification of the FA genes *A*, *C*, *D2/BRCA1*, *E*, *F*, *G*, *I*, *J*, and *L* (Table 3.1). Interestingly, it has long been known that the ratio of males to female diagnosed with the disorder is slightly more than one (1.06 to 1.2). This could be due to bias toward establishing the diagnosis more readily in males compared with females or due to pre-diagnosis early female death. However, the *FANCB* gene has recently been localized to Xp22.31, and it is thus inherited in an X-linked manner. Therefore, genetic counseling of families with FA should now depend on accurate genetic analysis.

A breakthrough in the search for the defective genes in FA evolved from the important observation that hybrid cells formed from FA and normal cells or from two unrelated FA patients resulted in correction of the abnormal chromosome fragility, a process known as complementation.^{20,21} This enables classification of FA patients into various complementation groups and subsequently identification of the respective genes. Currently, at least 11 FA subgroups have been proposed and nine of the genes associated with these groups have already been identified (Table 3.1).

There can be discordance in clinical and hematologic findings among siblings, even in affected monozygotic twins.

However, a certain degree of correlation exists between genotype and phenotype. FA-A patients with homozygosity for null mutations tend to have an earlier onset of anemia and a higher incidence of leukemia than those with mutations producing an altered protein.²² Also, FA-C patients with IVS4 + 4A > T or exon 14 mutations usually,^{22,23} but not always,²⁴ have more somatic abnormalities, earlier onset of hematologic abnormalities, and poorer survival compared with patients with the *FANCC* exon 1 mutation and the non-FA-C population. FA-G patients had more severe cytopenia and a higher incidence of leukemia. FA-D, FA-E, and FA-F had higher frequencies of somatic abnormalities.

Pathogenesis

Protein complex

Solid data exist showing that the FA proteins interact in a common molecular pathway. The FA proteins *FANCA*, C, E, F, G, and L bind and form a complex, which is required for *FANCD2* monoubiquitinylation. The ubiquitin ligase that performs this function might be *FANCL*.²⁵ After ubiquitination, *FANCD2* can colocalize with *FANCD1/BRCA2* and *BRCA1* in “nuclear foci” following genotoxic stress.^{25,26,29,30} Inactivating mutation of any one of the FA proteins in this pathway prevents the ultimate translocation of *FANCD2* to the target nuclear foci. The precise functions of the FA proteins in the nucleus at a biochemical level are still unknown.

Mouse models

Knockout FA mouse models are available for *FANCC*, *FANCA*, and *FANCG*, but they do not completely mimic the human FA phenotype.^{31,32} The mice do not exhibit developmental abnormalities or gross hematologic defects. However, their spleen cells have increased numbers of chromosomal aberrations in response to mitomycin C and diepoxybutane, the G₂-M progression of the cell cycle is abnormal,³³ hematopoietic progenitors are markedly sensitive to γ -interferon and have lower growth and differentiation potential in response to cytokines,³⁴ and both male and female mice have compromised gametogenesis and markedly impaired fertility.^{31,32,35}

Chromosome breakage studies and abnormal DNA repair

A major finding in FA is abnormal chromosome fragility; this is seen readily in metaphase preparations of phytohemagglutinin-stimulated peripheral blood lymphocytes or cultured skin fibroblasts. The karyotype shows “spontaneously” occurring chromatid breaks, rearrangements, gaps, endoreduplications, and chromatid exchanges in cells from homozygous patients with FA. The abnormal chromosome pattern, number of breaks/cell, and variations in proportion of abnormal cells have no direct correlation with the hematologic or clinical course of individual patients.²³

“Spontaneous” chromosomal breaks are occasionally absent in FA,³⁶ but are strikingly enhanced if clastogenic agents such as diepoxybutane or mitomycin C are added to the cultures.³⁶ Homozygous Fanconi cells are hypersensitive to many other oncogenic and mutagenic inducers, such as ionizing radiation, SV40 viral transformation, and alkylating and chemical agents including cyclophosphamide, nitrogen mustard, and platinum compounds. The increased chromosomal fragility is caused by a defect in DNA repair. Defects in mismatch repair, recombinational repair³⁷ and excision repair pathways³⁸ have been hypothesized. Mutations in any member of the FA protein complex reduce *FANCD2* ubiquitinylation and its colocalization with *BRCA1*.³⁰ Some hypomorphic homozygous *BRCA2* (*FANCD1*) mutations prevent Rad51 localization in damage-induced nuclear foci,^{39,40} which is required to protect cells and/or facilitate DNA repair.

Apoptosis

FA cells demonstrate G₂-phase cell cycle arrest.⁴¹ This effect cannot be induced by DNA cross-linking agents. Several groups have shown that FA cells undergo accelerated apoptosis and are intolerant of oxidative stress.⁴² *FANCC* enhances the function of *GSTP1*, which detoxifies by-products of redox stress and xenobiotics, whereby it might protect cells from inducers of apoptosis.⁴³ *FANCC* associates with hsp70, upon exposure to either combinations of tumor necrosis factor (TNF) and interferon- γ (IFN- γ) or double-stranded RNA and IFN- γ . This interaction facilitates hsp70 binding to and inactivation of double-stranded RNA-dependent protein kinase, thereby protecting from apoptosis.⁴⁴ Mutations in the *FANCA*, *FANCC*, and *FANCG* genes markedly increase the amount of RNA-dependent protein kinase, leading to hypersensitivity of hematopoietic progenitor cells to growth inhibition by IFN- γ and TNF- α .⁴⁵

The hematopoietic stem cell and progenitor phenotype

The frequency of erythroid colony-forming unit (CFU-E), erythroid burst-forming unit (BFU-E) and granulocyte-macrophage colony-forming unit (CFU-GM) cells is reduced in almost all patients after aplastic anemia becomes evident,^{46,47} as well as in a few patients prior to the onset of aplastic anemia.⁴⁸ A defect in the response of early hematopoietic progenitors to specific cytokines has been proposed.⁴⁹ Because all hematopoietic cell lineages are affected in these studies, the basic defect either involves pluripotent hematopoietic stem cells and early progenitors or is due to faulty proliferative properties, or both.

Production of growth factors by the FA marrow stroma and the expression of their receptors on hematopoietic cells have not been systematically studied, and the results are variable.⁵⁰ Generation of the inhibitory cytokine TNF- α has been shown to be markedly heightened.⁵⁰

Laboratory evaluation and diagnosis

About 75% of patients are between 3 and 14 years of age at the time of diagnosis with a mean age of about 8 years in males and 9 years in females.^{12,14} It is noteworthy that 4% of the patients are diagnosed in the first year of life, and 10% after 15 years of age.

The diagnosis of FA is usually suspected after obtaining a medical, developmental, and family history, as well as conducting a physical examination. Low blood cell counts, red blood cell macrocytosis, high hemoglobin F, increased expression of the i antigen, and varying degrees of marrow hypoplasia are common findings, but are not specific for FA and can be seen in other IMFSs. In patients without physical anomalies, chromosomal breakage analysis using diepoxybutane or mitomycin C will specifically identify FA and lead to the correct diagnosis.

Since it was introduced in 1981⁵¹ the chromosomal fragility test has become the gold standard for the diagnosis of FA. Fragile chromosomes can be readily seen in metaphase preparations of phytohemagglutinin-stimulated peripheral blood lymphocytes or cultured skin fibroblasts. "Spontaneous" chromosomal breaks are occasionally absent in true cases of homozygous FA, but become positive after the cells are treated with mitomycin C or diepoxybutane.³⁶ For definitive diagnostic purposes, the International FA Registry has defined FA as increased numbers of chromosome breaks/cell after exposure to diepoxybutane³⁶ with a mean of 8.96 (range 1.3–23.9) compared with normal controls of 0.06 (range 0–0.36). It must be noted that some patients with classical features of FA occasionally have a negative test. Whether this group represents a special subgroup of FA or a separate disorder has to be determined.

A new, rapid diagnostic test is Western blot of FANCD2 protein, which shows a slow band of monoubiquitinated isoforms in addition to a faster nonubiquitinated isoform. In most FA patients the defect lies upstream to this biochemical step, and thus only fast nonubiquitinated isoforms of FANCD2 are detected. Genetic testing for FA is complicated due to its association with multiple genes, and the inability to predict the location of the mutation in most cases. Complementation testing is done first followed by molecular analysis of the respective gene.

Prenatal diagnosis

Diagnostic testing can be performed on fetal amniotic fluid cells obtained at 16 weeks' gestation or on chorionic villus biopsy specimens at 9–12 weeks. A very high degree of prenatal diagnostic accuracy has been documented by looking at both spontaneous and diepoxybutane-induced breaks,³⁶ and genetic testing.⁵²

Therapy and prognosis

Because of their clinical complexity, patients with FA should be supervised at a tertiary care center using a comprehensive and multidisciplinary approach. Due to early diagnosis and newer approaches to HSCT, the prognosis of patients with FA has been improved, and the median survival is currently 24 years of age.¹⁴ Older female FA patients can be sexually active, become pregnant, and give birth to healthy children.⁵³

Complications in FA include severe cytopenia (hemoglobin < 8 g/L, platelet counts < 20×10^9 /L, absolute neutrophil count < 0.5×10^9 /L), MDS with excess blasts (5–30%), and acute leukemia (blasts > 30%). If the patient is stable and has only minimal to moderate hematologic changes and no transfusion requirements, a period of observation is indicated. Blood counts may be monitored every 1–3 months and bone marrow aspirates and biopsies performed annually for morphology and cytogenetics to identify transformation into MDS/AML. Depending on the types of congenital anomalies, subspecialty consultations, for example, with cardiologists and orthopedic surgeons, can be arranged during this interval.

Hematopoietic stem cell transplantation

As most patients need hematopoietic stem cell transplantation (HSCT) at some stage of their disease, the author recommends HLA-typing for the whole family shortly after diagnosis. If no family member is a match, other options such as prenatal genetic diagnosis and *in vitro* fertilization for the selection of healthy donors for transplantation might be discussed with the family.

HSCT is currently the only curative therapy for the hematologic abnormalities of FA and the best donor source is an HLA-matched sibling. Initial efforts to transplant FA patients using standard preparative regimens were plagued by severe cytotoxicity and graft-versus-host disease (GVHD).⁵⁴ HSCT protocols for FA patients were subsequently dose-modified by Gluckman *et al.*⁵⁵ and others, and outcomes improved substantially.

In an analysis of 151 cases of FA patients from 42 institutions, who had HLA-identical sibling HSCT, the 2-year survival rate was 66%.⁵⁶ Factors associated with a favorable outcome were a younger patient age, higher pre-HSCT platelet count, use of antithymocyte globulin (ATG), use of low-dose cyclophosphamide (15–25 mg/kg) plus limited-field irradiation for pre-HSCT conditioning, and cyclosporine for GVHD prophylaxis. In a later European study, where all patients received low-dose cyclophosphamide and thoracoabdominal irradiation as transplant conditioning, the survival estimate was 74.4% at 54 months and 58.5% at 100 months.⁵⁷ Another report with a smaller number of patients showed an approximately 85% survival with a median follow-up of > 3 years.⁵⁸ This approach included cyclophosphamide, 20 mg/kg/day, thoracoabdominal

irradiation 400 cGy and horse ATG. GVHD prophylaxis included posttransplant horse ATG, methylprednisolone, and ciclosporin.

Although there is still room for improving the overall survival rates of transplant in the matched sibling donor setting, the main challenges are currently in finding regimens with reduced long-term toxicity and eliminating a potential increase in the cancer risk above the inherent baseline rate. One such approach is eliminating irradiation. A conditioning regimen that omitted radiation and used a reduced dosage of cyclophosphamide showed 89% survival with a median follow-up of 285 days.⁵⁹ Fludarabine has increasingly been used as part of radiation-free conditioning regimens for FA since it was first used in this disease in 1997.^{60,61} The results of these studies are encouraging; however, results of larger series are not yet available.

Results of HSCT with matched unrelated donors in FA have not been as good as with matched sibling donor HSCT, with a probability of 1-year survival of 34%⁶² and 2-year survival of 29%.⁵⁶ Because of these dismal results, incorporating fludarabine in the preparatory regimens is of particular interest in this group of patients. Boulad *et al.*⁶³ analyzed 15 consecutive patients with FA with aplastic anemia, advanced MDS, or AML, who received granulocyte colony-stimulating factor (G-CSF) mobilized T-cell-depleted peripheral cell grafts from either partially mismatched related donors or unrelated donors (7–10 out of 10 HLA antigen match). Cyto-reduction included total body irradiation (450 cGy), fludarabine (150 mg/m²), and cyclophosphamide (40 mg/kg). Immunosuppression included rabbit ATG and tacrolimus. All patients were fully engrafted. No patients required treatment for GVHD. With a median follow-up of 2.5 years, 13 of 15 patients were alive, and 11 of 15 were disease-free.

Wagner and colleagues⁶⁴ evaluated 98 unrelated donor transplants in FA for aplastic anemia (69%) or MDS/AML (31%). Fifty-four percent received cyclophosphamide and irradiation, and 46% received a fludarabine-containing preparative regimen. Twenty-two percent had a mismatch at a single locus. Seventy-one percent of grafts were T-cell depleted. Fludarabine-containing regimens resulted in significantly better engraftment rates, lower mortality, and better overall survival, and overcame the problem of diepoxybutane mosaicism in peripheral blood lymphocytes. Poor outcome was associated with receiving > 20 blood products prior to transplant. A European study also showed that delaying transplantation by the use of androgens was associated with poorer outcome posttransplantation.⁶⁵

Cord blood cells are being used increasingly as a donor source. The first cord blood transplantation was performed in 1988 for a patient with FA using a matched sibling donor.⁶⁶ Cord cells from unrelated donors have been transplanted into FA patients.^{58,67} A recent retrospective analysis of 72 patients with FA complicated by severe aplastic anemia or leukemia/MDS using HLA-identical or one to three HLA

differences showed comparable overall survival (36%) to these authors' experience with the use of matched unrelated bone marrow transplant.⁶⁷ The main complications were non-engraftment and infections. Favorable factors were negative recipient cytomegalovirus (CMV) serology, nucleated cell dose of $> 4.4 \times 10^7$ /kg and use of fludarabine.

Transplant in FA with MDS or AML is associated with poorer outcome,⁶⁴ but is feasible. In these cases the preparative therapy was usually escalated, and included cyclophosphamide 40 mg/kg/day and total body irradiation 450 cGy with^{64,68} or without fludarabine.⁵⁸ However, successful transplant in this setting using a fludarabine-containing regimen without the use of irradiation was also reported.⁶⁰

Because of the increased risks associated with alternative donor marrow, the timing of the transplant when a matched sibling donor is not available is hotly debated. Traditionally only patients who failed androgen therapy were offered alternative donor transplant. However, a delay in the transplant and the use of androgen might expose the patients to more transfusions, infections, complications, and androgen-related toxicity, and may compromise the success of a subsequent HSCT.^{64,65}

Preimplantation genetic diagnosis has recently been offered in combination with HLA typing in order to select a sibling embryo that is negative or heterozygous (but not homozygous) for the patient's FA gene mutations as well as HLA-matched to the patient. Many ethical issues are associated with this advanced procedure,⁶⁹ however, several successful transplants using this advanced technology have already been reported.^{70,71}

Despite the clear-cut success in correcting the marrow failure of FA with HSCT, a subset of survivors will develop secondary cancers, particularly of the head and neck.^{14,18} These malignancies reflect the ongoing genetic susceptibility of host nonhematopoietic tissue to cancer despite successful HSCT for marrow failure.

Hematopoietic growth factors

The potential for recombinant growth factor (cytokine) therapy for FA has not been fully explored but short-term data are encouraging.^{72,73} An important multicenter clinical trial⁷² examined the effect of prolonged administration of G-CSF in 12 FA patients with neutropenia. By week 8 of the study, all patients showed an increase in neutrophil counts. Some patients had clinically significant increase also in platelet counts and hemoglobin. In another study, patients without a matched sibling donor who did not have a MCA were given combination cytokine therapy consisting of G-CSF 5 µg/kg with erythropoietin 50 units/kg administered subcutaneously or intravenously three times a week.⁵⁸ Of 20 patients treated, all but 1 showed improved neutrophil numbers, 20% achieved a sustained rise in platelets, and 33% showed an increase in hemoglobin levels. However, more than half of the responders did not sustain the response after 1 year.

Since a marked predisposition to cancer is a feature of FA, the use of growth-promoting cytokines on a chronic basis for this disorder is a central issue. Development of new clones on G-CSF treatment was reported, and remains a significant concern.^{72,73} However, appearance and disappearance of MCAs are common phenomena in FA patients and were not proven to be directly caused by G-CSF.⁷⁴

Androgens

Androgen therapy has been used to treat FA for more than four decades. The overall response rate in the literature is about 50%,^{12,18} heralded by reticulocytosis and a rise in hemoglobin within 1–2 months. If the other lineages respond, white cells increase next and finally platelets, but it may take many months to achieve the maximum response. When the response is deemed maximal, the androgens should be slowly tapered but not stopped entirely.

Oxymetholone is most frequently used at 2–5 mg/kg daily with preference for the lowest dose initially. Low-dose prednisone (5–10 mg orally every second day) is sometimes added to counter the androgen-induced growth acceleration. Danazol is another androgen that has recently been used in FA, but there are insufficient data to evaluate its efficacy and safety.

Almost all patients relapse when androgens are stopped. Many patients on long-term androgens eventually become refractory to therapy as marrow failure progresses. Potential side effects include masculinization, elevated hepatic enzymes, cholestasis, peliosis hepatis, and liver tumors. Those receiving androgens should be evaluated serially with liver chemistry profiles and ultrasonography and/or CT (computed tomography) scan of liver.

Gene therapy

The premise for gene therapy in FA is based on the presumption that corrected hematopoietic cells have a growth advantage. Strengthening this supposition are recent descriptions of rare patients with FA who had clinical improvement and spontaneous disappearance of cells with the FA phenotype due to intragenic mitotic recombination generating one allele with both FA mutations and one normal allele.⁷⁵

Preclinical studies using retroviral vectors showed that the *FANCC* and *FANCA* genes can be successfully integrated into normal and FA cells.⁷⁶ This prompted a clinical trial in three FA-C patients^{76,77} and four FA-A patients.⁷⁷ The patients underwent peripheral blood stem-cell harvesting. The CD34⁺ cell population was then infected with a retrovirus containing the wild-type copy of the respective *FANC* gene, followed by transfusion of these modified cells into the patient. These preliminary experiments failed to induce sufficient gene expression.⁷⁸ Lentivirus vectors have recently been studied for gene therapy in mice, and may be proven safe and useful for clinical gene therapy of FA hematopoietic cells.⁷⁹

Shwachman–Diamond syndrome

Shwachman–Diamond syndrome (SDS) is an autosomal recessive multisystem disorder first described in the early 1960s by several groups.^{80,81} The syndrome comprises a triad of bone marrow failure, pancreatic insufficiency and skeletal abnormalities.⁸² In addition, the liver, kidneys, teeth, and immune system may also be affected.^{9,10,82–85} SDS is also associated with a propensity for MDS and leukemia.^{9,82,86–88} SDS is the third most common IMFS after Fanconi anemia and Diamond–Blackfan anemia. Although SDS is an autosomal recessive disorder, the ratio of males to females diagnosed with SDS is 1.7:1.⁸³

Clinical manifestations

Hematologic features

Neutropenia is the most common hematologic abnormality, occurring in 88–100% of patients. It might be seen in the neonatal period,⁸² and it can be either persistent or intermittent, fluctuating from severely low to normal levels. SDS neutrophils have defects in migration and chemotaxis in most patients.^{84,86,89} The chemotactic defect might be due to abnormal distribution of concanavalin-A receptors or a cytoskeletal/microtubular abnormality,⁸⁹ and can be partially corrected *in vitro* and *in vivo*⁹⁰ by lithium.

Anemia with low reticulocytes occurs in up to 80% of the patients. The red blood cells are usually normochromic-normocytic, but can also be macrocytic. Fetal hemoglobin is elevated in 80% of patients.⁹¹ The anemia is usually asymptomatic. Thrombocytopenia, with platelets less than $150 \times 10^9/L$, is seen in 24–88% of patients. Trilineage cytopenias occur in 10–65% of patients. Severe aplasia requiring transfusions has occasionally been reported.^{82,92,93}

Bone marrow biopsy usually shows a hypoplastic specimen with increased fat deposition,^{82,91} but marrows showing normal or even increased cellularity have also been observed.^{83,86} Single-lineage hypoplasia is usually myeloid and occurs in 15–50% of patients.^{9,83} Left-shifted granulopoiesis is a common finding.^{82,83} Mild dysplastic changes in the erythroid, myeloid, and megakaryocytic precursors are commonly seen and may fluctuate; however, prominent multilineage dysplasia is less common, and if it occurs, may signify malignant myeloid transformation.

Multiple B- and T-cell defects have been reported in SDS.^{94–98} In our series 7 of 14 patients had B-cell defects, 6 of 9 had at least one T-cell abnormality, and 5 of 6 had decreased percentages of circulating natural killer cells.⁸⁴

Nonhematologic manifestations

Varying severity of pancreatic dysfunction due to abnormal acinar development and malabsorption is a hallmark of SDS.⁸³ Spontaneous improvement in pancreatic function occurs in up to 50% of the patients. Most patients with SDS

have skeletal abnormalities including metaphyseal dysostosis, rib-cage abnormalities, which can lead to thoracic dystrophy and respiratory failure in the newborn period, delayed appearance of secondary ossification centers, clinodactyly, syndactyly, pes cavus, kyphosis, scoliosis, osteopenia, vertebral collapse, slipped femoral epiphysis, and supernumerary thumb or toe.^{82,83,85,99–103}

Failure to thrive is common in SDS patients and is caused by various factors, including metaphyseal dysostosis, pancreatic insufficiency, feeding difficulties, and recurrent infections.^{82,83} Mean birthweight is at the 25th percentile, but by age 1 year and later, over half of patients are below the 3rd percentile for height. When treated with pancreatic enzyme replacement, most patients continue to show a normal growth velocity, but remain consistently below the 3rd percentile for height and weight.⁹

Hepatomegaly or elevated serum liver enzymes are seen in 50–75% of patients, most often in young children, and tend to resolve with age. The liver disease is usually of little consequence. Delayed dentition of permanent teeth, dental dysplasia, increased risk of dental caries, and periodontal disease may also occur. Abnormalities of the kidneys, eyes, skin, testes, endocrine pancreas, heart, nervous system, and craniofacial structures have been reported.^{82,83,104,105}

Cancer predisposition

A literature review identified 54 reported cases of SDS with marrow cytogenetic abnormalities (MCAs), MDS, or AML.¹⁰ Of the 54 cases, 37 developed MCA/MDS at a median age of 8 years (range 2–42 years) and an additional 17 were diagnosed at the stage of overt leukemia at a median age of 14 years (range 1.5–37 years). Of the patients with MCA/MDS, 68% were males; of those with leukemia, 92% were males.

MCAs have been reported in 40 SDS patients in various stages of malignant myeloid transformation;¹⁰ mostly i(7q) (44%) and del(12)(q12) (16%). i(7q) occurs rarely in other malignancies, and has not been reported in other IMFS. Among the patients with isolated i(7q), no progression into MDS with excess blasts or AML has been reported. However, 42% of the patients with non-i(7q) abnormalities of chromosome 7, particularly monosomy 7, either initially presented with advanced MDS/AML or progressed to them from earlier stages of MDS. Interestingly, MCAs in SDS can regress spontaneously.^{88,106}

With regard to the cytological description of MDS, various morphologic types have been described. Nineteen SDS cases have been reported with cytogenetic abnormalities without prominent marrow dysplasia and without an increase in blasts.^{86,87,103,106–111} Of these patients, four developed severe aplasia, and three developed more severe MDS/AML. Twelve reported SDS patients were diagnosed with MDS at the stage of refractory cytopenia with

dysplasia,^{86,95,107,109,112–116} eight of whom could be evaluated for disease progression: four developed AML. Only one case of refractory cytopenia with ring sideroblasts (without evidence of Pearson syndrome) in a patient with SDS, who eventually progressed to AML, was reported.¹¹⁷ Six published SDS cases were diagnosed with MDS at the stage of refractory cytopenia with excess blasts.^{86,108,119} Three of them progressed to AML.

Leukemia was reported in 26 SDS patients with a median age of 14 years (range 1.5–43 years).^{82,86,104,113,117,120–125} Of these cases, nine were preceded by a documented MDS phase. Various types of AML have been described in SDS patients: AML-M0, M2, M4, M5, and M6. Acute lymphoblastic leukemia and juvenile myelomonocytic leukemia were rare. It is noteworthy that AML-M6 was particularly common in SDS, occurring in about 30% of cases with classifiable leukemia.

SDS-related leukemia carries a poor prognosis. Of the 26 reported cases of AML (as their initial presentation or after a period with MDS), 21 patients died either because of refractory disease or treatment-related toxicity.¹⁰ Malignant myeloid transformation into MDS and AML in SDS patients while on G-CSF therapy has been reported,^{11,107} but the causal relationship is unproven.

Genetic aspects

SBDS was identified originally by Lai and colleagues¹²⁶ in 2000. It has recently been found that about 90% of the families with clinical diagnosis of SDS were found to have mutations in *SBDS*, and 96% of the mutations are in exon 2.¹²⁷ The type of mutations include missense, nonsense, frameshift, and splice-site mutations as well as complex rearrangements comprising deletion/insertion.^{127,128} Correlations are unlikely to exist between genotype and the phenotype in SDS, since patients with severe phenotype such as major skeletal abnormalities¹⁰⁰ or AML¹²⁹ have been found to have common mutations.

Pathogenesis

The function of the *SBDS* gene product is unknown. The mRNA is ubiquitously expressed.¹²⁷ The protein encoded by the *Saccharomyces cerevisiae* ortholog of *SBDS*, *YRL022c*, is essential for yeast survival. Indirect data from lower organisms suggested a role of the gene in RNA processing and ribosomal biogenesis.^{130,131} Synthetic genetic arrays of *YHR087W*, a yeast homolog of the N-terminal domain of *SBDS*, suggested interactions with several genes involved in RNA and rRNA processing.¹³² Austin and colleagues¹³³ have found that *SBDS* localizes to the nucleus, nucleolus, and cytoplasm of normal control fibroblasts, but it concentrates in the nucleolus during G₁ and G₂, and is diffusely distributed in the nucleus during S phase.

Bone marrow from patients with SDS is characterized by decreased frequency of CD34⁺ progenitors,⁹¹ which have a reduced ability to generate hematopoietic colonies of all lineages *in vitro*.^{91,134,135} The stem cell defect comprises both the myeloid and lymphoid compartments,⁸⁴ and is likely to be related to accelerated apoptosis.¹³⁶ The increased tendency toward apoptosis was linked to hypersensitivity of marrow cells to Fas stimulation and increased Fas expression on marrow CD34⁺, CD34-CD38⁺, and CD34-CD38⁻ cell populations.¹³⁶ In addition, SDS is characterized by an abnormal bone marrow stroma, which has decreased ability to support hematopoiesis from normal CD34⁺ cells in long-term marrow stromal cultures.⁹¹

Compared with normal controls, mean telomere length of patients' marrow mononuclear cells at all ages tested was significantly shorter.¹³⁷ The data available on chromosomal instability in SDS are inconclusive. Increased frequencies of spontaneous chromosome aberrations in a patient's phytohemagglutinin-stimulated circulating lymphocytes was demonstrated by some groups,^{138,139} but not by others.^{140,141}

To study the relationship between *SBDS* and leukemia, we studied the association between *SBDS* gene mutations and *de novo* AML in children. Although we have found no *SBDS* mutations in 125 patients with *de novo* AML and in 4 patients with 7q abnormalities,¹²⁹ changes in expression levels or posttranslational modifications are still possible. We also analyzed two SDS cases who developed AML, and found that they had commonly occurring mutations: homozygosity for 258+2T→C or heterozygosity for 183-184TA→CT and 258+2T→C.¹²⁹ When SDS cases with early MDS were studied, various molecular and cellular parameters did not distinguish cases with acquired marrow cytogenetic abnormalities from the other SDS patients, including G-CSF receptor expression or *RAS* and *p53* mutation analysis.⁸⁸ However, SDS marrows demonstrated many characteristic MDS features, including defects in marrow stromal support of normal hematopoiesis, increased apoptosis mediated through the Fas pathway, high frequency of clonal marrow cytogenetic abnormalities, *p53* protein overexpression and telomere shortening.^{137,142,143} This raises the possibility that SDS has prominent pre-leukemic features from its inception.

Diagnosis

Clinical diagnosis is generally made in the first few years of life. The clinical diagnosis requires evidence of exocrine pancreatic dysfunction and characteristic hematologic abnormalities.^{83,128,137} Low blood cell counts, red blood cell macrocytosis, high hemoglobin F, and varying degrees of marrow hypoplasia are usual findings. A cytogenetic finding of i(7q) is highly associated with SDS. Short stature, skeletal abnormalities, hepatomegaly, or biochemical abnormalities of the liver are supportive findings of the diagnosis. Attention should be given to ruling out:

- cystic fibrosis (most common cause of pancreatic insufficiency, with an abnormal sweat test);
- Pearson disease (pancreatic insufficiency and cytopenia, marrow ring sideroblasts, and vacuolated erythroid and myeloid precursors);
- cartilage hair hypoplasia (diarrhea, cytopenia, and metaphyseal chondrodysplasia, common in the Amish population); and
- other IMFSs.

Molecular diagnosis is now available. As the clinical diagnosis of SDS is usually difficult and patients may present at a stage when no clinical pancreatic insufficiency is evident it is probably advisable to test most or all suspected cases for mutations in the *SBDS* gene. It is noteworthy that about 10% of the SDS patients might be negative for mutations in *SBDS*.

Therapy and prognosis

As with Fanconi anemia, a multidisciplinary approach to the care of patients with SDS at a tertiary care center is recommended. Detection of asymptomatic MDS with excess blasts and AML with low blast count may prompt early treatment and improve prognosis. Therefore, in a stable patient with mild to moderate cytopenia, we routinely perform complete blood count and peripheral blood smear every 3–4 months as well as annual bone marrow testing to look for occult transformation. The frequency with which the screening tools should be applied is unknown, and probably depends on the severity of the bone marrow findings. The earliest reported ages of transformation were 1.5, 2, and 3 years, so if a screening program is planned it should probably start after diagnosis regardless of age.

Supportive care

In cases of fever and severe neutropenia, patients should be treated with intravenous antibiotics with broad-spectrum coverage until the infection clears up. G-CSF should be considered in such situations. G-CSF given for profound neutropenia has been effective in inducing a clinically beneficial neutrophil response.^{107,144,145} Granulocyte-macrophage colony-stimulating factor (GM-CSF) was also shown to be effective in one patient¹⁴⁶ but not in others.¹⁴⁵ Despite low serum erythropoietin levels in one patient, administration of erythropoietin did not improve hemoglobin levels.¹²³ Thrombocytopenia and anemia may require respective chronic transfusions, sometimes with an iron chelation program.

Androgens

A few patients have received androgens plus steroids in the manner of treating patients with Fanconi anemia. Transient responses⁹³ and unsuccessful trials^{92,123} have been reported. Because of the underlying liver abnormalities seen in SDS, the risk of androgen use might be even higher than it is

in Fanconi anemia. Moreover, the worse outcome seen in Fanconi anemia patients who received androgens before HSCT is worrisome.⁶⁵

Hematopoietic stem cell transplantation

The criteria for selecting patients for HSCT (related or alternative) should include severe cytopenia (hemoglobin < 8 g/L, absolute neutrophil count < 0.5×10^9 /L, platelet count < 20×10^9 /L), MDS with excess blasts and overt leukemia. In cases of frank leukemia, the patient may be started on chemotherapy to reduce tumor load before HSCT, but an effort to find a donor should be made at the time of diagnosis because of the high risk of therapy-related aplasia.

At present, HSCT provides the only curative option for the hematologic complications in SDS. Analysis of published case reports of SDS patients who underwent allogeneic HSCT suggested that complications are more common in SDS patients who receive chemotherapy or undergo HSCT than in patients with idiopathic blood dyscrasias.¹⁰ The European Group for Blood and Marrow Transplantation has recently published results of HSCT using either matched-related sibling donor (23%) or unrelated donor or a family mismatched donor (77%) in 26 patients with SDS.¹⁴⁷ The conditioning regimen was based on busulfan (54%), total body irradiation (23%), fludarabine (15%), or other chemotherapy combinations (8%). GVHD prophylaxis comprised ciclosporin with or without methotrexate or T-cell depletion. Neutrophil and platelet engraftment were achieved in 81% and 65% of the patients. The incidence of grade III and IV acute GVHD was 24% and of chronic GVHD 29%. Overall survival was 64.5% with follow-up of 1.1 years. A trend toward a higher mortality rate was found in cases of AML/MDS versus severe aplastic anemia (56% vs 19%), but the difference was not significant. Results of a series of ten cases of SDS with severe aplastic anemia or MDS/AML from the French registry using unrelated (six cases) and related (four cases) donors, showed 5-year event-free survival rate of 60%.¹⁴⁸

Complications are more common in SDS patients who receive chemotherapy or undergo HSCT than in patients with idiopathic blood dyscrasias. In a review of 36 patients with SDS who had been treated with chemotherapy alone¹⁰ or with HSCT with or without irradiation, 83% died from complications related to the therapy, including prolonged severe aplasia, infections, cardiotoxicity, neurologic and renal complications, veno-occlusive disease, pulmonary disease, posttransplant graft failure, and GVHD.

Prognosis

On the basis of a literature review, Alter calculated the projected median survival of SDS patients as 35 years.¹² During infancy, morbidity and mortality are mostly related to malabsorption, infections, and thoracic dystrophy. Later in life the main causes of morbidity and mortality are hematologic or the treatment for the hematologic complications. Cytopenias

tend to fluctuate in severity but never fully resolve. No remissions have been reported after symptomatic cytopenias or advanced malignant myeloid transformation.

Dyskeratosis congenita

Dyskeratosis congenita (DC) is characterized by ectodermal abnormalities,^{149,150} bone marrow failure,⁶ cancer predisposition,⁶ and extreme telomere shortening.¹⁵¹ With the recent advances in understanding the molecular basis of the disease, patients with hematologic abnormalities without dermatologic anomalies have been identified, which has changed dramatically the historical definition of the disease.⁵

Clinical features

Hematologic manifestations

The DC registry in Hammersmith, England, provides important data about the clinical features and genetic basis of DC.⁶ About 50% of X-linked male patients with DC and 70% of autosomal recessive patients develop aplastic anemia, usually in the teenage years. The actuarial probability of marrow dysfunction in males is 94% by the age of 40 years.⁶ Bone marrow dysfunction occurs less frequently in the autosomal dominant group. Some young patients can develop marrow failure prior to the clinical onset of the mucocutaneous manifestations. The initial hematologic change is usually thrombocytopenia, anemia, or both, followed by pancytopenia. The red cells are often macrocytic and the hemoglobin F can be elevated. Oddly, early bone marrow aspirations and biopsies may be hypercellular; however, with time all cellular elements decline.

Immunologic abnormalities, including reduced immunoglobulin levels, reduced T- and B-lymphocyte numbers, and reduced proliferation in response to mitogens, may occur in patients in DC. Severe combined immunodeficiency or abetagamaglobulinemia¹⁵² can occur in patients carrying the *DKC1* gene mutation.

Nonhematologic manifestations

In most cases skin pigmentation and nail changes appear in the first 10 years of life, mucosal leukoplakia and excessive ocular tearing appear later, and by the mid-teens the serious complications of bone marrow failure and malignancy begin to develop. In some cases the marrow abnormalities may appear before the skin manifestations.

Cutaneous findings are the most consistent feature of the syndrome. Lacy reticulated skin pigmentation affecting the face, neck, chest, and arms is the most common finding (89%), and increases with age. There may also be a telangiectatic erythematous component. Nail dystrophy of the hands and feet is the next commonest finding (88%) (Fig. 3.2). It usually starts with longitudinal ridging, splitting, or pterygium formation, and may progress to complete nail loss. Leukoplakia

Fig. 3.2 Dystrophic nails in dyskeratosis congenita.

Fig. 3.3 Leukoplakia of the tongue in dyskeratosis congenita.

usually involves the oral mucosa, especially the tongue (78%) (Fig. 3.3) but can also be seen in the conjunctiva, anal, urethral, or genital mucosa. Hyperhidrosis of the palms and soles is common, and hair loss is sometimes seen. Eye abnormalities are observed in approximately 50% of cases.⁶ Excessive tearing (epiphora) secondary to nasolacrimal duct obstruction is common. Other ophthalmologic manifestations include conjunctivitis, blepharitis, loss of eyelashes, strabismus, cataracts, and optic atrophy. Abnormalities of the teeth, particularly an increased rate of dental decay and early loss of teeth, are common. Skeletal abnormalities such as osteoporosis, avascular necrosis, abnormal bone trabeculation, scoliosis, and mandibular hypoplasia are seen in approximately 20% of cases.⁶ Genitourinary abnormalities include hypoplastic testes, hypospadias, phimosis, urethral stenosis, and horseshoe kidney. Gastrointestinal findings, such as esophageal strictures, hepatomegaly, or cirrhosis, are seen in 10% of cases.^{6,153}

The Hoyeraal-Hreidarsson syndrome is a severe variant

of *DKC1*-associated DC, with cerebellar hypoplasia, microcephaly, growth retardation, immunodeficiency, and early-onset severe aplastic anemia.¹⁵² A similar syndrome is Revesz syndrome, which is characterized by dystrophic nails, leukoplakia, aplastic anemia, cerebellar hypoplasia, growth retardation, microcephaly, and bilateral exudative retinopathy. The genetic defect has not yet been identified.¹⁵⁴

Patients with DC are also prone to interstitial pulmonary disease with a restrictive defect as well as pulmonary vascular disease. This complication has been reported in patients after HSCT and in untransplanted patients.^{6,155,175}

Cancer predisposition

Cancer develops in at least 10–15% of patients, usually in the third or fourth decades of life. The types of malignancies are similar to Fanconi anemia, although in DC solid tumors are more common than hematologic malignancies. All genetic subgroups can be affected with cancer.^{12,19} Most of the cancers are squamous cell carcinoma or adenocarcinomas; the oropharynx and gastrointestinal tract are involved most frequently. Patients can develop multiple separate primary tumors. MDS and AML occur rarely.⁶

Genetic aspects

Approximately 85% of the 300 published cases of DC are male. The X-linked disease is caused by mutations in *DKC1* on chromosome Xq28.¹⁵⁶ Heterozygous mutations in the *TERC* gene are the cause for the autosomal dominant form of DC.¹⁵⁷ Familial cases with affected male and female siblings in one generation, and cases with known parental consanguinity fit an autosomal recessive inheritance pattern. The gene(s) for this group have not yet been identified.

The X-linked and autosomal recessive forms appear to have more physical anomalies and earlier onset of aplastic anemia. The X-linked disease is characterized by a higher incidence or severity of immune dysfunction. Clinically, the autosomal dominant group seems to be milder in its manifestations.⁶

Pathogenesis

The gene associated with the autosomal dominant DC, *TERC*, encodes for the RNA component of human telomerase, which is responsible for telomere maintenance.¹⁵¹ DC cells are characterized by very short telomeres. In several acquired and inherited marrow failure syndromes, telomere length is reduced as a result of increased replicative stress. However, in DC there is also a telomerase defect, and the magnitude of this degenerative process is much more severe, so that patients develop aging-associated symptoms at an early stage.

The gene associated with the X-linked DC, *DKC1*, encodes for the protein dyskerin. Dyskerin is involved in

pseudouridylation of nascent rRNA. In addition, dyskerin binds to *TERC*, facilitating telomere maintenance.

Clastogenic stress studies of DC cells are normal.^{6,158} However, DC is a chromosome “instability” disorder of a different type than Fanconi anemia.¹⁵⁹ In some patients metaphase in peripheral blood cells, marrow cells, and fibroblasts in culture showed numerous spontaneous unbalanced chromosome rearrangements such as dicentrics, tracentrics, and translocations.

Clonogenic assays of marrow cells showed a marked reduction or absence of colony forming colonies of granulocytes, erythrocytes, monocytes and megakaryocytes (CFU-GEMM), BFU-E, CFU-E and CFU-GM progenitors.^{46,160} Marrow stromal cells showed a normal ability to support growth of hematopoietic progenitors from normal marrow in three patients who were studied, but generation of progenitors from patient marrow cells inoculated onto normal stroma was reduced, suggesting that the defect in DC is of hematopoietic stem cell origin.¹⁶⁰

Laboratory evaluation and diagnosis

The median age of diagnosis of the X-linked DC is 15 years (range 0.3–68 years), of the autosomal recessive form is 13 years (range 1.2–42 years), and of the autosomal dominant group is 25 years (range 7–58 years). Thrombocytopenia and anemia usually appear first, followed by pancytopenia. Severe cytopenia eventually develops in about 50% of the patients.

The diagnosis is frequently delayed, and some cases are accurately diagnosed many years after HSCT for apparently acquired aplastic anemia once the cutaneous manifestations become prominent. A detailed medical, developmental, and family history, along with a physical examination usually yield important diagnostic clues. Low blood cell counts, red blood cell macrocytosis, and high hemoglobin F are usual findings. Bone marrow cellularity can be normal or increased at the onset of cytopenia, but invariably decreases once the cytopenia deteriorates.

Mutation analysis of the *DKC1* and *TERC* genes can provide a molecular diagnosis for patients with the X-linked and autosomal dominant diseases. Selected patients with aplastic anemia who either have one or more DC-related nonhematologic manifestations or who do not respond to treatment with immunosuppressive therapy should be tested as well.⁵

Prenatal diagnosis

Prenatal diagnosis is now available to most patients with DC using molecular testing for *DKC1* and *TERC* of DNA from amniotic cells or chorionic villous cells.

Therapy and prognosis

The mean age of death is approximately 30 years.¹² The

main causes of death relate to either bone marrow failure or malignancy.

Androgens

Androgens, usually combined with low-dose prednisone, can be expected to induce improved marrow function in about 40% of patients. If a response is seen and deemed to be maximal, the androgen dose can be slowly tapered but not usually stopped. As in Fanconi anemia, patients can become refractory to androgens as the aplastic anemia progresses.

Growth factors

Four patients were reported who responded to G-CSF therapy with significant increases in absolute neutrophil counts.^{161,162} Similarly, GM-CSF therapy in two other patients resulted in improved neutrophil numbers.¹⁶³ A combination of G-CSF with erythropoietin was used in one case with DC and severe cytopenia, and improved counts of all cell lineages were observed.¹⁶⁴ Therefore, there appears to be potential benefit from cytokine therapy in selected patients with DC while waiting for HSCT or who are not eligible for transplant.

Hematopoietic stem cell transplantation

The only cure for patients who develop severe bone marrow complications is HSCT. To date, 25 patients with DC have reportedly undergone HSCT.^{6,155,161,165–174} In most cases standard conditioning regimens were used.

Of the 19 reported cases of DC patients who were transplanted from a matched related donor (MRD), 11 survived more than 3 years. However, an additional 6 of these 19 died subsequently at 6–29 years posttransplant. Of the six reported cases of DC patients who were transplanted from a matched unrelated donor (MUD), three are alive after more than 3 years (including two patients from our institution who were initially reported to survive more than 1.5 years posttransplant).¹⁶¹

Short-term transplant-related toxicity is common in these populations, including sepsis, GVHD, and early death.^{56,166,170} Vascular lesions and fibrosis involving various organs can occur in DC patients in both early and late periods after transplantation and carry a high mortality rate. Another striking complication for patients with DC after HSCT is bronchopulmonary disease. An inherent propensity for pulmonary disease¹⁷¹ may explain the high incidence (up to 40%) of early and late fatal pulmonary complications after HSCT.^{6,56,155,159,167}

Telomere shortening and chromosomal instability can explain hypersensitivity of DC patients to irradiation and chemotherapy.^{60,172,173} The increased predisposition to post-transplant complications, especially pulmonary and vascular, the chromosomal instability, and the tendency to develop tumors highlight the need to avoid certain conditioning agents such as busulfan and irradiation. Reports of a reduced-intensity regimen incorporating fludarabine for

MRD¹⁷⁰ and MUD¹⁶¹ HSCT in patients with DC have been published, showing decreased toxicity at short-term follow-up of 2–3 years. Longer follow-up is still needed to clarify whether long-term toxicity is also reduced by these regimens.

Congenital amegakaryocytic thrombocytopenia

In this section we refer to the syndrome of congenital amegakaryocytic thrombocytopenia (CAMT) as an autosomal recessive IMFS with predominantly pancytopenia, which usually presents in infancy with isolated thrombocytopenia due to reduced or absent marrow megakaryocytes, and frequently evolves into pancytopenia of varying degrees. In untreated cases, MDS with monosomy 7 and AML can develop at a later stage.¹⁷⁴ Nonhematologic manifestations occur in about a quarter of the patients.

Clinical features

Hematologic manifestations

Most patients present at birth or during the first year of life with a petechial rash, bruising, or bleeding. At presentation the platelets are typically moderately to severely reduced (with a median platelet count of $21 \times 10^9/L$,¹⁷⁴ but the hemoglobin levels and white blood cell counts are normal. Red cells may be macrocytic, and hemoglobin F can be increased. At diagnosis, bone marrow specimens show normal cellularity with markedly reduced or absent megakaryocytes. Aplastic anemia subsequently ensues in 39–75% of the patients at the age of 2–53 months.¹⁷⁴

A second group of patients with CAMT present with moderate thrombocytopenia either early in infancy or later during childhood.¹⁷⁴ These patients are initially platelet transfusion-free, but tend to develop aplastic anemia during the first decade of life.

Nonhematologic manifestations

Roughly a quarter of patients have characteristic physical anomalies. Some affected sibships manifest both normal and abnormal physical findings in the same family. The most common manifestations in those with anomalies are neurologic and cardiac. Findings relating to cerebellar and cerebral atrophy are a recurrent theme, and developmental delay is a prominent feature in this group. Patients may also have microcephaly and an abnormal facies. Congenital heart disease with a variety of malformations can be detected, including atrial and ventricular septal defects, patent ductus arteriosus, tetralogy of Fallot, and coarctation of the aorta. Some of these can occur in combinations. Other anomalies include abnormal hips or feet, kidney malformations, eye anomalies, and cleft or high-arched palate.

Cancer predisposition

Patients with CAMT are prone to MDS/AML.^{12,174} The typical course is the development of early thrombocytopenia, aplastic anemia, and then marrow cytogenetic abnormalities (usually monosomy 7), MDS and AML. The risk of malignant conversion is difficult to determine because of the rarity of the disease, paucity of published data, the possible patient heterogeneity, and the need for early HSCT due to the development of aplastic anemia. No solid tumors have yet been associated with the disease.

Genetic aspects

Mutations in the *MPL* (thrombopoietic receptor) gene are the cause of the disorder in most patients with CAMT, particularly,¹⁷⁸ but not exclusively,¹⁷⁹ in those without physical anomalies. Both alleles were mutated, confirming an autosomal recessive mode of inheritance.^{178,180}

Pathogenesis

MPL mutations cause inactivation of the thrombopoietin receptor. The compensatory elevated levels of thrombopoietin^{178,179} do not result in transmission of the receptor signals.^{180,181} Thrombopoietin plays a critical role in the proliferation, survival, and differentiation of early and late megakaryocytes. This clearly explains the thrombocytopenia. However, thrombopoietin also promotes survival of hematopoietic stem cells; thus, it is possible that a defect in its receptor results in depletion of their pool. The number of colony forming units of megakaryocytes (CFU-Meg) progenitors might be normal initially, but declines as the disease progresses.^{182,183}

Laboratory evaluation and diagnosis

The median age of diagnosis is 1.3 months (range 0–110 months) in the nonsyndromic cases and 2 days (range 0–18 months) in the syndromic cases.¹² The typical patient presents with isolated severe thrombocytopenia from birth. Once acquired diagnoses are excluded, IMFSs should be considered. In the first several months of life, red blood cell volume and hemoglobin F levels are difficult to interpret, but gradually can become abnormally high. If physical malformations, which are not characteristics of thrombocytopenia with absent radii syndrome, are observed, the diagnosis can be more readily suspected. The gold standard procedure for determining cellularity and marrow megakaryocyte pool is bone marrow biopsy. All patients with suspected CAMT should be offered *MPL* mutation analysis.

Therapy and prognosis

Without curative treatment, the mortality rate from thrombocytopenic bleeding, complications of aplastic anemia, or malignant myeloid transformation is close to 100%. For this reason, HLA typing of family members should be performed as soon as the diagnosis is confirmed to see if a matched related donor for HSCT exists. If not, a search for a matched unrelated donor should ensue as soon as the seriousness of the clinical picture dictates.

Platelet transfusions should be used as medically indicated and not just because of a low platelet count. Single donor platelets are preferred to minimize sensitization. All blood products should be irradiated and tested negative for CMV.

Corticosteroids have been used with no apparent efficacy. For aplastic anemia, androgens in combination with corticosteroids may induce a temporary partial response but the effect is short-lived. Based on the *in vitro* studies, several clinical trials have been conducted with interleukin-3 (IL-3), GM-CSF, and the fusion cytokine PIX321.¹⁸³ These cytokines may result in temporary hematologic improvement, but clearly are not curative. IL-3 and PIX321 are not available for clinical use. Other cytokines such as thrombopoietin and IL-11 are not licensed for children with IMFSs.

Hematopoietic stem cell transplantation

A review of publications from 1990 to 2000 yields five reports of a total of 15 CAMT patients who underwent HSCT.^{184–188} Seven patients had received stem cells from a matched related donor using busulfan-based myeloablative regimens; all patients engrafted with minimal GVHD and had a good outcome. However, the outcome of eight patients who received unrelated or mismatched related donor transplants was inferior; five received total body irradiation-based conditioning. Initial graft failure occurred in three patients. Three patients died due to bronchiolitis obliterans with organizing pneumonia and infections. We have recently used a reduced-intensity transplantation regimen incorporating fludarabine 180 mg/m², ATG 160 mg/kg, and cyclophosphamide 120 mg/kg in a CAMT patient with aplastic anemia and acquired monosomy 7 who had no matched related donor. The patient had rapid and durable engraftment with minimal complications and is well 2 years posttransplantation.¹⁸⁹

Other inherited marrow failure disorders with predominantly pancytopenia

Reticular dysgenesis is a congenital severe lymphohematopoietic stem cell disorder characterized by severe B- and T-cell immunodeficiency, thymic and lymph node aplasia, and cytopenia.¹⁹⁰ Neutropenia is the most common cytopenia, but anemia and thrombocytopenia can also occur. Bone marrow specimens are hypocellular with markedly

reduced myeloid and lymphoid elements; erythroid and megakaryocytic series are usually normal. Clonogenic assays of hematopoietic progenitors consistently show reduced to absent colony growth, indicating that the underlying defect resides at the pluripotential lymphohematopoietic stem cell level.¹⁹¹ The mode of inheritance is probably autosomal recessive, but an X-linked recessive mode is also possible in some cases. Similarly to other syndromes with severe combined immunodeficiency, the patients present with severe infections at birth or shortly thereafter. Neutrophil counts usually do not improve with administration of G-CSF,¹⁹¹ and the patients often die within the first weeks of life unless they receive HSCT.¹⁹¹

Pearson disease is caused by deletional mutations in mitochondrial DNA,¹⁹² and is associated with variable degrees of pancreatic dysfunction, pancytopenia, and metabolic acidosis.¹⁹³ Marrow aspirates show ring sideroblasts and vacuoles in myeloid and erythroid precursors. The cytopenia tends to improve with age.¹⁹⁴

Pancytopenia due to hypoplastic bone marrow was also observed in Dubowitz syndrome,^{195,196} Seckel syndrome,^{197,198} and Schimke immuno-osseous dysplasia.¹⁹⁹

Inherited marrow failure disorders with predominantly anemia

Diamond–Blackfan anemia

Diamond–Blackfan anemia (DBA) is an inherited form of pure red cell aplasia.²⁰⁰ The syndrome is heterogeneous with respect to inheritance patterns, clinical and laboratory findings, and therapeutic outcome. About 80% of cases are apparently sporadic,²⁰¹ but the familial cases (20%) point to either autosomal dominant or autosomal recessive or X-linked recessive modes of inheritance. Using data from the European DBA registries,^{202,203} the incidence of the disorder in Europe is 5–7 cases/million live births.

Clinical features

Hematologic manifestations

Anemia was once considered a universal component of the syndrome; however, studies of families with *RPS19* gene mutations have identified affected individuals without anemia.²⁰⁴ Patients may present at birth with severe anemia and hydrops fetalis. In other cases the patient become symptomatic after birth and presents with pallor, weakness, cardiac failure, hepatosplenomegaly, and edema.

Median hemoglobin level at birth is 7 g/dL (range 2.6–14.8 g/dL). At presentation the median hemoglobin level is approximately 4 g/dL (range 1.7–9.1). The reticulocytes are decreased or absent. Macrocytosis is difficult to diagnose in the first 2 month of life. This might explain the observation

that the mean corpuscular volume is abnormally high for age in 80% of the patients at presentation, and in apparently all patients afterward.²⁰⁵ Peripheral blood smear is nondiagnostic. Most patients have normal platelet and neutrophil counts. Mild thrombocytopenia and neutropenia may occur in DBA, but severe thrombocytopenia and neutropenia are unusual findings.^{206,209}

DBA erythrocytes manifest fetal erythroid characteristics, including²¹⁰ elevated levels of hemoglobin F, fetal amino acid profile of the hemoglobin F with high glycine to alanine ratio, and a high expression of the i antigen on the surface of red blood cells.

Studies of the red blood cell enzyme levels have shown an abnormal profile. For example, the activities of enolase, glyceraldehyde-3-phosphate dehydrogenase, phosphofructokinase, and glutathione peroxidase are increased;²¹¹ in some cases the profile is similar to cord blood. The levels of several other enzymes resemble those in adult erythrocytes. For instance, carbonic anhydrase isoenzyme B activity is elevated and hexokinase has an adult type isoenzyme distribution.²¹⁰

Glader and colleagues found elevated red blood cell adenosine deaminase levels in 90% of the patients, and in 17% of their parents.²¹² As this abnormality is not found in red blood cells from normal cord blood samples, healthy children, or other marrow failure disorders, determination of the red blood cell adenosine deaminase level became a useful diagnostic test for DBA. Abnormalities involving pyrimidine enzymes in DBA erythrocytes have also been described, including elevated activities of orotate phosphoribosyl transferase²¹³ and orotidine monophosphate decarboxylase.^{212,213}

Bone marrow biopsy and aspirate show a normocellular specimen in 90–95% of the patients. The myeloid to erythroid (mostly proerythroblasts) ratio is > 10:1. The myeloid and megakaryocytic lineages are usually unremarkable. In early stages of the disease, dyserythropoiesis changes might occur. Marrow cytogenetic abnormalities are extremely rare.

Nonhematologic manifestations

Obstetric complications such as miscarriages, stillbirth, pre-eclampsia, premature separation of the placenta and breech presentation have been reported in approximately 10% of the mothers of DBA patients. More than 10% of the patients have intrauterine growth retardation.

Physical anomalies have been reported in approximately 40% of the patients.^{201,209} Short stature and failure to thrive are common. Craniofacial dysmorphisms include microcephaly, hypertelorism, microphthalmos, cataract, glaucoma, strabismus, microretrognathism, high-arched palate, cleft palate, and ear malformations. Some patients have characteristic facies consisting of snub nose, wide-set eyes, thick upper lip, and intelligent expression. Another characteristic facies consists of microcephaly, almond-shaped eyes, mild antimongoloid slant, and pointed chin. Neck anomalies

Fig. 3.4 Radial aplasia with preservation of the thumb in a newborn with TAR syndrome.

include pterygium coli, Klippel–Feil anomaly (fusion of the cervical vertebrae with fusion of the trapezius muscle), and Sprengel deformity (congenital elevation of the scapula). Thumb anomalies include bifid thumb (see Fig. 3.4), duplication, subluxation, hypoplasia, absence of thumb, and triphalangeal thumbs. The combination of hypoplastic anemia and a triphalangeal thumb is commonly referred to as Aase syndrome or Aase–Smith syndrome. Less commonly, patients may have weak or absent radial pulse along with flat thenar eminence. Urogenital anomalies include dysplastic kidneys, horseshoe kidneys, duplication of the ureters, renal tubular acidosis, and hypogonadism. Congenital heart disease includes ventricular septal defect and atrial septal defect. Other manifestations include congenital dislocation of the hip, achondroplasia, clubfoot, tracheoesophageal fistula, and mental retardation.

Cancer predisposition

Of the 354 patients registered in the DBA Registry of North America, 6 (1.7%) developed malignancies.²¹⁴ Reported malignancies in this registry and in the literature include MDS, AML, acute lymphoblastic leukemia, osteosarcoma, soft tissue sarcoma, Hodgkin lymphoma, non-Hodgkin lymphoma, gastric carcinoma, colon carcinoma, hepatocellular carcinoma, breast carcinoma, vaginal melanoma, and malignant fibrous histiocytoma. DBA is probably an additional genetic disease with inherent predisposition for cancer.

Genetic aspects

DBA affects both sexes equally, and has been reported in many ethnic groups including white people, black Africans, Arabs, East Indians, and Japanese. The study of a sporadic female case with DBA and a constitutional balanced reciprocal translocation 46,XX,t(X;19)(p21;q13),²¹⁵ as well as the identification of microdeletions at chromosome 19q13.2 in DBA patients,²¹⁶ linked the first DBA gene to the 19q13.2 locus. The breakpoint of the translocation t(X;19)(p21;q13) was found in *RPS19*.²¹⁷ The *RPS19* gene is 11 kb with six exons. Mutations in *RPS19* occur in approximately 25% of DBA patients, and include nonsense, frameshift, splice-site, missense, and deletional mutations.²¹⁷ A hotspot for missense mutations was identified between codons 52 and 62 of the *RPS19* gene.²⁰⁴ The occurrence of mutations in one allele is congruent with the apparently autosomal dominant inheritance in this subgroup of patients. There seems to be no correlation between the *RPS19* genotype and phenotype. It is noteworthy that *RPS19* mutations were also found in some first-degree relatives presenting only with isolated high erythrocyte adenosine deaminase activity and/or macrocytosis.

A second DBA locus has been mapped to chromosome 8p22–p23 in about 35% of the cases,²¹⁸ but the candidate gene has not been identified yet. The linkage was found in families with vertical transmission of the disease, confirming an autosomal dominant inheritance in these families. About 40% of the patients neither carry *RPS19* mutations nor do they link to 8p22–p23.

Pathogenesis

DBA marrows are characterized by complete or nearly complete absence of erythroid precursors in 90% of the patients. The defect in DBA seems to be intrinsic to the hematopoietic stem cells and selectively limits their ability to differentiate into and expand the erythroid compartment. Clonogenic assays of marrow cells or CD34⁺ cells typically show absent BFU-E and CFU-E progenitors. Some patients show normal or even increased numbers of both progenitors or a block at the BFU-E stage.

Long-term bone marrow cultures showed normal stromal cell function in terms of its ability to support normal hematopoiesis.^{219,220} However, DBA CD34⁺ cells had impaired ability to undergo granulocytic–monocytic differentiation in addition to their erythroid differentiation defect. These results underscore a stem cell defect in DBA rather than an isolated erythroid defect. This is in keeping with the clinical observation that in addition to anemia, patients can have neutropenia and thrombocytopenia.^{206–208}

DBA erythroid progenitors demonstrate subnormal colony growth in response to erythropoietin.²²¹ The defect in colony growth can be partially corrected *in vitro* by the addition of combinations of factors, including glucocorticoids and

erythropoietin,²²² stem cell factor and interleukin-3,²²³ and stem cell factor and erythropoietin.²²⁴

RPS19 encodes for the ribosomal protein S19, which is associated with the ribosomal subunit 40S.²²⁵ The exact role of *RPS19* in erythropoiesis is unclear. *RPS19* expression is highest at the earlier stages of erythropoiesis and decreases with differentiation.²²⁶ Gene transfer of the wild-type *RPS19* into CD34⁺ cells from DBA patients with *RPS19* mutations improves erythroid colony growth,²²⁷ proving the causative role of mutations in the gene in the pathogenesis of DBA.

In studies of CD34⁺ cells from DBA patients and CD34⁺ cells in which *RPS19* expression was reduced by approximately 50%, it has been shown that *RPS19* promotes cell proliferation as well as differentiation into CFU-E progenitors.²²⁸ Intermediate levels of *RPS19* to approximately haploinsufficiency levels do not affect myeloid progenitors^{223,228} or megakaryocytic progenitors.²²³ It is likely that the genetic defects in the DBA gene(s) accelerates apoptosis of erythroid progenitor cells.^{229,230}

The DBA defect does not reside in production of the major erythropoietic cytokines stem cell factor, interleukin-3, and erythropoietin; all are produced in normal or high levels in DBA patients. In addition, molecular analysis of the stem cell receptor gene and the stem cell factor gene found no mutations.

Laboratory evaluation and diagnosis

The median age of diagnosis is 2–3 months (range 0–64 years).¹² The typical patient presents with isolated anemia in the first year of life (90%). Presentation in the neonatal period requires exclusion of common causes of congenital anemia such as infections and hemolytic disorders. After the neonatal period, other causes of macrocytic anemia as well as transient erythroblastopenia of childhood have to be excluded before a diagnosis of DBA is made. Features of transient erythroblastopenia of childhood that can help distinguish it from DBA include: (i) onset usually at 1–4 years; (ii) preceding viral illness in more than half of the patients; (iii) normal red blood cell mean corpuscular volume while still in the reticulocytopenic phase; (iv) normal hemoglobin F and i antigen during the reticulocytopenic phase; (v) normal adenosine deaminase levels; and (vi) spontaneous recovery within 4–8 weeks. Another important differential diagnosis is parvovirus infection.

Once peripheral destruction, bleeding, and splenic sequestration are excluded, a primary marrow disorder should be considered. Bone marrow aspirate and biopsy should be done. If pure red cell aplasia is found, the most likely diagnosis in this age is DBA. If physical examination reveals characteristic DBA anomalies, particularly of the thumbs, the diagnosis is easily made. At any age, red blood cell volume and hemoglobin F levels should be ascertained and compared with the reference values based on age. Red blood cell

adenosine deaminase level and clonogenic assays of marrow CD34⁺ cells can be important diagnostic tools, though not available in most centers.

The diagnosis is based on the following characteristic features:

- anemia;
- presentation in the first 12 months of life;
- normochromic-macrocytic red blood cells;
- relative reticulocytopenia;
- normocellular marrow with selective, marked deficiency of erythroid precursors;
- increased serum erythropoietin in the anemic patients;
- normal white cell count;
- normal platelet counts;
- elevated hemoglobin F; and
- elevated red blood cell adenosine deaminase.

None of these diagnostic features occurs in 100% of the patients. Thus, all patients with suspected DBA should be offered genetic testing whenever possible. Unfortunately only the *RPS19* gene is available for testing, and thus, only 25% of the cases can be confirmed.

Treatment

Transfusions

Until a diagnosis of DBA is confirmed, the only treatment should be packed red cell transfusions. Complete correction of the hemoglobin by transfusions is not recommended as it might not be necessary and may prevent recovery of erythropoiesis in case the diagnosis is transient erythroblastopenia of childhood.

Most DBA patients are treated with a lifelong red blood cell transfusion program, either because they did not respond to prednisone or other medical treatment or they required high prednisone doses to maintain response. Approximately 15 mL/kg of leukocyte-depleted packed red blood cells on a monthly basis is usually required to allow normal activity and growth. After approximately 15 units of red blood cells, body iron stores should be carefully assessed. Liver biopsy²³¹ or superconducting quantum interference device (SQUID) susceptometer²³² are more accurate than serum ferritin, and routinely performed in large centers. Magnetic resonance imaging (MRI) of the liver has been explored,²³³ but has not become a widely accepted method. The most common treatment of choice today for the treatment of iron overload is iron chelation with subcutaneous deferoxamine (desferrioxamine) infusion.

Hemoglobin levels before transfusions should be tailored to the individual patient and be maintained higher than 6–7 g/dL. Higher hemoglobin levels may be required to prevent symptoms and allow normal activity and optimal growth. Determination of pretransfusion hemoglobin levels is important also for detecting those rare patients who become transfusion independent either transiently or permanently.

Glucocorticoids

Oral prednisone or equivalent preparation is the mainstay of treatment for DBA.²²¹ Treatment with these drugs is usually begun once the diagnosis is confirmed. Some groups recommend waiting to administer glucocorticoids until the patient is approximately 1 year of age to minimize the adverse effect on growth. Approximately 65% of the patients respond to prednisone or prednisolone, and demonstrate reticulocytosis within 1–3 weeks followed by a rise in hemoglobin. The initial dose is usually 2 mg/kg daily, divided two to four times a day.²³⁴ The prednisone trial may last for approximately 4 weeks as most patients will respond during this period. There are no known factors that can predict responsiveness to glucocorticoids. Once the hemoglobin level rises to 10 g/L or reaches a plateau of 7–9 g/L, the steroid dose can be slowly tapered to the minimal single dose on an alternate-day schedule or even once a week, which maintains the hemoglobin levels with an acceptable degree of side effects. The minimal effective dose varies, and might be as low as 0.05 mg/kg once a week. If the required glucocorticoid dose is too high (>0.5 mg/kg daily) or causes significant toxicity an alternative treatment should be sought. Growth curves and bone mineral density should be monitored periodically. Two-thirds of patients who initially respond to prednisone will continue the drug for life. The rest will either lose the response or require unacceptably high doses, which necessitates discontinuation of the drug.

Several groups studied the efficacy of high-dose methylprednisolone (30–100 mg/kg daily) for patients with DBA who failed conventional treatment of prednisone with either no response, partial response, or complete response.^{235,236} However, relapses were common, and toxicity was significant.

Other medical treatment

Some patients who do not respond to prednisone can be treated successfully with ciclosporin.^{237,238} Treatment with interleukin-3 induced rare sustained remissions in DBA patients.²³⁹ However, it was removed from clinical use due to its unfavorable side effects. Erythropoietin levels are typically markedly elevated in DBA, and treatment trials have been unsuccessful.^{240,241}

Hematopoietic stem cell transplantation

Although HSCT is the only known cure for the marrow failure in DBA, the indications for transplantation in DBA are unclear. The first factor in making a decision is the severity of the disease. Patients who either need no therapy or respond to relatively low doses of prednisone or respond to other medical therapies with minimal side effects are obviously not candidates for HSCT. Those who eventually need regular red blood cell transfusions and have personal or medical difficulties with iron chelation are potential candidates. Patients who are red blood cell transfusion-dependent but are properly chelated might have equal or better quality of life and equal

or longer overall survival than transplanted patients. The second factor that has to be taken into account when consulting a patient or family about HSCT is that 10–15% of the patients may have spontaneous remission by their second decade of life. Third, the success of HSCT decreases when performed later in childhood or afterward.

The type of donor is critically important in DBA. Data from the European DBA Registry showed 11 of 13 (85%) successfully transplanted patients when performed with a matched sibling donor.²⁰³ Data from the North American DBA Registry showed an overall survival of 88% with matched related donors compared with 14% when unrelated or mismatched related donors were used.²⁴²

Cord blood transplantation^{243,244} and reduced toxicity regimens^{245,246} have also been applied successfully in DBA, but represent a relatively small number of patients.

Long-term prognosis

The long-term outcome of DBA patients has still to be clarified. Based on literature review, Alter found that the projected median survival of DBA patients was 65 years.¹² Deaths are mainly due to the complications of iron overload and infections, and less commonly due to HSCT, leukemia, other cancer, or nonhematologic/oncologic complications.

Pregnancies of DBA females have been reported.^{247,248} The pregnancy of a DBA mother might be complicated by worsening of the anemia, toxemia, labor arrest, fetal distress, intrauterine growth retardation, and preterm delivery.

Other inherited marrow failure syndromes with predominantly anemia

Congenital sideroblastic anemias are inherited or acquired disorders of mitochondrial iron utilization. Iron accumulation occurs in the mitochondria of red blood cell precursors. Perl's Prussian blue shows iron accumulation in a circular or ringed pattern around the nucleus in > 10% of cells. The genetic basis of the various forms of inherited sideroblastic anemias is summarized in Table 3.1. Treatment depends on the specific syndrome. Patients with X-linked sideroblastic anemia respond to pyridoxine. Patients with thiamine-responsive megaloblastic anemia respond to thiamine. In the other types of congenital sideroblastic anemia RBC transfusions are the mainstay of treatment. Hematopoietic stem cell transplantation is curative.²⁵² In Pearson syndrome the cytopenia improves with age and HSCT is not required.

Congenital dyserythropoietic anemias (CDAs) are inherited disorders with prominent morphologic dyserythropoiesis and ineffective erythropoiesis. Three main types of CDA exist, CDA I, II, and III, which differ in marrow morphology, serologic findings, and inheritance patterns (Table 3.1). The anemia in most patients is not severe and does not mandate chronic therapy. In cases with severe

anemia splenectomy, a chronic RBC transfusion program or HSCT should be considered. Due to ineffective erythropoiesis and multiple transfusions, patients can develop iron overload necessitating iron chelation.

Inherited marrow failure disorders with predominantly neutropenia

Confusion and controversy prevail with regard to the terminology of childhood neutropenia. In the present chapter the term “congenital neutropenia” will be used for all cases of neutropenia, acquired or inherited, first noticed at birth or in the neonatal period. Congenital neutropenia can be mild, moderate, or severe. The term “chronic neutropenia” is reserved herein for a heterogeneous group of inherited or acquired disorders of myelopoiesis that last more than 6 months. Chronic neutropenia can be mild, moderate, or severe. Inherited bone marrow failure disorders with predominantly neutropenia are subtypes of chronic neutropenia. They can either be categorized as congenital neutropenia (such as Kostmann syndrome) or present later on in life (such as cyclic neutropenia).

Kostmann syndrome

Kostmann syndrome (KS) is a severe subtype of congenital neutropenia with onset in early childhood of profound neutropenia (absolute neutrophil count < 200/mL), recurrent life-threatening infections, and a maturation arrest of myeloid precursors at the promyelocyte-myelocyte stage of differentiation. KS was initially believed to be an autosomal recessive disorder, but with the clarification of the molecular basis of the disease it became evident that at least the majority of the cases (including the original families described by Dr Kostmann) are inherited in an autosomal dominant manner.

Clinical features

KS was first described in a large intermarried kinship in northern Sweden in 1956.²⁵⁴ Subsequently, the disorder has been recognized widely, despite its rarity, and in various ethnic groups including Asians, American Indians, and black people.

About half the patients develop clinically impressive infections within the first month of life and 90% do so by 6 months. Skin abscesses are common but deep-seated tissue infections, septicemia, recurrent otitis media, pneumonia, advanced gingivostomatitis, and gut bacterial overgrowth also occurs.²⁵⁴ Birth weights are generally unremarkable and physical examination is normal. Some patients with KS develop bone demineralization before and during G-CSF therapy.²⁵⁵ The underlying pathogenesis is unclear but patients can develop bone pain and unusual fractures.

Neutropenia is profound in KS (usually < 200/ μ L but

often absolute). Compensatory monocytosis and sometimes eosinophilia is seen. At diagnosis, platelet numbers and hemoglobin values are normal. Humoral and cellular immunology is completely normal. Bone marrow specimens are usually normocellular. The striking classical finding is a maturation arrest at the promyelocyte-myelocyte stage of granulocytic differentiation. Cellular elements beyond are markedly reduced or totally absent. The other hematopoietic lineages are normal.

Genetic aspects

Most KS cases are inherited in an autosomal dominant fashion,²⁵⁶ with the minority being sporadic or recessive.²⁵⁷ More than 80% of the cases of KS are associated with mutations in one copy of the *ELA2* gene, which is the cause for almost all the autosomal dominant and the sporadic cases.²⁵⁶ Although both healthy and affected family members have been reported to have the same *ELA2* genotype,²⁵⁸ and although there is a lack of neutropenia in homozygous and heterozygous knockout mice,²⁵⁹ it is now widely accepted that *ELA2* mutations are causative rather than just simply associated with KS.^{260,262}

ELA2 encodes neutrophil elastase, a glycoprotein synthesized in the promyelocyte/myelocyte stages,²⁶³ packed in the azurophilic cytoplasmic granules, and released in response to infection and inflammation.²⁶⁴ Computerized modeling of neutrophil elastase showed that *ELA2* mutations in KS tend to cluster on the opposite face of the active site of the enzyme in contrast to cyclic neutropenia, where the mutations tend to cluster near the active site of the molecule.²⁵⁶

Mutations in the gene encoding the transcriptional repressor *GFI1* were also identified in severe congenital neutropenia.²⁶⁵ In addition, *WASP* gene mutations were described as a cause of severe congenital neutropenia in five related males from three generations.²⁶⁶ In these cases the neutropenia was accompanied by monocytopenia and lymphocyte abnormalities.

Pathogenesis

The mechanisms for neutropenia in cases of mutations in *ELA2*, *GFI1*, or *WASP* are unknown. Neutrophil elastase normally localizes diffusely throughout the cytoplasm. *ELA2* mutations causing severe congenital neutropenia result in intracellular targeting of mutant neutrophil elastase to the nuclear and plasma membrane compartments.^{267,268} The mutations are predicted to disrupt the AP3 protein recognition sequence, resulting in excessive membrane accumulation of elastase,²⁶⁸ leading to premature apoptosis of differentiating (myeloblasts and promyelocytes) but not proliferating myeloid progenitor cells.^{267,269} Data from clonogenic assays suggest that the defect is at the level of CFU-GM/CFU-G.^{270,271} In case of *GFI* mutations, the mutated protein appears to cause overexpression of *ELA2*, and higher

neutrophil elastase levels in all subcellular compartments. *GFI1*-deficient mice also exhibit severe neutropenia.²⁷² In cases of *WASP* gene mutations, it has been suggested that the mutant protein is constitutively activated due to disruption of an autoinhibitory domain.²⁶⁶

Some patients with KS acquire G-CSF receptor mutations restricted to the myeloid lineage. These alterations are associated with the development of MDS/AML, and are not the cause of the neutropenia.²⁷³

Cancer predisposition

There is concern regarding the phenomenon of malignant myeloid transformation, which occurs in about 12.9% of the patients with KS, or an annual transformation rate of 2%.²¹⁹ Conversion to MDS/AML in the KS patients was associated with one or more cellular genetic abnormalities.¹⁰⁹ More than 90% of the patients develop clonal marrow cytogenetic abnormalities, mostly -7, or -7(q), but other abnormalities such as +21 or +8 have also been seen.^{109,274,275} An activating *RAS* oncogene mutation, *K12D*, is acquired in approximately 50% of the patients with KS who develop malignant myeloid transformation.¹⁰⁹

More than 80% of the patients who develop MDS/AML also acquire point nonsense G-CSF receptor mutations resulting in a truncated carboxy-terminal cytoplasmic domain of the receptor,^{273,276} which leads to impaired ligand internalization, defective receptor downmodulation, enhanced proliferation in response to G-CSF,^{277,278} diminished apoptosis,²⁷⁹ and development of clonal marrow cytogenetic abnormalities.²⁷⁸

It is unclear whether G-CSF can be implicated in the malignant conversion of congenital neutropenic patients. On one hand, the crude number of MDS/AML among G-CSF-treated KS patients is 12.5%, or an annual transformation rate of 2%.²¹⁹ Furthermore, remission of AML after discontinuation of G-CSF was reported in a patient with KS on G-CSF.²⁸⁰ On the other hand, leukemic transformation occurred in patients with KS also prior to the availability of G-CSF therapy.²⁸¹⁻²⁸⁵ With G-CSF therapy, most patients survive, which might thereby allow for the natural expression of leukemogenesis in this population. Also, MDS/AML has not been seen in patients with cyclic neutropenia who had been treated with G-CSF. Thus, it is still to be determined whether G-CSF hastens the appearance of leukemia in patients with an underlying genetic predisposition by giving growth advantage to the malignant clones.

Laboratory features and diagnosis

About half the patients present with infections within the first month of life. Complete blood counts and bone marrow testing in a neonate with severe infections are characteristic of KS. Later on in the first year of life, viruses are the most com-

mon cause of isolated neutropenia. An antecedent history of good health, the occurrence of a viral illness, active granulopoiesis up to the band stage in the bone marrow, demonstration of specific antibodies, and the transient nature of the neutropenia, distinguish this disorder from KS. The diagnosis can be supported by demonstrating specific antibodies on the patient granulocytes. Determination of immunoglobulin levels is an important part of the initial work-up of the neutropenic patients. Other IMFSs such as Shwachman–Diamond syndrome have to be ruled out. Genetic testing of the *ELA2* gene should be offered to all patients and families. If the test is negative a search for mutations in other genes such as *GFI1* or *WASP* can be considered.

Therapy and prognosis

Cytokines

Life-long treatment with G-CSF is currently the mainstay of management of patients with KS, and should be initiated as front-line treatment when the diagnosis is established.²⁷⁴ Since the initial report of G-CSF treatment in KS in 1989,²⁸⁶ hundreds of additional patients have been treated. The daily starting dose is 5 µg/kg subcutaneously, and this can be escalated by 5–10 µg/kg/day every 14 days until the desired neutrophil number is achieved. Neutrophils $> 0.5 \times 10^9/L$ generally provide protection from infection, but target counts of about $1\text{--}2.5 \times 10^9/L$ are clearly safer.

Complete response is defined by neutrophil counts of $1 \times 10^9/L$ with doses up to 120 µg/kg/day. Ninety percent of patients show a complete response to G-CSF therapy, and infection-related events and antibiotic use are significantly decreased.²⁸⁷ No response, as defined by absolute neutrophil counts of less than $0.5\text{--}1 \times 10^9/L$ with doses of up to 120 µg/kg/day, is seen in less than 10% of the patients.

The vast majority of patients benefit substantially from G-CSF therapy with minimal adverse reactions, which include headache, general musculoskeletal pain, transient bone pain, and rash. These do not usually require discontinuation of G-CSF.²⁸⁸ Osteopenia has been reported in KS patients who were treated with G-CSF for long periods. This complication might be related either to the treatment or to the underlying disorder,^{289,290} and require periodic evaluation of the bone mineral density. The overall safety of long-term administration of G-CSF has been reviewed in detail by Freedman.²⁷⁴

The basis for the refractory state to G-CSF in the 10% of the patients with KS is unknown. In one case, a mutation in the extracellular domain of the G-CSF receptor was identified. Interestingly, small daily doses of oral prednisone administered to the patient with conventional doses of subcutaneous G-CSF resulted in complete neutrophil response and clinical improvement.²⁹¹ GM-CSF is not as effective as G-CSF, does not induce a consistent neutrophil response, and has more side effects. Prior to G-CSF, antibiotics were the mainstay of management for active infection and for prophylaxis.

Hematopoietic stem cell transplantation

Due to the extremely successful results with G-CSF in KS, HSCT is rarely offered to the patients. The current indications are either no response to G-CSF or malignant myeloid transformation with severe other lineage cytopenia or increased marrow blasts. Whether the accumulation of certain cytogenetic (e.g., monosomy 7) and molecular events (e.g., *G-CSFR* and *RAS* mutations) justifies transplant is unclear as a portion of these patients have stable disease for many years.

In the Severe Congenital Neutropenia International Registry database, 29 patients were transplanted; 18 due to MDS/AML²¹⁹ and 11 due to insufficient response to G-CSF.²⁹² Of the 11 patients who underwent HSCT due to a refractory disease, 8 had an HLA-matched sibling. Nine of the 11 patients survived without disease. Of the 18 transplanted patients who underwent HSCT for MDS/AML (mostly using mismatched related or unrelated donors), only 3 were cured.

Other inherited marrow failure syndromes with predominantly neutropenia

Cyclic neutropenia is an autosomal dominant disorder characterized by a regular, repetitive decrease in peripheral blood neutrophils at approximately 21-day intervals.²⁹³ Patients usually present in infancy or childhood, and have a less severe infectious course compared with Kostmann syndrome. However, life-threatening infections such as *Clostridium* sp. sepsis, acute peritonitis, *Staphylococcus aureus* septicemia, mouth sores during the neutrophil nadir, and chronic gingivitis have been reported.^{294,295} Diagnosis requires the demonstration of regular neutrophil cycles of 19–23 days, during which the neutrophil count typically fluctuates from normal/nearly normal for 16–19 days to moderately/severely low for 3–4 days. Daily treatment with G-CSF at doses of 1–5 µg/kg typically improves symptoms in most patients. Cyclic neutropenia is caused by heterozygous mutations in the *ELA2* gene, usually at the active site of neutrophil elastase,^{257,296} without disrupting the enzymatic substrate cleavage by the active site.²⁵⁷ The mutations seem to disturb a predicted transmembrane domain, leading to excessive granular accumulation of elastase and defective membrane localization of the enzyme.²⁶⁸ The myeloid precursors are characterized by cycling increase in apoptosis.²⁶⁹

Myelokathexis is a rare autosomal dominant disorder with recurrent bacterial infections caused by reduced number and function of neutrophils.²⁹⁷ Neutropenia is typically moderate to severe. Degenerative changes in the granulocytes are characteristic and include pyknotic nuclear lobes, fine chromatin filaments, and hypersegmentation.²⁹⁷ Bone marrow specimens are usually hypercellular with granulocytic hyperplasia. The pathophysiology of myelokathexis has been attributed to a defective release of marrow cells into the

peripheral blood.²⁹⁷ Neutrophil precursors are characterized by depressed expression of Bcl-x and accelerated apoptosis.²⁹⁸ G-CSF and GM-CSF ameliorate the neutropenia and lead to clinical improvement during episodes of bacterial infection.^{297,299}

WHIM syndrome (warts, hypogammaglobulinemia, infections, and myelokathexis) is a subtype of myelokathexis,³⁰⁰ caused by mutations in the chemokine receptor gene CXCR4.³⁰¹ The mutations result in enhanced chemotactic response of neutrophils in response to the CXCR4 ligand, CXCL12, which might account for the pathological retention of mature neutrophils in the bone marrow.³⁰²

Other disorders with isolated neutrophil production defects are glycogen storage disease type Ib,^{303,304} and Barth syndrome.^{305,306}

Inherited marrow failure disorders with predominantly thrombocytopenia

Thrombocytopenia with absent radii

The syndrome of thrombocytopenia with absent radii (TAR) was first described in 1929,³⁰⁷ and subsequently defined in 1969.³⁰⁸ The two features that are currently essential for the definition of the syndrome are hypomegakaryocytic thrombocytopenia and bilateral radial aplasia. This definition may change once the genetic basis is deciphered.

Clinical features

Hematologic manifestations

Most patients present with petechial rash or overt hemorrhage such as bloody diarrhea in the first week of life or later during the next 4 months. The diagnosis is usually made in the newborn period when thrombocytopenia is found in a patient with absent radii. Platelet counts at birth are usually between 15 and $30 \times 10^9/L$ (range $7-92 \times 10^9/L$).^{309,310}

Transient leukocytosis with a “left-shifted” granulocytic cell population is seen in the majority of patients, and is sometimes extreme ($>100 \times 10^9/L$). Anemia due to blood loss is sometimes present. Red cell size and hemoglobin F levels are normal.

Marrow specimens show normal to increased cellularity with decreased to absent megakaryocytes. The erythroid and myeloid lineages are normally represented. When a few megakaryocytes can be identified in biopsies, they are small, contain few nuclear segments, and show immature nongranular cytoplasm. If platelet counts increase spontaneously in patients after the first year of life, megakaryocytes increase in parallel and appear more mature morphologically. Platelet size is generally normal, with rare exception,³¹¹ and function is unremarkable,³¹² although some patients may show abnormal platelet aggregation and storage pool defects.³¹³

Nonhematologic manifestations

Patients have radial aplasia (Fig. 3.4) with preservation of thumbs and fingers; this occurs bilaterally in almost all patients. Additional deformities in the upper extremity may be found and include radial club hands, hypoplasia of the carpals and phalanges, ulnae, humeri, and shoulder girdles, syndactyly, clinodactyly, and phocomelia. Characteristic findings also include a selective hypoplasia of the middle phalanx of the fifth finger and altered palmar contours. Malformations of the lower extremities are seen in about half of cases, and include hip dislocation, coxa valga, femoral torsion, tibial torsion, abnormal tibiofibular joints, small feet, valgus and varus foot deformities, syndactyly, clinodactyly, and phocomelia. Abnormal toe placement is commonly seen, especially the fifth toe overlapping the fourth. Other skeletal abnormalities include asymmetric first rib, cervical rib, cervical spinae bifida, fused cervical spine, and micrognathia.

One-third of patients have congenital heart defects. The most common are septal defects and tetralogy of Fallot. Facial hemangiomas are common, as well as redundant nuchal folds. Other abnormalities include dorsal pedal edema, hyperhidrosis, cows’ milk intolerance, and kidney and genitourinary defects.³¹⁴

Cancer predisposition

Of the 200 TAR patients reported in the literature, two developed AML^{315,316} and one developed acute lymphoblastic leukemia.³¹⁷ Rare cases of solid tumors have also been reported. This literature might suggest a true, but low, predisposition to develop cancer.

Genetic aspects

The underlying genetic defect is unknown. Also, the inheritance of TAR syndrome has not been fully defined. However, family studies demonstrating occurrence of more than one sibling in the same families suggest that at least in some families the inheritance is autosomal recessive. Typically, parents of TAR patients are phenotypically normal, and females with TAR syndrome can conceive and give birth to hematologically and phenotypically normal offspring.

Pathogenesis

Thrombocytopenia in TAR syndrome is due to a defect in megakaryocytopoiesis/thrombocytopoiesis.^{318,319} Marrow CFU-Meg progenitors are usually absent or reduced.^{318,320,321} The few CFU-Meg colonies produced from these progenitors are small³²² or of abnormal morphology.³¹⁹ In differentiating liquid cultures, mature megakaryocytes (CD41⁺CD42⁺) demonstrated accelerated apoptosis, and earlier megakaryocytic precursors (CD34⁺CD41⁺CD42⁺) accumulated.³²⁰

Thrombopoietin levels in serum are consistently elevated in TAR syndrome.³²³ Thrombopoietin-induced tyrosine phosphorylation of platelet proteins is absent or markedly decreased, but conflicting results have been published with regard to the expression of the thrombopoietin receptor.^{320,323}

Laboratory evaluation and diagnosis

Almost all patients are diagnosed at the neonatal period or shortly after. The diagnosis can be missed if the patients do not bleed and a platelet count is not performed. The diagnosis is largely based on physical examination, skeletal survey, and blood counts. Extensive work-up to rule out acquired and other inherited causes of congenital thrombocytopenia is not always necessary, as most of the affected neonates are clinically well. Bone marrow examination is helpful to confirm hypomegakaryopoiesis as the cause of the thrombocytopenia.

The main differential diagnosis of TAR syndrome is Fanconi anemia. In contrast to TAR syndrome, Fanconi anemia patients who lack their radii also have hypoplastic or absent thumbs. Fanconi anemia patients do not have skin hemangiomas, which are common in TAR patients, whereas TAR patients do not manifest skin pigmentation, as occurs in 65% of Fanconi anemia patients. Chromosome fragility testing is normal in TAR syndrome. Prenatal diagnosis has been demonstrated by quantitating platelet numbers obtained by fetoscopy or cordocentesis, and by ultrasound. In one confirmed case, a prenatal *in utero* platelet transfusion was given to effect a safe delivery.³²⁴

Therapy and prognosis

The thrombocytopenia is treated mostly with platelet transfusions, which should be used judiciously to avoid refractoriness and other transfusion reactions. Clinical bleeding and prophylaxis before surgical procedures are appropriate indications. Persistent platelet counts $< 10 \times 10^9/L$ may require preventive platelet transfusions on a regular basis. Whenever possible, single donor platelets should be considered to minimize the risk of alloimmunization. HLA partially matched donors for platelets may be required if patients become refractory to transfusions.

In exceptional situations, profound persistent life-threatening thrombocytopenia can be successfully treated by HSCT.³²⁵ The role of thrombopoietic growth factors such as IL-11, IL-6, IL-3, and thrombopoietin in the management of TAR patients is unclear. Androgens, corticosteroids, and splenectomy are ineffective therapies for TAR syndrome.

The overall prognosis for survival and spontaneous remission is good, and patients rarely develop aplastic anemia or cancer. Deaths are usually due to intracranial or gastrointestinal bleeding. If patients survive the first year of life, platelet counts spontaneously increase inexplicably to levels that

are hemostatically safe and which do not require platelet transfusional support. A minority of patients have sustained, profound thrombocytopenia. The actuarial survival reaches a plateau of 75% by the age of 4 years.¹²

Other inherited marrow failure syndromes with predominantly thrombocytopenia

The various syndromes with thrombocytopenia have been reviewed recently.^{326,327} Clues for the specific diagnosis of the syndromes can be provided by a family history suggestive of an inherited pattern, age at diagnosis, and associated nonhematologic manifestations. A battery of tests, including bone marrow aspiration and biopsy, is usually required to establish a diagnosis. An algorithm to assist clinicians in the diagnosis of the inherited thrombocytopenia has been reported.³²⁸

MYH9-associated familial macrothrombocytopenia comprises an array of several syndromes (Alport, Fetchner, Ebstein, Sebastian, and May–Hegglin) that have classically been classified according to their nonhematologic manifestations.^{326,327} *MYH9* encodes nonmuscle myosin heavy chain IIA, a cytoskeletal contractile protein.³²⁹ The common features include autosomal dominant inheritance, large platelets, mild to moderate thrombocytopenia, normal numbers of megakaryocytes in the bone marrow, and variable platelet aggregation and secretion defects, which may rarely cause bleeding, requiring platelet transfusions.³³⁰ Progression into aplastic anemia or leukemia has not thus far been reported.

Nonsyndromic thrombocytopenia associated with FLJ14813 gene mutations is characterized by an autosomal dominant inheritance, mild to moderate thrombocytopenia, normal platelet size and morphology, and mild bleeding tendency. Progression to leukemia is unlikely. Bone marrow specimens are of normal cellularity with normal to mildly reduced numbers of megakaryocytes, which can be small and have hypolobulated nuclei. Clonogenic assays show increased megakaryocytic progenitors.³³¹ FLJ14813 is a novel putative kinase.³³²

Familial thrombocytopenia with dyserythropoiesis is an X-linked disease with mild to severe bleeding tendency and mild to moderate dyserythropoiesis.^{333,335} Platelets are normal to large size and the immune system is intact. Platelet counts are moderately to severely affected ($10\text{--}40 \times 10^9/L$), have variably low expression of GPIb, and their aggregation in response to ristocetin is reduced.³³⁴ The anemia is variable in severity. Bone marrow biopsy specimens are hypercellular with dysplastic megakaryocytes having a peripheral nucleus and lack of nuclear segmentation or fragmentation as well as dysplastic erythroid precursors with mild megaloblastic changes with delayed nuclear maturation.³³⁵ There are no reports of progression to severe aplastic anemia, MDS, or leukemia. The disorder is caused by missense mutations in *GATA1*,³³³ a transcription factor important for both

megakaryopoiesis and erythropoiesis. The treatment consists of platelet transfusion in case of bleeding, trauma, or preparation for surgery. Severe cases can be cured by allogeneic related or unrelated HSCT.³³³

Familial platelet disorder with associated myeloid malignancy is an autosomal dominant disease with a striking predisposition for hematologic malignancy.³³⁶ The thrombocytopenia is mild to moderate, and platelets have normal size and morphology. The disorder is caused by mutations in the gene *CBFA2* (also called *AML1*).⁷ Treatment of the thrombocytopenia is usually not required, but regular screening for leukemia is probably advisable and HSCT is potentially curative in the leukemic phase.

Thrombocytopenia associated with radioulnar synostosis is an autosomal dominant disorder with congenital thrombocytopenia, proximal radioulnar synostosis, clinodactyly, syndactyly, congenital hip dysplasia, and sensorineural deafness.³³⁷ Patients are heterozygous for small deletional mutations in the *HOXA11* gene, which lead to truncation of the protein.³³⁸ The thrombocytopenia can be severe and require platelet transfusions. The bone marrow shows absence of megakaryocytes. If the thrombocytopenia is severe or progresses to aplastic anemia, allogeneic HSCT can be curative.³³⁷

Thrombocytopenia is also part of Wiskott–Aldrich/XL-thrombocytopenia syndrome,³³⁹ Mediterranean macrothrombocytopenia,³⁴⁰ and Montreal platelet syndrome.³⁴¹

Unclassifiable or poorly classified inherited marrow failure syndromes

Multiple cases of apparent IMFSs with or without anomalies have been reported. Further studies are needed to determine whether the cases are related to already categorized IMFSs or whether they constitute new syndromes. Because these disorders are rare, broad conclusions about management are difficult to formulate. For full-blown aplastic anemia with a hypocellular, fatty marrow, curative therapy with HSCT remains the first choice if a matched donor is identified. In familial cases, potential marrow donors must be thoroughly assessed clinically, hematologically, and by marrow morphology, clonogenic activity, and cytogenetics to ensure that latent or masked marrow dysfunction is not present. If a matched donor is not available, alternative options are androgens, growth factors and matched unrelated donor HSCT.

Acknowledgments

The author thanks Dr Melvin Freedman, the previous author of this chapter, Ms Roxanne Francis, and Ms LuAnn Brooker for their help in preparation of the chapter.

Acquired aplastic anemia

Juliana Teo and Yigal Dror

Introduction

Acquired bone marrow failure or acquired aplastic anemia (AA) is characterized by pancytopenia with a hypocellular bone marrow in the absence of an inherited syndrome. The International Agranulocytosis and Aplastic Anemia Study¹ has defined aplastic anemia as hemoglobin ≤ 100 g/dL, platelet count $\leq 50 \times 10^9$ /L, granulocytes $\leq 1.5 \times 10^9$ /L, and a bone marrow biopsy demonstrating a decrease in cellularity and the absence of significant fibrosis or neoplastic infiltration.

Severe aplastic anemia (SAA) is diagnosed when there is less than 25% of normal bone marrow cellularity, determined by bone marrow biopsy, and at least two of the following peripheral blood findings: granulocytes $< 0.5 \times 10^9$ /L, platelets $< 20 \times 10^9$ /L, or absolute reticulocytes $\leq 40 \times 10^9$ /L ($< 1\%$ when corrected for hematocrit).²

Very severe AA is defined when the above criteria for SAA are met and the granulocyte count is $< 0.2 \times 10^9$ /L. Moderate AA is defined when the criteria for SAA are not met. The category of disease severity is vital in dictating the urgency and choice of therapy, and is valuable in assessing prognosis. Due to the communality in referring to severe acquired aplastic anemia as SAA in the medical literature we will use herein these terms interchangeably.

Epidemiology

The incidence of AA in childhood (< 15 years) is reported as 1–3 per million children per year.^{1,3–5} The age of presentation peaks at 15–25 years and older than 60 years.^{1,4} A high proportion of children ($> 70\%$) have severe disease at the time of presentation.^{4,6} There is a slightly higher proportion of males. Most reports from Asia cite a two- to three-fold higher incidence of AA than that in the West, possibly due to environmental or genetic differences.^{7,8} The strong inverse association

between incidence of disease and socioeconomic standing in Thailand⁸ supports an environmental etiology.

Etiology

Acquired AA can be classified into “idiopathic” and “secondary”. Secondary AA can be attributed to a definable cause including:

- drugs and toxins;
- viral infections;
- hepatitis-associated AA, notably seronegative hepatitis;
- immune disorders, e.g., thymoma;
- paroxysmal nocturnal hemoglobinuria.

Seventy to eighty percent of the AA cases are idiopathic.^{4,6,9} In a large prospective study by the French Cooperative Group,⁴ the suspected etiology was recorded for 243 cases of AA in children and adults: 74% were idiopathic, 13% were associated with drugs, 5% with hepatitis, 5% with toxins, and the rest were categorized as miscellaneous including two cases that were pregnancy related. Of the drug exposures, only one was associated with chloramphenicol. Reduction in the use of chloramphenicol has not been accompanied by a parallel reduction in the incidence of AA,^{10,11} and there is no evidence of its association with AA in Thailand.^{8,12} The causative role of chloramphenicol in AA remains controversial.

Many case reports, case series, and large epidemiologic studies implicated a multitude of drugs in the etiology of AA, although the association might be circumstantial rather than causative.^{4,8,12–14} Nevertheless, some studies have convincingly implicated certain medications. Kaufman *et al.*¹⁵ incorporated data from several large-scale series studying the relationship of drugs in the etiology of AA. Comparisons were made between 454 patients with AA and 6458 controls. The strongest associations between AA and drugs were for penicillamine, gold, and carbamazepine. The other associated drugs include butazones, indometacin, diclofenac,

sulfonamides, and furosemide. Chloramphenicol exposures were too few to provide an estimated risk. These studies, however, lacked accurate data about the drug exposure period and dose.

The French Cooperative Group studied 147 cases of AA compared with 287 hospitalized controls and 108 neighbors.¹³ The results implicated gold salts, D-penicillamine, salicylates, and colchicine as risk factors for AA. However, the association between rheumatoid arthritis and AA confounded the ability to clearly link antiinflammatory agents with AA. Similarly, the use of non-phenicol antibiotics appeared to be linked to AA, but the history of a recent infectious episode confounded the interpretation of this result. The use of chloramphenicol and thiamphenicol was too limited to allow any conclusions.

Most of the patients in the above studies were adults. The incidence of drug-related AA in children was generally low, as the commonly implicated drugs are rarely used in childhood, with the exception of anticonvulsants (e.g., valproate and carbamazepine) and some nonsteroidal antiinflammatory drugs (NSAIDs, e.g., indometacin).

Exposure to environmental toxins, such as pesticides (e.g., DDT, chlordane, lindane),^{8,16,17} paints,¹⁸ and solvents⁸ has often been implicated as a cause of AA, but not in all studies.⁸ Prolonged exposure to benzene and its derivatives carries a particularly high risk of hematologic toxicities. Its metabolites have been implicated as a cause of aplasia,¹⁹ DNA damage,²⁰ and apoptosis of hematopoietic cells.²¹ A recent report demonstrated that chronic low-level exposure to benzene, at air levels considered safe by occupational guidelines, was also toxic to hematopoietic cells, particularly in susceptible individuals.²²

A number of viruses have been implicated in the development of AA in a small portion of the patients. However, attributing causality to some viral agents may be difficult due to their ubiquitous nature. Implicated viruses include Epstein-Barr virus,²³ cytomegalovirus,²⁴ human herpesvirus 6,²⁵ human immunodeficiency virus,²⁶ parvovirus B19,^{27,28} hepatitis A²⁹ and B,³⁰ measles, mumps, rubella,³¹ varicella, and flaviviruses.³²

Hepatitis-associated AA occurs several weeks to several months after the onset of acute hepatitis of variable severity.^{3,5,13,14,33} Most commonly, the hepatitis is seronegative for any known hepatitis viruses.³³⁻³⁵ Preceding hepatitis is seen in 2-5% of patients with AA in studies from the West,^{4,35} but is much higher in the East,⁷ where it was implicated in up to 24% of the cases.³⁶ It appears to be more common in young males.³³ The hepatitis may follow a relatively benign course; however, the aplasia is associated with high mortality if untreated³⁷ or refractory.

The association between AA and fulminant liver failure following acute non-A, non-B, non-C hepatitis is well recognized. It appears to be more common in younger individuals, with a mean age of 10 years.³⁸ Aplastic anemia was reported

in 28-33% of children and 5% of adults who underwent orthotopic liver transplantation for fulminant seronegative hepatitis.^{39,40} In contrast, AA was reported in less than 1% of liver transplants for other reasons.^{38,40} Although the cause of hepatitis and the associated AA is not known, there is evidence to support a T-cell immune-mediated mechanism against both systems.^{33,41}

Paroxysmal nocturnal hemoglobinuria (PNH) is very uncommon in childhood, particularly before adolescence. It is characterized by episodic hemolysis, thrombosis, AA, and myelodysplastic syndrome (MDS). It is an acquired clonal disorder of hematopoietic stem cells due to an X-linked somatic mutation of the *PIGA* gene.⁴² This results in abnormal biosynthesis of the cell membrane-anchoring phospholipid, glycosylphosphatidylinositol, and an absence of glycosylphosphatidylinositol-linked proteins, including the complement regulatory proteins, CD55 and CD59. Approximately 25% of adult patients with PNH present with or develop AA, and about 15% of adult patients with AA develop PNH in the recovery phase after immunosuppressive therapy (IST).⁴³⁻⁴⁷ The pathophysiology of AA in PNH remains poorly understood. A small percentage of patients with PNH progress to leukemia.

Immunologic disorders are occasionally associated with acquired AA, albeit rarely. AA has been reported in patients with eosinophilic fasciitis,⁴⁸ thymoma,⁴⁹ Graves disease,⁵⁰ systemic lupus erythematosus,⁵¹ rheumatoid arthritis,¹³ Sjögren syndrome,⁵² and transfusion-related graft-versus-host disease (GVHD).⁵³

Inherited marrow failure syndromes have been estimated to represent approximately one-third of childhood AA, and are discussed in Chapter 3. Some of these patients may present with AA without characteristic physical anomalies, and even in their fifth and sixth decades. Recently, *TERC* and *TERT* mutations have been identified in some patients with apparently acquired AA,^{54,55} suggesting that some of these patients may indeed have an inherited disorder. Advances in genetic and molecular diagnostic techniques may allow the diagnosis of these cases of seemingly "acquired" aplastic anemia. Differentiating inherited AA from the acquired forms is crucial since their therapy and prognoses differ.

Pathophysiology

Three main mechanisms have been implicated in the pathophysiology of acquired AA: an "autoimmune attack" on hematopoietic progenitor cells; inherent stem cell defects; and defects of the bone marrow stroma or microenvironment.

Cell-mediated autoimmunity was proposed as a major mechanism in the pathophysiology of idiopathic AA. The strongest evidence yet comes from the observed clinical response to IST. Also, there is an overrepresentation of HLA-DR2 in patients with AA as in autoimmune diseases.⁵⁶ *In vitro*

hematopoietic colony formation was inhibited by patients' lymphocytes from both the circulation and bone marrow.⁵⁷ Predominance of CD8⁺ phenotype⁵⁸ or CD4⁺ cytotoxic cells⁵⁷ have been reported. *In vitro* and *in vivo* increases in inhibitory lymphokines have been demonstrated, including interferon- γ (IFN- γ), tumor necrosis factor- α (TNF- α), and interleukin-2 (IL-2),^{58,59,60–62} reflecting a T-helper cell (Th1)-type response. These suppressive factors interfere with the mitotic cycle of hematopoietic precursors,⁵⁹ upregulate Fas receptors on CD34⁺ hematopoietic stem cells, and cause apoptosis.^{63,64} The hematopoietic progenitor cells in patients who develop aplasia may have an enhanced sensitivity to these lymphokines, such as TNF- α .⁶⁵

Many investigators have demonstrated oligoclonal expansion of specific T cells and skewed T-cell receptor V β repertoire in patients with AA.^{57,59,66,67} The restricted T-cell clones can be cytotoxic to both autologous and allogeneic hematopoietic progenitor cells.⁵⁷ The size of the expanded T-cell clones correlates with disease activity, but they persist at low levels even after remission is achieved with IST.^{59,66} Interestingly, there is molecular homology of these clones between patients, suggesting a limited number of antigens driving the immune response.⁵⁹ The detection of autoantibodies against hematopoietic antigens such as kinectin in some patients with AA⁶⁸ also suggests an immune mechanism.

Primary hematopoietic stem cell abnormalities have been demonstrated in acquired AA, including reduced numbers of CD34⁺ cells,⁶⁹ reduced multipotent and committed colony-forming cells, reduced long-term culture-initiating cells,^{70,71} and a decrease in cobblestone area-forming cells.⁷² The cure of AA following an infusion of hematopoietic stem cells implicates this deficiency. This is further supported by crossover experiments, in which patients' marrow cells that have been depleted of adherent cells grow poorly on normal stroma.^{71,73} Also, bone marrow stroma has been shown to be of host origin, rather than donor, after hematopoietic stem cell transplantation (HSCT).⁷⁴ In addition, the observations of clonal evolution and persistence of stem cell deficiency and macrocytosis in some patients after recovery following IST further supports an underlying stem cell abnormality.

Several investigators have recently reported shortened telomere lengths in peripheral blood leukocytes from patients with AA compared with normal age-matched controls.^{75,76} Telomere length improved after successful treatment with IST.^{75,76} Like hemoglobin F, this might reflect "stress" hematopoiesis. However, telomere shortening might also be due to telomerase dysfunction.^{54,55}

Abnormalities of the marrow stroma have been reported in a small proportion of the patients with AA. Approximately 50% of the patients have abnormal stromal cell proliferation⁷⁷ and do not form a confluent stromal layer in long-term cultures, or have morphologic differences from normal stroma.⁷¹ Those patients with no stromal cell growth had a longer duration of aplasia.⁷⁷ Abnormal stromal secretion of

hematopoietic growth factors has been found in patients with AA, including higher levels of macrophage inflammatory protein-1 α and leukemia-inhibitory factor, a decrease in IL-1 receptor antagonist, and decreased IL-6 production in response to IL-1, TNF- α , and cytomegalovirus.^{77,78} Despite these abnormalities in stromal morphology and in secretion of certain cytokines, the function of the aplastic stroma as measured by support of hematopoiesis from normal CD34⁺ cells was intact.^{71,73} Also, patients with AA can be cured by HSCT despite preservation of their marrow stroma. This suggests a minor role of the marrow stroma in the pathogenesis of acquired AA.

Toxins, drugs, or their metabolites may be directly injurious by binding to macromolecules, triggering a hapten-directed immune response against stem or stromal cells. Similarly, viruses can directly infect stem cells, progenitor cells, or stromal cells leading to cytokine-mediated cell death by cytotoxic lymphocytes.⁷⁹ These mechanisms can lead either to stem cell loss through direct toxicity, microenvironmental failure, or to immune suppression of marrow elements by an activated immune system.⁸⁰ Individuals might be genetically more susceptible to toxins or viruses.

Clinical presentation

Children with AA usually present with symptoms related to their cytopenias. Thrombocytopenia causing increased bruising with or without mucosal bleeding is the most common initial presentation.⁵ Pallor and fatigue are also common at presentation.⁵ However, severe anemia of gradual onset is usually well compensated for by young children. Serious infections due to neutropenia are uncommon presenting symptoms. Apart from these presenting signs and symptoms, generally patients have been previously well with normal physical examinations and no dysmorphic features. Lymphadenopathy and hepatosplenomegaly are atypical. Most children have symptoms for less than 1 month, and >80% for less than 3 months.^{4,5}

Family history is often unremarkable; however, one study found an overrepresentation of bone marrow hypoplasia and hematologic malignancies in first-degree relatives.⁵

Natural history

In a series of 112 children with idiopathic AA, 71% met the criteria for SAA, 21% for moderate AA, and less than 5% for mild AA.⁶ Two-thirds of patients with moderate disease progress to SAA at a median of 9.5 months (range 2–290 months) after diagnosis. The remaining patients persisted with moderate disease (21%), with a median of 32 months of follow-up, or underwent spontaneous complete resolution (12%), at a median of 7 months.⁶

Fig. 4.1 Overall survival of all children receiving antithymocyte globulin. Three children in group A, and six in group B received a bone marrow transplant after failure of primary immunosuppressive therapy. Group A, 1973–1988 ($n = 38$); Group B, 1989–1996 ($n = 37$). Reproduced with permission from Ref. 83.

Fig. 4.2 Overall survival of children treated for aplastic anemia in three time periods. Group A, 1973–1988 ($n = 38$); Group B, 1989–1996 ($n = 37$). Reproduced with permission from Ref. 83.

Untreated SAA has a high mortality due to either infections or hemorrhagic events.⁸¹ Supportive modalities, including transfusion and antibiotic therapy, have substantially improved survival. Accessibility to specific therapy, such as IST or HSCT, has dramatically changed the outlook for children diagnosed with AA. In this era of supportive and specific therapies, survival closely depends on the neutrophil count and duration of severe neutropenia. Causes of death include infections, bleeding and treatment-related complications. About one-third of the infections in AA are due to fungal infections.⁵ A British study of acquired AA in childhood reported actuarial survival of 84% at 8 years for children treated between 1989 and 1996.⁸² Figs 4.1–4.2.

Diagnosis and laboratory evaluation

Evaluation of the child with AA should include detailed family and developmental histories as well as careful physical examination to exclude other diagnoses and to screen for potential etiologies such as inherited bone marrow failure syndromes. A history of any previous hematologic derangements, drug exposure, and history that may suggest non-hematologic manifestations should be elucidated.

A complete blood count demonstrates pancytopenia and absolute reticulocytopenia. The peripheral blood smear commonly shows red blood cell macrocytosis. Levels of hemoglobin F and red cell mean corpuscular volume can be high in acquired AA, but less frequently and to a lesser degree compared with inherited bone marrow failure syndromes. The levels may remain elevated in patients who have clinically recovered.

Bone marrow examination is essential for confirmation of hypoplasia and to rule out other causes of pancytopenia. Bone marrow architecture can be determined and cellularity can be reliably graded according to severity by an adequate trephine biopsy of the bone marrow (Fig. 4.3). Prominent fibrosis is usually absent. Bone marrow aspirate usually shows empty particles and increased fat, reticulum, plasma, and mast cells, but is inadequate for accurate assessment of cellularity. Cellular morphology is usually normal. Bone marrow cytogenetics should be performed to rule out clonal disorder suggesting a hypoplastic MDS. Rarely, an acute leukemia presents initially with a period of hypoplastic anemia.⁸³ Clonogenic assays of marrow CD34⁺ cells might be helpful to distinguish between marrow underproduction versus peripheral destruction.

Fig. 4.3 Bone marrow biopsy specimen from a patient with severe aplastic anemia showing active hematopoiesis in less than 25% of the bone marrow space.

Careful attention to a possible underlying inherited marrow failure syndrome should be given, as a proportion of these patients will not have a dysmorphic appearance. Unfortunately, the only widely available screening test is the chromosome fragility test with mitomycin C or diepoxybutane to rule out Fanconi anemia (see Chapter 3). Rapid and cost-effective screening tests for other inherited bone marrow failure syndromes are greatly needed. A work-up for PNH is recommended, although this is a very uncommon finding in childhood AA. Deficiency of CD55 and CD59 on erythrocytes and leukocytes can be demonstrated by flow cytometry, which is currently the most sensitive test for detecting PNH clones.⁸⁴ Alternatively, a Ham acid serum test should be performed to look for evidence of PNH.

Measurement of serum vitamin B₁₂ and red blood cell folate should also be undertaken to exclude dietary deficiency as a cause of pancytopenia and red blood cell macrocytosis. A limited immune work-up may implicate other etiologies and direct therapy differently. This might include quantitative immunoglobulins, direct antiglobulin test and antinuclear factor.

Viral serology, including cytomegalovirus, Epstein-Barr virus, parvovirus B19, hepatitis A, B, and C, human immunodeficiency virus, and herpes simplex virus type 6, is of value in diagnosis and for later management. Bone marrow may also be tested for viruses by culture or polymerase chain reaction (PCR) if aplasia is suspected to be due to a viral infection. A patient's cytomegalovirus (CMV) status has an impact on the choice of blood products used in supportive measures: a CMV-negative patient should ideally be offered CMV-negative blood products wherever possible.

Liver function tests, plasma electrolyte, urea, and creatinine determinations, and urinalysis are useful before specific therapy is administered. Extended red blood cell antigen phenotyping is recommended in addition to routine blood group and antibody screening. Provision of phenotypically matched red blood cells for transfusion would reduce sensitization, particularly in patients requiring long-term transfusion support. HLA-typing of the patient and the immediate family members is advisable at diagnosis, even when HSCT is not conducted as the first-line treatment, to facilitate the search for a suitable bone marrow donor in case treatment with IST is unsuccessful.

Treatment

Supportive care

Supportive modalities include chronic transfusion programs that treat and prevent major bleeding episodes and maintain hemoglobin, and antibiotics to treat infections. The provision of phenotypically matched red blood cell transfusions and single-donor platelet units would reduce alloimmunization,

particularly for the chronically transfused patients. Donation of blood products from members of the patient's family is not advisable, as HSCT using related donors might be warranted in the future. CMV-negative recipients should receive CMV-negative blood products wherever possible. We recommend filtering and irradiating all blood products.

Maintaining hemoglobin with transfusion of red blood cells allows for normal activities. Children better tolerate a greater degree of anemia than adults and can generally handle transfusion thresholds of between 60 and 70 g/L. Platelet transfusion support to treat and prevent life-threatening bleeding has probably resulted in the largest impact on the survival of patients with SAA. It has changed the leading cause of death from bleeding to infections. Reducing the transfusion threshold to 10×10^9 /L in a stable patient has been found to be safe.⁸⁵ Other measures to prevent bleeding include avoidance of antiplatelet agents (e.g., NSAIDs) and avoidance of trauma.

The risk of serious bacterial and fungal infections correlates with the neutrophil count and duration of severe neutropenia. This risk is exacerbated during IST or HSCT. Prophylaxis for *Pneumocystis carinii* and fungal infections should be considered during IST. Neutropenic patients with fever should be treated aggressively with broad-spectrum antibiotics and with antifungal agents when clinically appropriate.

Hematopoietic stem cell transplantation (HSCT)

Matched sibling donor HSCT

The first successful HSCT in a patient with SAA was reported in 1970.⁸⁶ During the 1970s, HSCT was established as the best therapy for AA.² For children and young adults afflicted with SAA, early HSCT from an HLA-matched sibling donor is widely considered as the gold standard of care. Several trials reported overall survivals of 79–100% following matched sibling donor HSCT.^{46,87–90} (Fig. 4.4) Cyclophosphamide (200 mg/kg over 4 days) is the most commonly used conditioning agent in HSCT for SAA. Various groups have used cyclophosphamide either alone or with limited-field irradiation or with low-dose total body irradiation.⁹¹ Following the published excellent results from the Seattle group, there has been increasing enthusiasm for the use of cyclophosphamide with antithymocyte globulin (ATG) without irradiation,^{88,89} showing superior survival outcomes, in the order of 80–90%,^{46,89} in contrast to 55–67% when irradiation-based conditioning was used.⁹² The need for conditioning therapy is borne out by the high incidence of graft failure seen with syngeneic HSCT. In a large report, 16 of 23 patients given syngeneic marrow without preparation failed to engraft.⁹³

Failed engraftment in up to 32% was a significant problem in matched sibling HSCT for SAA in the 1970s.⁹⁴ Early transplantation with minimal pretransplant transfusion, the

Fig. 4.4 Overall survival of all children receiving bone marrow transplantation. Group A, 1973–1988 ($n = 38$); Group B, 1989–1996 ($n = 37$). Reproduced with permission from Ref. 83.

addition of irradiation, and marrow nucleated cell dose $> 3 \times 10^8$ cells/kg were all associated with a lower incidence of graft rejection.^{87,91,94} Interestingly, the use of cyclosporin (cyclosporin) in the GVHD prophylactic regimens was associated with lower rates of graft failure.^{91,94} Regimens incorporating cyclophosphamide and ATG in the preparation and cyclosporin with short-course methotrexate as GVHD prophylaxis reduced the engraftment failure rate to $< 5\%$, even in heavily pretreated patients.⁸⁹

Conditioning regimens incorporating thoraco-abdominal irradiation (TAI) are particularly associated with acute GVHD grades II–IV,^{88,91} with a cumulative incidence of over 40% in a French study.⁸⁸ However, the use of cyclosporin with methotrexate, in particular when ATG was used in the conditioning regimen, reduced the incidence of acute GVHD to about 11%.⁹⁵ The incidence of chronic GVHD has not been influenced by cyclosporin, occurring in about 30% of patients.^{87,89} Approximately one-fifth of patients who develop chronic GVHD die of associated complications.⁸⁷

Long-term sequelae for growth and endocrine function have been minimal. Inclusion of irradiation in the preparatory regimen is a risk factor for reduced ultimate height.⁹⁶ The use of chemotherapeutic agents alone or with only low doses of radiation spares the thyroid gland. Secondary sexual characteristics develop at an appropriate age and the frequency of impairment to ovarian or testicular endocrine function is low. Many of these children have been able to have children.⁸⁷

Secondary malignant tumors are of concern after successful HSCT. Although MDS and leukemia of donor origin can develop in up to 1% of the patients after HSCT for AA,^{97–99} the more common problem is solid tumors, particularly epidermoid carcinomas. The reported incidences of secondary malignancies in AA are 3.5% at 10 years,¹⁰⁰ approximately 12% at 15 years,^{88,100} and 13% at 20 years post-HSCT,⁹⁹

respectively. Risk factors included treatment of GVHD with azathioprine and cyclosporin, the patient age, the use of irradiation, male sex, age at diagnosis, and the use of a radiation-based conditioning regimen.^{88,99,100} The incidence of secondary solid tumors in patients transplanted without irradiation is generally lower than in those transplanted with irradiation: 1.4% at 10 years posttransplant according to the Seattle group.¹⁰¹ Further, patients treated with TAI-based regimens who developed secondary solid malignancies did so within the radiation fields.¹⁰²

The most common secondary solid tumors after HSCT for AA and for other indications are squamous-cell carcinomas of the head and neck, predominantly of the oropharynx, even if patients with Fanconi anemia or immunodeficiency are excluded.^{88,99,101,103} Other types of secondary solid tumors in AA include brain tumors, papillary carcinoma of the thyroid, squamous-cell carcinoma of the skin, mammary carcinoma, gastric adenocarcinoma, and hepatocarcinoma. The outcome of patients with secondary tumors was poor as subsequent therapy is difficult.

Alternative donor HSCT

Matched sibling donors for HSCT are not available in the majority of cases with AA. Alternative HSCT generally requires a greater intensity of conditioning therapy to prevent graft failure and greater postinfusion immunosuppression to prevent GVHD.

The use of HLA-matched non-sibling family donors appears to give favorable outcomes,^{104,105} although the reported cases are very few. The outcome of HSCT from mismatched family donors seems to depend on the degree of mismatch¹⁰⁴ and the preparatory regimens.¹⁰⁵ In the Seattle series¹⁰⁵ 12 of 16 patients with one-antigen mismatch donors, who were prepared with cyclophosphamide and TBI engrafted and 8 survived, compared with none among those transplanted with cyclophosphamide with or without ATG, but without TBI. Rare cases in which parental haploidentical hematopoietic stem cells have successfully been used for HSCT in SAA, have been reported.¹⁰⁶ The conditioning regimens included fludarabine, cyclophosphamide, and either total lymphoid irradiation (TLI) or busulfan, with high CD34⁺ dose.

The outcome of HSCT from a matched unrelated donor for SAA is improving, but is inferior to that of matched sibling donors. In a multicenter North American report of 141 pretreated patients (median age 17.7 years), who received HSCT from unrelated donors for SAA, favorable outcomes were associated with age < 20 years (overall survival of 63%), HSCT within 3 years of diagnosis, and HLA-DRB1 matching (56% vs. 15% at 3 years).¹⁰⁷ Investigators in Japan have reported an overall survival of 69% at 5 years for those under 20 years. In addition to age, other unfavorable factors were transplantation more than 3 years after diagnosis, mole-

cularly determined HLA-A or -B mismatch, and conditioning without ATG.¹⁰⁸ Encouraging results with novel conditioning regimens based on the use of Campath-1G have also been reported.¹⁰⁹

The use of umbilical cord blood (UCB) as a source of stem cells for HSCT has been expanding.¹¹⁰ Comparable outcomes were reported in a cohort of pediatric recipients of HSCT using unrelated donor UCB (predominantly 1–2 antigens; the rest were fully matched or 3-antigen mismatched) and unrelated donor (6/6 antigen matched) bone marrow transplanted for both hematologic malignancies and nonmalignant disorders.¹¹⁰ Neutrophil recovery was significantly slower after UCB transplantation, but the probability of engraftment at day 45, the incidence of acute GVHD and 2-year survival (approximately 50%) were comparable between the groups. Chronic GVHD was less in UCB recipients although not statistically significant.

Immunosuppressive therapy

Autologous bone marrow reconstitution was noted, in the late 1960s and early 1970s, in a number of patients who received mismatched marrows.^{86,111,112} This was also observed in some patients who were conditioned with cyclophosphamide and ATG but did not proceed with HSCT. These clinical observations combined with the extensive laboratory data discussed in the sections on Pathophysiology and Etiology above strongly suggested immune mechanisms in the pathogenesis of AA and led to the development of IST regimens in the treatment of AA.¹¹³

ATG with or without other agents or modalities, such as androgens, steroids and HSCT clearly emerged as more effective than supportive care alone.¹¹⁴ Survival ranged from 30 to 70%, with responses typically occurring within the first 3–6 months following therapy. Equine ATG (e.g., Atgam; Pharmacia & Upjohn, Milton Keynes, UK) is more commonly used, and is usually administered at 100–160 mg/kg, in divided doses over 4–10 days. Rabbit ATG (e.g., Thymoglobuline; Imtix-Sangstat, Lyon, France) has also been shown to be effective, at doses of 2.5–3.5 mg/kg daily for 4–5 days.¹¹⁵ Acute allergic reactions are common. Immune complex-mediated serum sickness typically manifests 10–14 days after initiation of therapy. These adverse effects have largely been ameliorated by the concurrent administration of prednisone, usually at 1–2 mg/kg/day, and premedication with antihistamines and acetaminophen (paracetamol).

Cyclosporin was shown to be effective.^{116,118} The German group compared ATG and methylprednisolone versus ATG, methylprednisolone, and cyclosporin.¹¹⁶ The response rate at 3 months was significantly higher in the group receiving cyclosporin (65 vs. 39%, $P < 0.03$), primarily because of an increased response rate in patients with severe disease.

The European Cooperative Group for Bone Marrow Transplantation (EBMT) compared ATG and methylprednisolone

with or without oxymetholone.¹¹⁹ Responses were significantly higher in the oxymetholone arm at 120 days (68% vs. 48%); however, the overall survival at 3 years did not reach statistical difference: 71% with androgens versus 65% without. Survival was influenced by the severity of the aplasia: the very severe group had a 43% 3-year survival compared with 78% for severe disease and 83% for moderate disease. This was particularly pronounced in females with severe aplasia.

Children treated with IST generally have better survival outcomes compared with adults;^{118,120} but the reported survivals are variable and ranged from 54 to 100%.^{22,46,121–124} This variability in outcomes may reflect the heterogeneity of treatment regimes, including administration of hematopoietic growth factors, inclusion of patients with clonal marrow cytogenetic abnormalities, and patients with inherited marrow failure syndromes. The EBMT SAA group recently reported a 5-year survival of 83% in 84 pediatric patients treated with IST.⁴⁶ Combination IST commonly used in most centers treating children with acquired AA consists of ATG, cyclosporin, and low- or intermediate-dose corticosteroids.^{46,121,122} The authors use Atgam 40 mg/kg daily for 4 days, prednisone 0.5 mg/kg per dose twice daily for 14 days, and cyclosporin 6 mg/kg per dose twice daily to maintain blood levels of 150–200 µg/L.

Patients who failed to respond to the initial course of ATG treatment still have a substantial chance of response to repeated courses, using ATG from the same or an alternative animal source.^{45,110} The EBMT SAA reported a 43% chance of response to a second treatment with ATG after the initial failure, and actuarial survivals at 13 years of 68.5% in those who responded after two courses versus 24.4% in those who did not receive a second course.¹²⁰ There was no significant increase in adverse effects following repeated ATG (of the same animal source)¹²⁰ and no significant difference in the risk of clonal disorders between patients receiving a single or multiple courses of ATG.⁴⁵

A common problem in this treatment modality is recurrence of the aplasia in up to 35% of the patients at 5 years,¹¹⁴ and a need for retreatment in 10–20%^{111,112,114,121} within 4–37 months after withdrawal of cyclosporin. Patients treated with IST regain apparently normal hematopoiesis, but detailed studies revealed persistent defects in the number and function of hematopoietic progenitors.^{70–73} IST reduces but does not eradicate the pathogenic T-cell clones, even in patients who respond.^{57,66} Relapse was not associated with patient age, gender, interval between diagnosis and therapy, or absolute neutrophil count prior to treatment or 3 months post-therapy;¹¹⁴ but it might be associated with rapid response to the original IST.¹²¹ Approximately 50–70% of those who relapse respond to subsequent therapies,^{111,114,121,125} with 60% still dependent on cyclosporin at 6–7 years.

There were promising results from an early pilot study of high-dose cyclophosphamide without HSCT in SAA.¹⁴⁷

However, a prospective randomized study comparing ATG and cyclosporin with cyclophosphamide and cyclosporin had to be terminated prematurely due to an unacceptable incidence of invasive fungal infections and early deaths in the cyclophosphamide arm.¹²⁷ Follow-up of the survivors showed responses in 46% for the cyclophosphamide group compared with 75% in the ATG group, with no difference in relapse rate or clonal evolution.¹²⁸

HSCT versus immunosuppressive therapy

There are no randomized trials comparing the two modalities. However, when compiling data from various studies, it appears that HSCT from an HLA-matched sibling generally gives superior long-term engraftment and survival (75–97%)^{46,82,89,90,122,129} compared with IST (55–85%),^{46,129,130} and is usually considered as the initial treatment of choice for children with SAA. Both the Seattle and Japanese experience demonstrated a considerable survival advantage of HSCT from an HLA-matched sibling over IST in children with AA.^{44,90} Among 100 children in a Japanese study the overall survival was 97% in the HSCT group versus 55% in the IST group. In contrast, the data from the EBMT SAA group on a cohort of 227 children showed comparable overall survival at 5 years after treatment for both treatment modalities: 85% for HSCT from an HLA-matched sibling donor and 83% for IST.^{46,129}

Successful HSCT is curative, results in a shorter duration of neutropenia and transfusion dependence in comparison with IST, and minimizes the risk of relapse and clonal evolution. The risks of HLA-matched sibling transplant versus the benefits are generally lower for patients younger than 40 years of age, although longer follow-up is necessary to evaluate morbidity associated with HSCT, particularly secondary malignancies.

For the majority of patients without a suitable HLA-matched sibling donor, IST remains the main treatment modality, and HSCT from an alternative donor is usually offered as a salvage therapy. Results of HSCT from alternative donors have generally been inferior to IST, and long-term survivals ranged up to 69%.^{46,107,108} As outcomes improved with advances in donor selection, pretransplant conditioning incorporating high-dose cyclophosphamide, and GVHD prophylaxis, alternative donor HSCT may be offered at an earlier stage of the disease.

Androgens and growth factors

Androgens have no role as a single treatment agent for SAA,⁹ unless other modalities are unavailable.¹³¹ Androgen treatment can induce remission in 38% of children with nonsevere AA. The role of androgens as part of multiagent IST has been alluded to above. Bacigalupo *et al.*¹¹⁹ demonstrated an increased rate of response in females with severe aplasia,

who received oxymethalone with the IST, although they were unable to demonstrate an improved survival.

Growth factors such as granulocyte colony-stimulating factor (G-CSF), granulocyte–macrophage colony-stimulating factor (GM-CSF) and interleukin-3 (IL-3) have been used as single agents in AA.^{124,126,132–135} However, responses are rare and transient, and very high doses are sometimes necessary. Several studies have examined the impact of adding G-CSF to IST on response and long-term survival.^{124,134} Although the use of G-CSF improves neutrophil counts in many patients, there was no significant difference in the rates of infectious episodes, overall hematologic response or survivals.^{124,134}

Myelodysplastic syndrome

Several large studies have demonstrated an increased risk of MDS and/or leukemia in survivors of AA who had been treated with supportive care, androgens or IST.^{43,45,47} Most commonly, patients are diagnosed at the stage of MDS and progress to leukemia, although occasionally patients present with overt leukemia. The actuarial risk of MDS/AML is 15% at 7 years post-IST.⁴⁴ MDS occurred at a median of 4.6 years (range 2.5–7.5) post-IST and AML at 5.0 years (range 2.8–7.6). The median age of these patients at the time of diagnosis of AA was 21 years (range 9–56).

Chromosomal aberrations can appear without morphologic signs of MDS/AML.¹²³ In one study, in 50% of the cases with marrow cytogenetic abnormalities after IST, the aberrant clone was present at diagnosis but detected retrospectively.¹²³ The group from the US National Institutes of Health¹²¹ evaluated a large number of patients of all ages, with acquired AA whose bone marrow cytogenetics were normal at diagnosis.¹³⁶ The estimated rate of clonal evolution was 14% at 5 years and approximately 20% at 10 years.^{136,137}

The relationship of G-CSF with MDS/AML in acquired AA is controversial.^{137–139} In a prospective randomized study of IST with and without G-CSF in children with acquired AA, the risk of clonal evolution was proportional to the duration of G-CSF administration, particularly if it was longer than 180 days. Failure to respond to IST at 6 months was another risk factor in multivariate analysis. An earlier report also identified the duration and cumulative dose of G-CSF therapy as risk factors in the development of MDS/AML in children with acquired AA.¹⁴⁰ These observations have not been borne out by other studies.^{141–143} In these reports, there was no difference in the incidence of cytogenetic abnormalities between patients who received IST with or without G-CSF. Further studies are, therefore, required to investigate the safety of G-CSF in patients with AA.

A number of clonal marrow cytogenetic abnormalities have been reported at diagnosis of MDS/AML in patients with AA. The most common abnormalities are monosomy 7 (40–50%) and trisomy 8.^{136,140,144} Patients with monosomy 7

and complex cytogenetics had higher rates of transformation to AML.¹³⁶

As MDS/AML have also been reported in patients who received androgens or were treated with supportive care without IST,^{47,145} it is likely that patients with AA have an inherent predisposition to malignant myeloid transformation, although the mechanism is unclear. MDS/AML secondary to AA are associated with poor survival.

Paroxysmal nocturnal hemoglobinuria

The incidence of PNH post-IST for AA is 8–22% at a median of 30 months (range 6–97 months),^{45,47,136} or an actuarial risk of 13% at 7 years post-IST.⁴⁵ According to one study, 20% of PNH patients were less than 20 years old at the time of diagnosis with AA.⁴⁷ The hypothesis that PNH is a late complication of AA was refuted by demonstrating that PNH clones were always present at the time of diagnosis with AA, and no patient with normal glycosylphosphatidylinositol-linked proteins at diagnosis developed PNH after therapy.⁸⁴ Interestingly, PNH clones as determined by flow cytometry were not detected in patients who underwent HSCT or received ATG for renal transplantation, cancer patients on chemotherapy, large granular chronic lymphocytic leukemia, and normal controls.

PNH rarely presents in childhood. Twenty-six children were diagnosed with PNH between 1966 and 1991 at the Duke University Medical Centre.¹⁴⁶ More than 50% of them presented with AA, in contrast to adults (25%). All these children progressed to bone marrow failure during the course of their disease. In another study, none of the children who developed PNH post-AA progressed to MDS/AML, and at least one had spontaneous resolution of PNH.⁴⁷

The cause of the high incidence of PNH in SAA patients treated with IST is unclear. The absence of PNH in patients with hypocellular marrow due to chemotherapy, irradiation, or inherited marrow failure syndromes suggests that PNH clonal expansion is not merely the result of hematopoietic failure.⁸⁴ Similarly, PNH clones are absent in patients with large granular chronic lymphocytic leukemia, whose cytopenias are thought to be due to natural killer-cell-mediated hematopoietic injury. Furthermore, their absence in patients who had received ATG for other reasons suggests that ATG-based therapy is not the cause of PNH.⁸⁴

3 Red Cell Disorders

5

Disorders of iron metabolism: iron deficiency, iron overload and the sideroblastic anemias

Andrew M. Will

The disorders of iron metabolism are of great importance in pediatric hematology. Iron deficiency anemia is arguably the commonest pediatric hematologic disorder and is certainly the most frequent cause of anemia in childhood. The problems of iron overload dominate the clinical course of all children receiving regular blood transfusions, and the sideroblastic anemias, although rare, need to be considered in the differential diagnosis of patients with anemias of uncertain origin.

Iron metabolism

Despite being one of the commonest substances in the natural world, iron is treated by the body as if it were a trace element. Iron is efficiently recycled and excretion is limited. In part, at least, this is because most naturally occurring iron is in the ferric (Fe^{3+}) form, which is highly insoluble and therefore relatively unavailable for absorption from the diet. Complex mechanisms to facilitate iron absorption have had to evolve.

Iron's importance in biochemistry lies in its ability to exist in two stable forms: the relatively inactive ferric (Fe^{3+}) and biochemically active ferrous (Fe^{2+}) state. This property makes it an ideal atom to be involved in electron transfer, which forms the basis of many enzyme-controlled biochemical reactions. Iron is therefore not just important as heme iron to carry oxygen but is also essential to the working of many of the body's enzyme systems (Table 5.1). Approximately half the enzymes of the Krebs cycle contain iron or require it as a cofactor. Therefore, although most of the iron metabolized each day is used to synthesize hemoglobin, chronic iron deficiency may produce a wide variety of effects other than anemia.

The potential reactivity of iron has led to the evolution of a group of specialized proteins to transport and store iron and regulate the iron-dependent synthetic pathways. Providing the ability of these proteins to contain ionic iron is maintained, iron can be safely stored and metabolized. In iron overload these systems become overwhelmed and the

uncontrolled reactivity of ionic iron causes life-threatening tissue damage.

Humans appear to be unique in their inability to excrete excess iron.¹ Iron loss (about 1–1.5 mg/day) is achieved almost exclusively in the male by desquamation of skin and loss of mucosal cells from the gastrointestinal and urinary tracts.² In the female, iron is also lost through menstruation and during pregnancy. Iron loss by any of these means is relatively constant and cannot be altered in response to changes in body iron status. In the absence of a physiologic mechanism for the excretion of excess iron, iron balance is achieved by control of iron absorption.³

Iron absorption

Three factors are important in determining the amount of iron absorbed from the diet: total iron content of the diet, bioavailability of the iron in the diet, and control of iron absorption by the intestinal mucosal cells. Only the latter is responsive to body iron status and requirements.

Dietary iron content

Total iron content is probably the single most important dietary factor in determining the amount of iron absorbed

Table 5.2 Iron content of foodstuffs.

Foodstuff	Iron/100 g	Percent available for absorption
Rice flour	0.9	1
Bread	2.0	5
Wheat flour	2.3	5
Cod	0.9	10
Mackerel	1.0	10
Sardines in oil	1.5	10
Oysters	7.1	10
Beef sausages	2.4	
Chicken	3.0	>10
Pork chops	3.0	>10
Bacon (cooked)	3.3	
Beef (rump)	2.4	>10
(kidney)	6.5	
(liver)	12.1	

from the gut. A mixed Western diet contains about 6 mg iron per 1000 kcal (4200 kJ).⁴ An adult male will absorb about 10% of this (0.5–1 mg/day). In iron deficiency, the amount of iron absorbed can be increased to a maximum of 3.5 mg/day.⁵ Large amounts of dietary iron do not block iron absorption but as the amount in the diet increases, the percentage absorbed decreases. Different foodstuffs contain different proportions of iron (Table 5.2); vegetarian diets are more likely to have an inadequate iron content than mixed diets.

Bioavailability of dietary iron

The bioavailability of dietary iron is also important in determining the amount of iron absorbed from the diet.⁶ Dietary iron is in two forms: organic or heme iron derived from hemoglobin and myoglobin, and inorganic or nonheme iron. There is a different absorptive pathway by which iron can enter the gut mucosal cells for each of the two types of dietary iron.^{3,7}

1 Heme iron is taken up directly by specialized receptors in the mucosal membrane⁸ and passes unchanged into the cytoplasm where the porphyrin ring is cleaved and the iron released.⁹ The heme iron pathway is relatively efficient and, unlike nonheme iron, absorption is little affected by the intraluminal factors discussed below. Although heme iron only accounts for about 10% of the total iron in a mixed diet, it accounts for up to 25% of the total iron absorbed.

2 Nonheme iron exists almost exclusively as insoluble ferric salts. To be absorbed the ferric salts must first be converted to the ferrous form and then bound to the intestinal iron transport protein, mucosal apotransferrin. Bound to apotransferrin, the nonheme iron can enter the gut mucosal cell. Within the cell, iron is cleaved from the mucosal transferrin and joins the same pool as heme-derived iron.

Table 5.3 Factors affecting iron absorption of nonheme iron from the gastrointestinal tract.

Increased absorption

Phytates

Phosphates

The uptake of nonheme iron by the gastrointestinal mucosal cells is affected by factors that enhance and inhibit absorption.^{10,11}

- Foodstuffs vary in their ability to give up iron for absorption (see Table 5.2).¹² Rice, for example, is not only poor in total iron content but only 1–2% of this is available for absorption. Even relatively iron-rich vegetables such as spinach and wheat have only a small percentage of their total iron content available for absorption (1–2% and 5% respectively). In contrast, heme-rich animal-derived foodstuffs not only contain more iron per gram but a much higher percentage is available for absorption.

- Different foods can interact to either increase or decrease the absorption of iron from them (Table 5.3). Meat in the diet increases the absorption of even nonheme iron from the gut lumen. The addition of veal to a meal of maize can double the amount of iron absorbed from the cereal.¹³ On the other hand, tannates in tea or coffee¹⁴ and substances such as egg yolk have the opposite effect and reduce nonheme iron absorption.¹⁵

- Intraluminal factors influence the percentage of nonheme iron that can be reduced from the insoluble ferric to the soluble absorbable ferrous form.¹⁶ Acids such as hydrochloric acid and vitamin C promote the production of ferrous iron, enhancing absorption, whereas antacids and hypochlorhydria reduce the amount of ferrous iron available from the diet. Phosphates and phytates, which are common in vegetables, also prevent the reduction of ferric to ferrous salts, thereby inhibiting iron absorption by forming insoluble complexes with iron salts.

The bioavailability of iron is clinically important. Vegans are at risk of iron deficiency even if their total dietary iron content appears satisfactory because the assimilation of iron from vegetable sources is inefficient. Moreover, the

absorption of nonheme-derived iron is reduced by the absence of heme iron, and the increased intake of phytates and phosphates further reduces the availability of absorbable iron. In contrast, human milk has a low total iron content but the iron is in a form which is highly bioavailable¹⁷ and which is also able to directly enhance the amount of iron absorbed from other foodstuffs in the early weaning diet.¹⁸ Therefore, the vegan even with an apparently adequate total dietary iron content is at risk of iron deficiency but the breast-fed infant is less so.

Mucosal cell control

Gut mucosal cell control of iron absorption is not well defined but the amount of iron absorbed via the mucosa is responsive to body iron stores¹⁹ and the erythropoietic activity of the bone marrow.²⁰ Increases in body iron lead to a reduction in iron absorbed from the gastrointestinal tract and when body iron stores are reduced, more iron is absorbed. Erythropoietic activity has the opposite effect: in conditions associated with high levels of erythropoietic activity, iron absorption is increased, but in disorders such as hypoplastic anemia where erythropoietic activity is reduced, iron absorption is reduced. The amount of dietary iron absorbed can be controlled at both phases of mucosal cell absorption.

1 At the uptake of iron from the gut lumen into the mucosal cells. For nonheme iron to be absorbed from the gut lumen across the brush border of the intestinal mucosal cells, iron must first be attached to the mucosal cell transport protein apo-transferrin.²¹ The transferrin-iron complex produced is internalized by the small intestine, mainly in the duodenum and jejunum. Control of the uptake of dietary iron can be achieved during this phase of absorption because the amount of apo-transferrin secreted by the liver into the bile is inversely proportional to hepatic iron stores. Increased hepatic storage reduces the synthesis of apo-transferrin by the liver, hence reducing gut mucosal cell iron uptake. A reduction in hepatic iron stores has the opposite effect.²²

2 During the transfer of iron to the portal blood. Once inside the mucosal cells, the iron released from the transferrin-iron complex joins with heme-derived iron. Iron from this combined intracellular pool has two possible fates. It is either transferred to the portal blood for further metabolism within the body or combined with the mucosal cell storage protein apoferritin.²³ If the latter, the iron becomes trapped in the mucosal cell as storage ferritin. After 3–4 days the cell and any ferritin it contains are sloughed off into the intestinal lumen as the villus mucosal cell completes its lifespan. Control of absorption is achieved because the amount of apoferritin produced by the mucosal cells is dependent on body iron stores. When body iron stores are low, little is produced by the gut mucosal cells and a high percentage of the absorbed dietary iron can pass into the portal venous system. Conversely, when body iron stores are replete, the gut mucosal

Fig. 5.1 Distribution of iron in man (adult male = 3.5–4.0 g).

cells produce more apoferritin, which traps absorbed dietary iron in the intestinal villus cells and this is later excreted in the feces.

Body iron distribution and turnover

The adult contains about 55 mg/kg of iron⁴ and an adult male will have 3.5–4 g of iron in his body. The majority of that iron, about 70%, is carried in red blood cells as hemoglobin and most of the rest is stored as ferritin and hemosiderin, with approximately two-thirds within macrophages and one-third in hepatocytes. Small amounts of iron are present in myoglobin and traces in cellular enzymes (Fig. 5.1).

Although the distribution of iron in the body is fairly constant, the iron in the different compartments is continually being recycled. Each day about 25 mL of red blood cells need to be replaced. This represents a need for 25 mg of iron but only about 1 mg/day is absorbed from the diet. The other 24 mg required for red cell replacement alone needs to be recycled from senescent red cells and tissue stores. This daily iron cycle (Fig. 5.2) is reliant on plasma transferrin (TF), cell surface transferrin receptors (TFRs), and the storage protein ferritin. Intracellular control, in the erythroid cell at least, depends on the interaction of an iron-responsive binding protein (IRE-BP) with iron-responsive elements (IREs) present on the mRNA of TFR, ferritin and erythroid cell-specific δ -aminolevulinic acid synthetase (ALAS), the initial enzyme involved in the production of heme from glycine and succinyl-CoA in mitochondria (Fig. 5.3).

Transferrin

TF is the specialized plasma transport protein for iron.²⁴ It is a single polypeptide β -globulin of 679 amino acids with a molecular mass of 7957 kDa, and is mainly synthesized in the

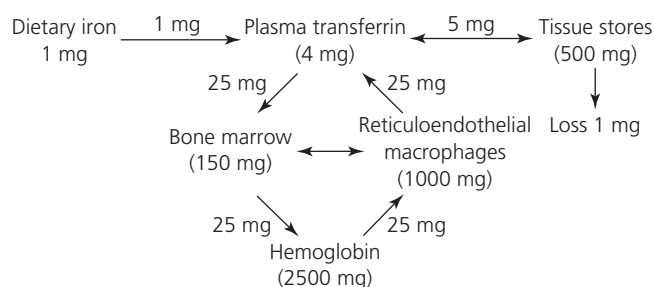

Fig. 5.2 Daily iron cycle. Values in parentheses represent average quantities of stored iron in a normal adult male. Other values represent average daily turnover in milligrams.

liver. Unusually for a transport protein, TF can be recycled after intracellular delivery of iron and it has a half-life of 8–10 days.²⁵ TF is produced from a single gene q21–qter on chromosome 32,²⁶ near the gene for its receptor.²⁷ Normally active structural variants have been described.

TF has two iron-binding sites, one at the N-terminal and one at the C-terminal domain.²⁸ It can therefore exist in four states: apotransferrin with no bound iron, as two different monoferric transferrins, and as diferric transferrins. At neutral pH, TF has a high affinity for binding ferric iron, and when fully iron saturated undergoes a conformational change that makes the diferric molecule more soluble and more resistant to enzymatic degradation. Diferric TF has about 3.5 times the affinity for TFR than either of the monoferric transferrins²⁹ and because of this the diferric form is

preferentially bound to cells for intracellular iron delivery. At neutral pH, apoferritin binds poorly to TFR.

Production of TF by the liver is inversely related to hepatocyte ferritin concentration, being increased when hepatic stores of iron are low and reduced when stores are increased.³⁰ Plasma TF concentration, usually measured as total iron-binding capacity (TIBC), is therefore a convenient assessment of iron stores.

Plasma TF is crucial for the daily iron cycle (see Fig. 5.2). At any one time, only about 4 mg of body iron is present bound to TF, yet every 24 hours > 30 mg of iron is transported throughout the body. Therefore, every day each molecule of TF carries several molecules of ferric iron between cells, and > 80% of this iron is transported to or reutilized in the bone marrow to make heme. The bulk of other daily iron turnover involves iron exchange with hepatocytes. There appears to be no alternative pathway for the iron to enter the red cell precursors. Congenital absence of TF is associated with severe iron deficiency anemia but uptake by nonerythropoietic tissues continues even in the absence of TF.³¹

Transferrin receptor

The TFR is a transmembrane glycoprotein that exists as a dimer of two subunits joined by a disulfide bond.³² Each TFR can bind two TF molecules. At the neutral pH of the cell surface, TFR has an increased affinity for diferric TF compared with monoferric TF and this in turn is greater than the affinity of TFR for apotransferrin. Each TFR can therefore bind up to

Fig. 5.3 Heme synthesis. Binding of iron-saturated transferrin to cell membrane transferrin receptors, endosome formation, release of iron into the cytosol, and the role of mitochondrial and cytosolic enzymes in the production of heme. ALAS, δ -aminolevulinic acid synthase.

four ferric ions and because the efficiency of TFR binding to TF is dependent on the degree of TF iron saturation, the plasma TF saturation (TIBC) directly affects the availability of iron for intracellular metabolism. In adults, a TIBC > 16% is needed to maintain normal erythropoiesis. Lower levels of about 7% are adequate to maintain red cell production in children.^{33,34}

The number of TFRs present on a cell's surface reflects the ability of that cell to accept iron from circulating TF. TFRs are particularly numerous on cells that metabolize a large amount of iron, such as erythroid precursors, reticulocytes, and placental trophoblasts.³⁵

Ferritin and hemosiderin

Iron can be stored as either ferritin or hemosiderin.³⁶ Ferritin is a water-soluble protein whose iron stores are relatively available for iron metabolism as and when required. In sudden hemorrhage, for example, iron loss can temporarily exceed supply. However, the extra blood cells required can be produced without interruption by using iron supplies mobilized from stored ferritin.

Hemosiderin in an insoluble protein-iron complex whose iron is less available, in the short term at least, for metabolic requirements. Unlike ferritin, hemosiderin is visible on light microscopy and stains deep blue with Perl's (Prussian Blue) reagent. It is found primarily in the Kupffer cells of the liver and the macrophages of the spleen and bone marrow. In iron overload, hemosiderin begins to be deposited in the parenchymal cells of the liver and other organs.

Ferritin is produced as a hollow spherical protein with 22–24 apoferritin subunits.³⁷ It has a molecular mass of 468 kDa. Six channels penetrate the spherical shell through which iron passes into the core. Up to about 4500 iron atoms can be contained in one ferritin molecule, mostly as ferric hydroxide with some ferric phosphate. Ferritin is usually about 50% saturated.

Two types of apoferritin subunit have been identified: L (light) and H (heavy).³⁸ In different tissues, different proportions of L and H chains are found in their respective ferritin molecules. Liver, a site of iron storage, contains ferritin consisting mainly of L chains but the heart, not normally a site of iron storage, has mainly H chains in its ferritin molecules. Ferritin with an excess of L chains may well be essential for long-term storage, whereas those mostly consisting of H chains may be more active in iron metabolism.³⁹

Although different tissues may produce differing apoferritin spheres, all tissues need to be able to assemble the spheres quickly to protect themselves from the potential toxicity of free iron. As ferritin is produced, a small amount proportional to the intracellular ferritin concentration leaks into the plasma. Thus plasma ferritin concentration is related to cellular iron stores.⁴⁰

Table 5.4 Sequence of detectable reduction in iron stores as iron deficiency anemia develops.

7 Red blood cell morphology	Iron deficiency anemia

Assessment of body iron stores

Reduced iron stores

Detectable abnormalities occur in sequence as the magnitude of iron deficiency worsens (Table 5.4).⁴¹ The eventual changes in red cell morphology are nonspecific and occur late. Of more importance, and usually the first indication of iron deficiency, are changes in red cell indices. Most modern automated instruments measure red blood cells, hemoglobin, and mean corpuscular volume (MCV) directly. The direct measurement of MCV has made this a sensitive parameter of red cell changes and it has overtaken the more traditional measurements of mean corpuscular hemoglobin concentration (MCHC) and mean corpuscular hemoglobin (MCH) as the primary indication of possible iron deficiency. Many modern blood counters produce two-dimensional red cell maps that can often demonstrate the presence of iron-deficient red cells.

No single confirmatory test is appropriate in all situations.

- Serum ferritin is a sensitive measurement of iron deficiency^{40,41} but is an "acute-phase reactant" whose synthesis increases nonspecifically in response to inflammation, infection, or malignancy. Liver cell damage also raises the serum ferritin independently of body iron status.

- The increasing availability of radioimmunoassays of plasma TFR has provided a new method of diagnosing iron deficiency.⁴² Plasma TFR concentration is proportional to marrow red cell turnover: erythroid hypoplasia (hypoplastic anemia, chronic renal failure) reduces and erythroid hyperplasia (chronic hemolytic anemia) increases plasma TFR. TFR levels are also increased in iron deficiency and, in the absence of other conditions causing erythroid hyperplasia, plasma TFR is a sensitive indicator of iron deficiency.⁴³ Unlike serum ferritin, plasma TFR is not affected by chronic inflammation or liver disease. Although available for a number of years, these methods have not been taken up by many hematology laboratories.

- Plasma iron and transferrin saturation (ratio of plasma iron to TIBC) provide a measure of current iron supply to the tissues. These tests are widely used but are strongly influenced by physiologic variation, concurrent inflammatory disease, and recent prior ingestion of iron.

- Free erythrocyte zinc protoporphyrin (ZPP) is a simple test

that can be performed on a drop of EDTA blood. This makes ZPP a convenient adjunct to MCV estimation and red cell mapping, as it is immediately available from the same blood sample that went through the blood count analyzer. In iron deficiency, protoporphyrin IX cannot combine with iron to form heme in the final step of heme synthesis. In the absence of iron, protoporphyrin combines with zinc to form ZPP, which is stable and persists throughout the lifespan of the red cell. Estimation of red cell ZPP provides an indication of iron supply to the red cell over a longer period than serum ferritin or plasma iron.⁴⁴ ZPP can therefore be used to confirm iron deficiency in a patient who has recently been started on iron supplements. ZPP may be affected by chronic inflammation but less so by acute infections of recent onset than the more traditional measurements of body iron.

- In difficult cases, bone marrow examination after staining with Perl's reagent will clarify the situation. In iron deficiency, neither the marrow macrophages nor erythroblasts contain iron. In the anemia of chronic disease there is plenty of iron present in the macrophages but none in the red cell precursors. Normally, about 20% of erythroblasts contain iron (sideroblasts).

Increased iron stores

In routine clinical practice, assessment of increased iron stores relies on repeated serum ferritin estimations and, if definitive diagnosis is required, on liver biopsy. However techniques developed using magnetic resonance imaging (MRI) are beginning to become increasingly used and in time are likely to have a major role in both the assessment and monitoring of the treatment of iron overload.

Plasma iron and TF saturation are poor indicators of reticuloendothelial iron overload. They are not reliably elevated by increased macrophage iron as occurs during the early stages of transfusion hemosiderosis. Serum ferritin, on the other hand, is elevated early even in macrophage iron deposition. As mentioned above, serum ferritin is influenced by several factors other than body iron status. Repeated measurements give a more reliable estimation of body iron stores than a single result.

Although marrow biopsy can give a subjective assessment of iron overload, liver biopsy provides much more useful information, including histologic assessment of the degree and distribution of hepatic iron stores and quantification of hepatic iron concentrations (fmol/g dry weight of liver tissue).⁴⁵ Liver biopsy is not to be undertaken lightly and is not practicable for regular assessment of body iron stores. Currently, repeat serum ferritin estimations have to be undertaken but noninvasive radiologic approaches are being developed and evaluated. Magnetic susceptibility using a superconducting quantum interference device (SQUID)⁴⁶ and dual-energy computed tomography⁴⁷ have both been developed but are not available for routine clinical use.

In the last few years, techniques using MRI have been developed.^{48,49} These methods offer a repeatable and non-invasive quantitative assessment of body iron stores. Recent reports suggest that iron deposition among the internal organs is not uniform and that the oral chelator deferiprone may have the ability to preferentially remove cardiac iron compared with hepatic stores.⁵⁰ More work needs to be done but, if confirmed, the role of liver biopsy as the gold standard for estimating body iron stores will be called into question as it has always been assumed that liver iron levels reflect similar iron overload in the other internal organs.

Control of heme synthesis within the erythroblast (see Fig. 5.3)

In plasma, iron binds to apotransferrin to form monoferric and diferric TFs. At the neutral pH on the outside of the cell membrane, diferric TF binds preferentially to TFRs on the cell surface.⁵¹ The iron-bearing TF-TFR complex rapidly clusters with other similar complexes and is internalized. Here, the clusters of iron-TF-TFR complexes coalesce with other similar clusters to form endosomes. Once within the cytosol, the pH within the endosome is lowered permitting release of iron into the cytosol. The apotransferrin-TFR complex remains tightly bound until it reaches the cell surface. Under the neutral pH conditions at the cell surface, the unsaturated apotransferrin is released to be recycled and bind with more iron. The TFRs remain at the cell surface ready to bind more diferric TF.⁵²

Control of intracellular iron metabolism is mediated at the mRNA level by IRE-BP.⁵³ IRE-BP appears to be structurally identical to cytosolic aconitase, an iron-sulfur enzyme active in the Krebs cycle.⁵⁴ Evidence suggests that IRE-BP and cytosolic aconitase can reversibly convert from one form to another in response to alterations in intracellular iron availability.⁵⁵ This is mediated by changes in the molecular iron content of aconitase/IRE-BP internal iron-sulfur cluster.⁵⁶ Where intracellular iron is readily available, the aconitase enzymatic activity predominates, whereas low intracellular iron promotes the mRNA-binding activity of IRE-BP.

In the erythroid progenitors, IRE-BP acts by binding to IREs present on the mRNA of TFR, ferritin and ALAS, the first enzyme in the pathway for the formation of heme from glycine and succinyl-CoA. IRE-BP binding to the TFR IRE stabilizes TFR mRNA, reducing its cytoplasmic degradation and hence increasing the amount of cytoplasmic mRNA and the rate of TFR synthesis. More TFRs become available on the cell surface to bind diferric TF.⁵⁷ IRE-BP binding to ferritin and ALAS mRNA has the opposite effect of reducing translation of both ferritin and ALAS,^{39,58} and thus reducing intracellular iron metabolism.

The effects of increased IRE-BP binding in the presence of low cytosolic iron and reduced IRE-BP binding in the presence of high cytosolic iron are summarized in Fig. 5.4. When

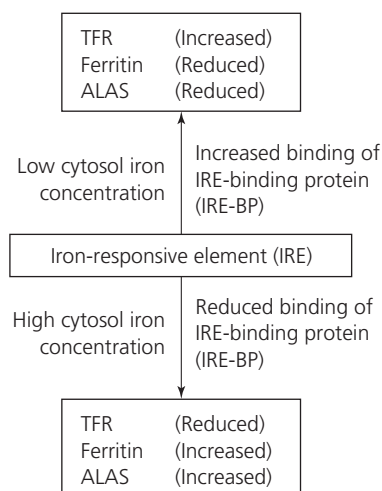

Fig. 5.4 Effect of cytosol iron content on the intracellular synthesis of transferrin receptors (TFR), ferritin, and δ -aminolevulinic acid synthase (ALAS) mediated via the iron-responsive element (IRE).

cytosolic iron is low, more TFRs are produced, which in turn increases the amount of iron-saturated TF taken into the cell. Storage and metabolism of iron by ferritin and ALAS are reduced, which again will tend to increase the iron content of the cytosol. The situation is reversed in the presence of high cytosolic iron levels. In consequence, iron uptake by erythroid cells has a positive effect, promoting ALAS activity. Increased ALAS activity increases protoporphyrin synthesis, thus coupling protoporphyrin production to iron availability within the erythroblast.⁵⁹ Under physiologic conditions, IRE-BP controls intracellular iron homeostasis.

Red cell cycle (Fig. 5.5)

Each day 25 mL of senescent red cells are destroyed. The globin chains are broken down into amino acids, which are then recycled to make more globin chains. The heme groups are split into iron and porphyrins. The porphyrins are metabolized and excreted as bilirubin. The iron is recycled

Fig. 5.5 Red cell cycle.

into the production of more red cell heme and combined with globin chains to form hemoglobin in erythroblasts and reticulocytes. Mature red blood cells survive 120 days on average before expressing red cell senescent antigen on their surface. This signals their imminent destruction and the initiation of the recycling process.

Iron deficiency

With the exception of the first few weeks of life, iron deficiency is by far the commonest cause of anemia in childhood. Depletion of iron stores, as indicated by a low serum ferritin without anemia, is even more frequent. Any child may develop iron deficiency but children from deprived inner-city backgrounds and from some ethnic minorities, notably Asian children, are particularly at risk, with the highest prevalence being seen in inner-city Asian toddlers. One UK study demonstrated iron deficiency in 39% of Asian infants.⁶⁰ Iron deficiency is not limited to Asian children and in the same study 20% of Afro-Caribbean and 16% of white inner-city toddlers were also iron deficient. In the vast majority of cases the deficiency of iron could have been prevented by simple dietary measures. In the USA, health education and public health programs introducing iron supplementation to the early weaning diet have significantly reduced the prevalence of iron deficiency in the pediatric population.⁶¹ In the UK, similar approaches have been less successful.⁶²

Etiology

In children, as in adults, iron balance is related to the ratio of iron absorbed from the diet to the amount lost from the tissues by desquamation and bleeding. However in children other factors are also important, namely the total amount of iron present at the time of birth and the increased demand for iron for growth, which is maximal in the first 6 months of life and during puberty.

In the adult, the approach to determining the cause of iron deficiency is dominated by the search for blood loss. In the child, especially under the age of 3 years, evaluation of the causes of iron deficiency requires an understanding of the developmental and dietary factors that affect total body iron stores.

Developmental factors

Fetus and neonate

The developing fetus is little affected by maternal iron stores. Only in extreme maternal iron deficiency is any degree of anemia seen in the fetus.⁶³ In general, the fetus acts as a parasite, receiving maternal iron at the expense of the mother. In the vast majority of cases, babies of iron-deficient mothers are born with normal hemoglobin concentrations. Infant serum

iron and TIBC are also usually normal in the presence of maternal iron deficiency.^{64–66} At the same time as being able to sequester iron from the mother into the fetus, the placenta also acts as a barrier, excluding excess iron and preventing fetal iron overload. Consequently, maternal iron supplementation does not influence fetal iron status.⁶⁷

A full-term infant at birth is iron replete, with an iron concentration of about 80 mg/kg body weight compared with 55 mg/kg body weight for an adult male;⁶⁸ 50 mg/kg is present as red blood cell iron, 25 mL/kg as storage iron, and 5 mg/kg as myoglobin.⁶⁹ The extra iron is needed to cope with the additional requirements of the accelerated rate of growth that takes place in the first few months of life. Iron stores at birth may be almost completely independent of maternal iron status but they are dependent on two other factors: birthweight and neonatal red cell mass.

Placental iron transport is insignificant until the third trimester when iron transport increases dramatically to as much as 4 mg/day. Infants born before 26 weeks' gestation have very low iron stores; in those born in the third trimester, iron stores are proportional to birthweight. A 1-kg preterm infant will have about 50 mg of total body iron compared with the 320 mg of a 4-kg full-term baby. The effect of this reduction is accentuated by the greater relative growth potential of the 1-kg preterm infant.

Red cell mass is determined by hemoglobin concentration and red cell volume. Although red cell volume is more or less uniform at 80–90 mL/kg, hemoglobin concentration at birth can vary from 13.5 to 21 g/dL in normal infants. The timing of umbilical cord clamping influences birth hemoglobin concentration (see also Chapter 9). At delivery, two-thirds of the red cells in the fetal circulation are in the infant and one-third in the placenta and cord. In the 3 min immediately following birth, uterine contractions will increase the amount of blood cells in the fetus to > 85%,⁷⁰ so early clamping of the cord can reduce the infant's iron content by between 15 and 30%.⁷¹

Infancy

During the first few weeks of life, erythropoiesis almost stops as the infant's red cell mass drops to a level appropriate for the oxygen-rich extrauterine environment.⁷² Iron is stored until erythropoiesis resumes, usually when the infant's hemoglobin concentration has dropped to 11–12 g/dL.⁷³ In the normal term infant, the iron stored during this time is adequate to cope with the expected doubling of body weight that takes place in the first 5 months of life. After this time, iron absorption from the diet becomes critical to the maintenance of normal iron balance. It has been estimated that a term infant needs 100 mg of iron in the first year of life from the diet to maintain a hemoglobin level of 11 g/dL but a preterm infant may require two to four times as much.⁷⁴

As stated above, newly born infants are iron replete. This is reflected by laboratory findings. Cord blood iron levels are

high at 150–250 µg/dL, dropping to 130 µg/dL after 24 hours. Following resumption of erythropoiesis at 8 weeks, iron levels drop further to 80 µg/dL.³³ Serum ferritin is also raised at birth with levels between 100 and 200 µg/L; it then increases further over the first 8 weeks of life but then begins to drop following resumption of erythropoiesis.³⁷ At 1 year, the mean serum ferritin is usually 30 µg/L. Serum TF levels are proportional to gestational age. This is a developmental phenomenon and, at least in the preterm infant, is not related to iron status.⁷⁵

Early childhood

During childhood total body iron increases in proportion to body weight. After 6 months of age, growth slows and the diet becomes more varied. As long as the diet has an adequate iron content, iron deficiency anemia is unusual. Even so, measured parameters of serum iron and TF saturation remain persistently low. TF saturations of 10% are not uncommon during early childhood but despite this erythropoiesis continues satisfactorily. Serum ferritin also remains low but levels < 10 µg/L indicate depletion of iron stores.

Puberty

At puberty, the secondary growth spurt increases iron requirements to allow for the increase in red cell and muscle mass. Another 80–90 mL of blood alone are required for every extra kilogram of lean body weight, equivalent to an extra 45 mg of iron; in addition to this is the iron required for new muscle myoglobin. This need for more iron is particularly marked in boys whose increase in lean body mass is on average double that seen in girls. In girls, however, as the growth spurt ends, menstruation begins and there is a need for extra iron to compensate for menstrual blood loss. Pregnancy can further increase the iron intake requirement of fertile females.

Dietary factors

The importance of dietary factors and the bioavailability of iron-containing foods has already been discussed in the section on iron absorption (see p. 79).

These dietary factors are particularly important to the development of iron deficiency in early childhood. Human breast milk has a low total content of iron but, like heme iron, the iron present in breast milk is highly bioavailable and able to enhance the amount of iron absorbed from other foodstuffs in the early weaning diet.¹⁸ Cows' milk, on the other hand, has a low total content of poorly bioavailable iron and its high phosphate content interferes with the absorption of iron from other foods. Cows' milk may also be associated with increased intestinal blood loss.¹⁹ Thus, despite having an apparently low total iron intake, the breast-fed infant is relatively protected from iron deficiency in early childhood compared with the child with a high intake of cows' milk.

A list of the causes of iron deficiency in childhood is given in Table 5.5. When considering the likely cause in a particular patient it is important to bear in mind the age of the child (Table 5.6). Under the age of 3 months, iron deficiency is rare and other causes of hypochromia and microcytosis should be sought. From 3 months to 3 years of age, poor diet often with excessive intake of cows' milk is the usual cause of a hypochromic, microcytic anemia. There may be history of premature birth or low birthweight. From 3 years of age to puberty, pure dietary iron deficiency becomes increasingly less likely and other etiologies, particularly gastrointestinal causes, should be considered. At puberty, the associated growth spurt in both sexes and onset of menstruation in girls make physiologic causes more common but other pathologies need to be excluded.

Diagnosis

The diagnosis of iron deficiency is usually straightforward. The patient is anemic with a low MCV. Some modern blood counters produce two-dimensional red cell maps that can aid the diagnosis by demonstrating the presence of iron-deficient

red cells. In all cases confirmatory tests should be performed. There are a number of confirmatory tests available for diagnosing iron deficiency but as discussed above (see p. 85) no single one is appropriate in all situations. Most laboratories use the serum ferritin, although at times of rapid growth, particularly in early childhood and during puberty, a low serum ferritin may not reflect iron-deficient erythropoiesis. Furthermore, ferritin is an acute reactive protein and thus may be elevated during infections even in the presence of iron deficiency. ZPP levels are less affected by concomitant infection and are not affected by growth spurts and so may be a preferable method of diagnosing iron deficiency during childhood.

Usually one confirmatory test is adequate to confirm the diagnosis. In difficult cases, more investigations will be required and direct assessment of marrow iron stores may be needed. In others a trial of iron therapy may be useful. A dose of 3 mg/kg of elemental ferrous sulfate for 1 month should increase the hemoglobin of an iron-deficient subject by at least 1.0 g/dL in 4 weeks.⁷⁶ As long as the patient is compliant with iron therapy, failure to respond to a therapeutic trial excludes iron deficiency as the cause of anemia.

Differential diagnosis

The various causes of the hypochromic anemias are set out schematically in Fig. 5.6. Any process interfering with the formation or rate of production of hemoglobin will induce a reduction in mean red cell hemoglobin with resultant hypochromia of the red cells. The development of hypochromia is often associated with concomitant red cell microcytosis. A full clinical history, with particular reference to the age and racial origin of the child, birth history, any abnormal bleeding and, most importantly, a detailed assessment of

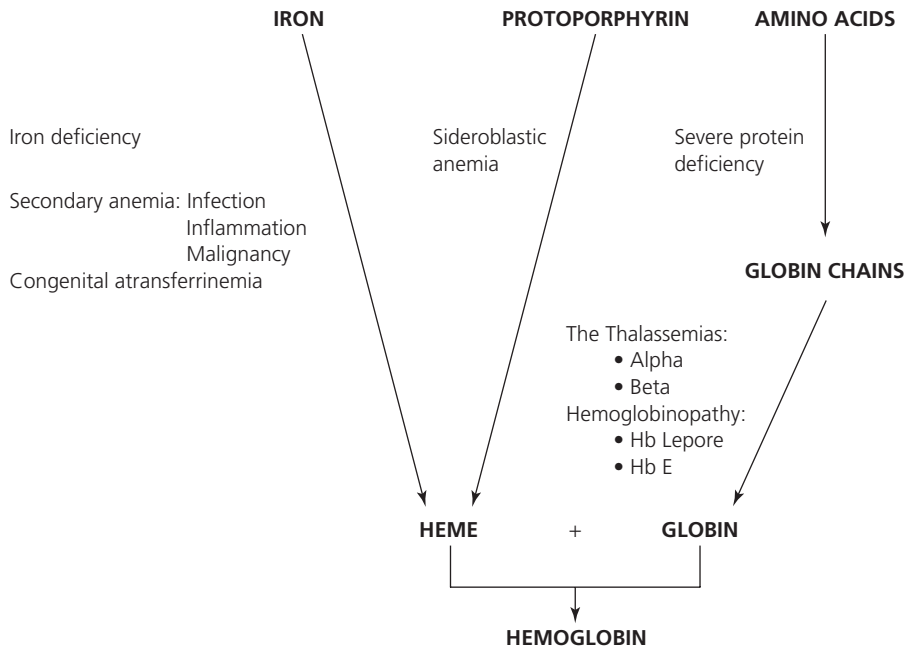

Fig. 5.6 Causes of the hypochromic anemias.

dietary intake, is essential to ensure the correct diagnosis of the cause of iron deficiency.

In most cases the differentiation between iron deficiency, secondary anemia, or a thalassemia trait is not difficult. However, it is not unusual for these conditions to coexist. Asian toddlers have a high incidence of iron deficiency but also commonly carry α - or β -thalassemia genes. In patients whose MCV improves but does not return to normal after an apparently adequate course of iron, thalassemia traits should be excluded.

In childhood, trivial viral infections are very common. These infections may falsely elevate iron and ferritin estimations and so can lead to diagnostic confusion. It is important to repeat any abnormal test results after the patient has recovered. Within a few weeks of recovery, any red cell abnormalities caused by infection should have returned to normal.

Although dietary iron deficiency is the predominant cause of iron deficiency anemia in children, abnormal blood loss must be considered in all patients. Worldwide, intestinal worm infections are the commonest cause of iron deficiency anemia due to blood loss. Hookworm infections with *Necator americanus* and *Ancylostoma duodenale* predominate but whipworm infection with *Trichuris trichiura* are also common. However, both these types of parasitic worms are mainly found in hot climates and are only likely to be seen in travellers to the tropics or in recently arrived immigrants. In the temperate regions of northern Europe, parasitic iron deficiency is uncommon and bleeding from a Meckel diverticulum, intestinal polyps, or peptic ulceration have to be considered as possible causes of iron deficiency secondary to intestinal hemorrhage.

Renal tract bleeding is usually obvious and is reported immediately by the patient or parent. However, pulmonary hemorrhage is sometimes less obvious, either because of chronic loss of iron into pulmonary macrophages (as seen in chronic pulmonary hemosiderosis) or because there is confusion as to whether the blood is coming from the upper airway or the gastrointestinal tract.

Although generally an idiopathic condition, *chronic pulmonary hemosiderosis* is occasionally associated with other disorders such as celiac disease and Goodpasture syndrome.^{77,78} This rare condition affects predominantly children. It is characterized by repeated intraalveolar microhemorrhages, with the lost blood being taken up by pulmonary macrophages. The iron taken up by these macrophages is not recycled and over a period of time the patient becomes increasingly iron deficient. Pulmonary fibrosis develops and, if untreated, patients develop a severe restrictive lung defect with a significant degree of pulmonary arterial shunting. Chest radiography is often abnormal and diagnosis is made from the presence of iron-laden macrophages in bronchiolar lavage fluid. Limited successes with chloroquine,⁷⁹ cyclophosphamide,⁸⁰ and a combination of prednisolone and azathioprine⁸¹ have been reported but for most patients the outlook is poor.

Malabsorption syndromes need to be considered, especially in patients with symptoms suggestive of diarrhea, abdominal distension, and failure to thrive. This is in stark contrast to the toddler with excessive cows' milk intake, who is usually distinctly well-rounded.

Failure to respond to iron is usually due to failure to comply with therapy. However in some cases the diagnosis of iron deficiency will be incorrect. In addition to the common

secondary anemias and thalassemia syndromes, there is a variety of inherited rare syndromes that may need to be considered such as congenital atransferrinemia or one of the sideroblastic anemias.

Inherited disorders of iron metabolism

Inherited disorders of iron metabolism are extremely rare. They are characterized by iron-deficient erythropoiesis with absent marrow iron stores despite the absorption of excessive quantities of iron into other tissues such as the heart and liver.

*Congenital atransferrinemia*³¹

Congenital absence of TF is an autosomal recessive disorder. Affected infants present at birth with a severe microcytic hypochromic anemia with a low serum iron and TIBC. Plasma TF is absent. The anemia does not respond to iron but transfusion with plasma can induce a reticulocyte response. Treatment is with blood transfusion and TF.⁸²

Although bone marrow iron is absent, iron is absorbed from the gastrointestinal tract and deposited in the liver, pancreas, heart, and kidneys. One affected child died from the effects of myocardial hemosiderosis. Therefore, TF does not appear to be required for the release and transport of iron from the intestinal mucosal cells. However, the absence of TF prevents iron transport to the erythron.

Congenital microcytic hypochromic anemia with iron overload

Two sets of siblings have been described with a severe microcytic hypochromic anemia despite fully saturated TIBC and an increased serum iron.^{83,84} Liver parenchymal cells contained excess iron and there was associated fibrosis. No iron was present in liver macrophages or the bone marrow, suggesting a functional defect of the transfer of iron to red cell precursors and macrophages.

Other syndromes

Three siblings have been described with a microcytic hypochromic anemia apparently due to an isolated abnormality of malabsorption and defective utilization of iron.⁸⁵ A single patient has also been described as having reduced iron incorporation into red cell precursors in the presence of a raised serum iron caused by an IgM autoantibody to TFR.⁸⁶

Effects of iron deficiency

Anemia

Classically, there are four stages in the development of dietary iron deficiency.⁷⁶

- Iron sufficiency: no anemia, red blood cells normal in number, microscopic appearance, size and biochemistry in the presence of adequate body iron stores.

- Iron deficiency: no anemia, red blood cells normal but iron stores are depleted with a low serum ferritin.
- Iron-deficient erythropoiesis: no anemia, iron stores depleted and abnormal red cells as demonstrated by a low MCV and abnormal biochemistry, i.e., raised ZPP.
- Iron-deficiency anemia: as above but with coexisting anemia.

However, as discussed above, during periods of rapid growth, children have reduced iron stores but with iron-sufficient erythropoiesis. So it is often difficult to assess a child with a low serum ferritin but a normal full blood count. Perhaps the best approach is to take a dietary history and give advice to improve dietary iron content if appropriate. It is also critical to evaluate the hemoglobin level found in the patient with the reference value for the child's age (see Chapter 37).

In most cases there is no difficulty in making the diagnosis. Dietary iron deficiency leads to a slow onset of anemia and the majority of toddlers present with a moderate to severe reduction of hemoglobin. Patients with abnormal bleeding will become symptomatic depending on the rate of blood loss. As for dietary-deficient toddlers, the peripheral blood changes are usually very obvious, with anemia, reduced MCV and MCH, and a raised red cell distribution width. The blood film is hypochromic and microcytic with pencil-shaped cells and occasional target red cells. Mild thrombocytosis of $500\text{--}700 \times 10^9/\text{L}$ is often present. The etiology of the increase in platelets is unclear but the platelet count returns to normal with appropriate treatment of the iron deficiency.

The presence of symptoms depends on the degree of anemia and its rate of onset. Symptoms become more likely as the hemoglobin drops below 7 g/dL but many of the toddlers will have few if any symptoms despite often having much lower levels of hemoglobin than this. Children will often present with pallor, which has sometimes been missed by the usual carers and only noticed by a relative who has not seen the child for some time, reflecting the insidious onset of the anemia. Irritability is usual with excessive crying; less often there is a history of pica.

The clinical history is all-important in making the correct diagnosis as to the underlying cause of the iron deficiency. Physical signs other than pallor are unusual. The presence of abnormal bruising may suggest the presence of a bleeding diathesis, while telangiectasia of the mucous membranes of the mouth and lip or on the underside of the lower eyelid would point to a diagnosis of hereditary hemorrhagic telangiectasia. Nail abnormalities such as koilonychia are not often seen in children.

Growth and development

There is good evidence that iron deficiency, even in the absence of frank anemia, is associated with impaired testing of psychomotor function and reduced scholastic achievement.^{87–91} Experiments in young rats have confirmed that

iron deficiency during the early stages of development produces reversible changes in neurotransmitters and neural lipids and a permanent reduction in brain iron concentration.^{92–98} Studies to determine whether treatment with iron can reverse the effects of iron deficiency in the developing human brain have produced variable results.^{99,100} However there is no doubting the clinical transformation from an irritable listless child to a happy active toddler that is so often seen even in the first few weeks of iron therapy.

Growth is also affected. Even taking into account the poor overall nutrition prevalent in iron-deficient populations, treatment with iron has been shown to reverse the detrimental effects on growth.¹⁰¹

Although there remain gaps in our knowledge, iron deficiency must be taken very seriously especially in the first few years of life when neurodevelopment is as yet incomplete. Treatment needs to be effective, aggressively implemented, and followed up diligently to ensure compliance so that any avoidable neurologic damage might be prevented.

Management

Iron deficiency should be considered as a symptom and not as a specific disease entity *per se*. A thorough clinical history is an essential part of the assessment and management of the iron-deficient child. The extent of investigation required will depend on the age of the child and the patient's medical history. Where abnormal blood loss is suspected, technetium scanning for ectopic gastric mucosa in a Meckel diverticulum or endoscopy of the gastrointestinal tract may be an essential part of the patient's investigation. However, the majority of children with iron deficiency will be between 1 and 3 years of age with a generally poor diet and a history of excessive cows' milk intake. Some will have been born prematurely or with a low birthweight.

For all children the underlying cause needs to be found and treatment directed to this and not just to the prescription of iron, which will only temporarily improve the hemoglobin concentration. In most cases appropriate dietary advice will be necessary.

Prevention

Primary prevention, which aims to prevent the development of iron deficiency altogether, is an extremely important public health issue. Very many children are affected by iron deficiency and at a very early age before the nervous system has fully developed, at a time when it is potentially vulnerable to the effects of iron deficiency. Health education needs to be aimed at persuading mothers of young children of the benefits of breast-feeding in the first few months of life followed by appropriate weaning schedules. Infant formula milk is already fortified with iron, as are many preprepared infant foods and cereals. In particular, mothers need to be

made aware of the dangers of excess cows' milk in the toddler diet, the primary cause of most early iron deficiency.

The evidence for a high incidence of iron deficiency in UK toddlers is incontrovertible (Table 5.7).^{60,87,101–108} The impetus for systematic screening of young children in order to detect and treat iron deficiency early (i.e., secondary prevention) is increasing. Particularly as many clinical studies have demonstrated the potential reversibility of the neurologic effects of iron deficiency, there is increasing interest in screening for iron deficiency in early childhood. However, much work needs to be done to determine the best timing and most appropriate diagnostic methods.

Clinical management

- 1 Diagnosis: full blood count, blood film, confirmatory test of iron deficiency (i.e., ZPP).
- 2 Assessment of underlying cause: dietary history, birth history, presence of abnormal bleeding, family history, past medical/surgical history.
- 3 Investigation and treatment of any underlying cause found: dietary advice, scan for Meckel diverticulum, endoscopy.
- 4 Iron therapy.

Iron therapy

Oral iron

Elemental iron should be prescribed in a dose of 3 mg/kg up to a daily maximum of 180 mg, usually given as two divided doses. To avoid accidental iron overdosage, parents or guardians should be warned of the dangers of medicinal iron and all preparations should be kept in childproof containers and out of the reach of young children. The following preparations provide 3 mg of iron:

- 15 mg of ferrous sulfate;
- 9 mg of ferrous fumarate;
- 26 mg of ferrous gluconate;
- 9 mg of ferrous succinate;
- 17 mg of ferrous glycine sulfate;
- 21 mg of sodium iron edetate.

Note that adult preparations contain too much elemental iron and are unsuitable for young children.

Failure to respond to oral iron preparations is not uncommon and usually represents poor compliance. In most cases a change of preparation and impressing on the parent or carer the importance of adequate treatment, particularly with regard to neurodevelopmental problems, is all that is necessary to ensure an improved response. However, it is important to be aware that failure to respond or an incomplete response may be because the initial diagnosis of iron deficiency was incorrect or may indicate the coexistence of another abnormality such as a thalassemia trait.

All patients must be followed up until the blood count has returned to normal. After that time a further 3 months of treatment should be given to build up body iron stores. Ideally all patients should be checked again 6 months later to ensure that there has been no recurrence of the iron deficiency. Any recurrence needs to be investigated and the reason elucidated. In many cases the dietary advice given at diagnosis will not have been followed and needs to be reiterated. In others the possibility of underlying occult blood loss needs to be reconsidered.

Parenteral iron

Parenteral iron preparations are rarely indicated for the treatment of childhood iron deficiency and must only be considered if the diagnosis of iron deficiency is absolutely certain. The indications for parenteral iron preparations are:

- demonstrated intolerance to oral preparations;
- where there is a need to deliver iron rapidly to iron stores;
- in active inflammatory bowel disease where there is intolerance to oral iron;
- where there is demonstrated patient noncompliance with oral iron with a definite diagnosis of iron deficiency;
- where follow-up of the patient is impossible.

Contraindications for parenteral iron preparations include:

- anemias not due to iron deficiency;
- iron overload;

- history of hypersensitivity to parenteral iron preparations;
- history of severe allergy or anaphylactic reactions;
- clinical or biochemical evidence of liver damage;
- acute or chronic infection;
- neonates.

Only the intramuscular preparation containing iron, sorbitol, and citric acid (Jectofer) is licensed for use in children above 3 kg in weight. However some pediatricians are using the intravenous iron sucrose preparation Venofer, which has yet to be fully licensed for use in pediatrics.

The majority of children with iron deficiency are toddlers with inadequate diets. These children can be managed in the primary care setting in collaboration with the local hematology laboratory. However, all other children with iron deficiency need to be assessed in the hospital setting, where the full diagnostic facilities required are readily available. All cases without an obvious underlying cause for the iron deficiency and those who fail to respond as expected to therapy should be referred to a pediatric hematologist.

Sideroblastic anemias

The sideroblastic anemias are a heterogeneous group of disorders characterized by variable red cell hypochromia, anemia, and the presence of a significant number of ringed sideroblasts in the marrow. By definition, the ringed sideroblasts should total 10% or more of the nucleated red cell precursors.¹⁰⁹ Diagnostic ringed sideroblasts contain six or more siderotic granules arranged in a perinuclear collar around one-third or more of the erythroblast nucleus. These perinuclear granules consist of iron-laden mitochondria.¹¹⁰

All forms are characterized by failure to utilize iron properly during home synthesis in the mitochondria. Iron accumulates within the mitochondria and eventually adversely affects mitochondrial function. Premature erythroblast cell death follows, resulting in ineffective erythropoiesis.

The classification of the sideroblastic anemias is shown in Table 5.8. All forms of sideroblastic anemia are rare in childhood.¹¹¹ The congenital forms are occasionally encountered but the acquired forms are much less commonly seen in children than in adults.

Congenital sideroblastic anemias

Etiology

In most families affected by sideroblastic anemia, inheritance is X-linked and may be associated with the coinheritance of other X-linked traits such as glucose 6-phosphate dehydrogenase deficiency¹¹² or ataxia.¹¹³ Female carriers may show minor changes with a variable population of circulating hypochromic red cells; the size of the hypochromic population in female carriers is probably dependent on random

Autoimmune disorders

X-chromosome inactivation (lyonization). In some cases where lyonization is extreme, females are more severely affected.¹¹⁴ In other families, females are affected because the sideroblastic anemia is inherited as an autosomal trait.^{115,116}

Molecular basis (see Fig. 5.3)

The first step in the synthesis of heme from glycine and succinyl-CoA is catalyzed by ALAS in the presence of pyridoxal phosphate. Two types of ALAS exist in the body: one is a ubiquitous enzyme found in all tissues and is coded for by a gene on chromosome 3; the other is expressed by a gene on the X chromosome and is specific to erythroid cells.¹¹⁷ This explains why most cases of inherited sideroblastic anemia are X-linked and why the synthesis of heme proteins other than hemoglobin is unaffected.

ALAS requires the presence of pyridoxal phosphate as a coenzyme to initiate mitochondrial heme production efficiently. In some cases of inherited X-linked sideroblastic anemia, mutant ALAS enzymes have been demonstrated.¹¹⁸ Theoretically, pyridoxine in pharmacologic doses could act to improve the enzyme activity of a mutant ALAS in several ways and thereby improve the production of heme. It could stabilize the quaternary structure of mutant ALAS and thereby improve enzyme activity.¹¹⁹ In other situations, pyridoxine might protect mutant ALAS from premature degradation by mitochondrial proteases.¹¹⁹ Finally, the mutant enzyme might require a higher concentration of pyridoxal phosphate than is usually necessary to promote normal activity.¹²⁰

In other families with sideroblastic anemia, defects of ferrochelatase and copro-oxidase have been described.^{121,122} Copro-oxidase does not have pyridoxal phosphate as a cofactor, so these patients would not be expected to respond to pyridoxine therapy. In other patients, multiple or ill-defined enzyme deficiencies interfere with mitochondrial function and heme synthesis.¹²³ Some of these patients may respond to pyridoxine, others will not. Nevertheless, in all cases of inherited sideroblastic anemia a trial of pyridoxine therapy is indicated.¹²⁴

Diagnosis

Most cases present in infancy or early childhood but less severe forms may pass unnoticed until adulthood. Some patients are discovered during routine testing of close relatives of a suspected patient. Others present late with the clinical effects of iron-overload liver disease, diabetes mellitus, or heart failure. Late presentation with iron overload most often occurs in cases where anemia is mild or occasionally in female carriers. Examination is usually normal except for pallor but splenomegaly or hepatomegaly may be present.

Investigation reveals microcytosis with a variable degree of anemia. The microcytosis can be severe and an MCV of 50 fL can be seen in the more anemic patients. A novel form of macrocytic hereditary sideroblastic anemia was recently described.¹²⁵ The characteristic red cell dimorphism is most marked in cases with milder anemia and in female carriers. This can be detected by microscopic examination of the blood film or mechanically from erythrocyte volume distribution curves or red cell maps depending on the type of blood counter technology used. Serum iron and ferritin are elevated and TIBC reduced.

The dimorphic blood picture, raised serum iron, raised serum ferritin, and reduced TIBC may be confused with partially treated iron deficiency anemia, particularly as many patients will have already received iron, blood transfusions, or both. However, free erythrocyte porphyrins are normal and help to distinguish partially treated iron deficiency. Levels of protoporphyrin are reduced and coproporphyrin levels remain normal.

Other nonspecific abnormalities are often present, i.e., mild hyperbilirubinemia and reduced haptoglobins in the presence of a normal or only slightly increased reticulocytosis. Iron staining of peripheral blood will demonstrate circulating red cells that contain iron-laden mitochondrial remnants (Pappenheimer bodies). However, definitive diagnosis is most often made following microscopic examination of a bone marrow aspirate. Iron staining reveals the presence of large numbers of pathologic ringed sideroblasts. In inherited sideroblastic anemia, the ringed sideroblasts are predominantly seen in the late erythroblast population.

Table 5.9 Differentiation of hereditary from primary acquired sideroblastic anemia.

	Hereditary	Acquired
Red blood cell size	Microcytic	Macrocytic or normocytic
Ringed sideroblasts	Late erythroblasts	Early erythroblasts
Free red blood cell porphyrins	Normal	Increased
Red blood cell coproporphyrins	Normal	Increased
Marrow chromosomes	Normal	Abnormal in 60%
Relatives	Often abnormal	Normal

Differential diagnosis

Initial confusion with partially treated iron deficiency anemia will be clarified following iron staining of a bone marrow aspirate. It is important to consider performing a bone marrow aspirate in infants, especially males with unexplained iron deficiency anemia, or where investigation of microcytosis fails to elucidate a cause for the reduction in red cell size, particularly if the MCV has remained low despite iron therapy.

Once significant (>10%) numbers of ringed sideroblasts have been demonstrated, inherited sideroblastic anemia has to be differentiated from acquired disorders associated with the presence of excess ringed sideroblasts in the marrow (see Table 5.8). It is usually possible to differentiate inherited sideroblastic anemia from the primary acquired form on clinical grounds alone. In cases where there is uncertainty, laboratory findings will allow differentiation (Table 5.9). Red cell macrocytosis, raised red cell porphyrins, and the presence of marrow chromosomal abnormalities are particularly helpful. Investigation of close relatives is important as it helps to identify cases of inherited sideroblastic anemia and at the same time permits quantification of iron loading in asymptomatic siblings and carriers.

Other rare inherited disorders presenting in childhood can be associated with the presence of significant numbers of ringed sideroblasts in the marrow. Pearson *et al.*¹²⁶ have described a syndrome of refractory anemia presenting in early childhood as a severe transfusion-dependent normocytic or macrocytic anemia with reticulocytopenia. Neutropenia is usually present and a variable thrombocytopenia is common. Examination of the marrow reveals prominent degenerative cytoplasmic vacuolation in both erythroid and granulocytic precursors. Iron stores are markedly increased and ringed sideroblasts are prominent. The disease is not limited to the bone marrow; marked fibrosis of the exocrine pancreas was found at post-mortem examination of two children with the syndrome who died in the first 3 years of life, and three less severely affected children also showed *in vivo* evidence of abnormal pancreatic function. Pearson anemia probably represents a disorder of multiorgan cellular mitochondrial

dysfunction. A possible variant of Pearson anemia with early onset of severe pancytopenia and thyroid fibrosis has been described.¹²⁷

Two children with DIDMOAD syndrome (Wolfram syndrome)¹²⁸ have been described as having a megaloblastic and sideroblastic anemia.¹²⁹ The patients were first cousins and both demonstrated a response to thiamine, with improvement in anemia and associated neutropenia and thrombocytopenia. Insulin requirements also reduced significantly following the introduction of thiamine therapy. The authors speculated that DIDMOAD syndrome might be a multi-system degenerative disorder caused by an inherited abnormality of thiamine metabolism.

Three reports have been published describing sideroblastic anemia in the presence of excess erythrocyte protoporphyrins.^{130–132} These cases share some similarities with erythropoietic porphyria; two patients had skin photosensitivity and one developed liver disease with increased hepatic protoporphyrins.

Although primary acquired sideroblastic anemia is very unusual in childhood, secondary acquired cases do occur (see Table 5.8). A full drug history needs to be taken. Some drugs, like isoniazid, act as pyridoxine inhibitors; others like chloramphenicol may inhibit mitochondrial protein synthesis by interfering with ferrochelatase activity.

Lead toxicity is not uncommon in preschool children¹³³ and it can be associated with anemia and ringed sideroblasts in the marrow. Acute lead intoxication usually presents as lead encephalopathy with anemia as a late manifestation. However, chronic lead poisoning often coexists with iron deficiency and consequent microcytic anemia. Basophilic stippling, a precipitation of RNA and mitochondrial fragments, is often prominent on the blood film.¹³⁴ Lead binds to the red blood cell membrane and is absorbed into the red cell, interfering with several enzymes including ferrochelatase that are involved with heme synthesis.¹³⁵ Iron, heme intermediates, and ZPPs accumulate inside the red cells. An increase in free erythrocyte protoporphyrins is a useful screening test for lead poisoning and also helps to differentiate lead toxicity from sideroblastic anemia.¹³⁶ Diagnosis is confirmed by estimation of blood lead concentration. Treatment is based on the removal of the sources of lead ingestion and dual chelation therapy with dimercaprol (BAL) and calcium EDTA.¹³⁷

Ringed sideroblasts may also be seen with abnormalities of other metals and occur in copper deficiency and zinc overload. Copper deficiency is only seen in malnourished premature babies¹³⁸ and in patients receiving long-term parenteral nutrition with inadequate copper supplementation.¹³⁹ Copper is absorbed almost exclusively during the last trimester and deficiency in a premature infant may be accentuated if the child is given copper-deficient feeds such as cows' milk at an early age. Early severe copper deficiency presents as a hypochromic anemia and neutropenia.

Examination of the marrow reveals ringed sideroblasts, vacuolation of erythroid and granulocytic precursors, and granulocytic maturation arrest. More chronic cases produce osteoporosis, depigmentation of the skin and hair, and central nervous system changes. The diagnosis is made by demonstrating a low serum copper and ceruloplasmin. The effects of copper deficiency are quickly reversed by daily treatment with 2–5 mg of copper sulfate orally or by the addition of 100–500 µg of copper to intravenous feeds. In excess, zinc interferes with copper absorption and can cause a secondary copper deficiency.¹⁴⁰ A high serum zinc is associated with low serum copper and ceruloplasmin levels. Discontinuation of zinc ingestion will reverse the changes over 2–3 months.

Other causes of secondary sideroblastic anemia are much commoner in adults than children. Ringed sideroblasts are only occasionally found in the marrows of children with myelodysplastic syndromes other than primary acquired sideroblastic anemia (refractory anemia with ringed sideroblasts). They can also rarely be seen in cases of acute myeloid leukemias. Careful examination of the marrow will distinguish these from primary inherited sideroblastic anemia. Significant numbers of ringed sideroblasts can sometimes be seen in juvenile rheumatoid arthritis,¹⁴¹ and a single case of an antibody-mediated acquired sideroblastic anemia has been reported.¹⁴²

Management

Between 25 and 50% of patients with hereditary sideroblastic anemia show some response to oral pyridoxine. A trial of pyridoxine 25–100 mg three times a day for 3 months is indicated in all patients. Response is variable and in many cases the MCV remains abnormal and residual microcytic hypochromic cells can be seen on the blood film. Responders should continue pyridoxine for life but because pyridoxine can produce a peripheral neuropathy, the dose should be titrated to the lowest daily dose that maintains response.¹⁴³ In one report, a patient who had not responded to oral pyridoxine responded to parenteral pyridoxal 5'-phosphate.¹⁴⁴ Folic acid supplements should also be given.

The majority of patients do not respond to pyridoxine and require regular blood transfusions that further increase iron overload. Strict adherence to chelation therapy with deferoxamine (desferrioxamine) is essential for long-term survival.

Mildly affected patients and even some female carriers may eventually develop symptoms of iron toxicity as a result of excess absorption from the diet.¹⁴⁵ These patients should be carefully monitored for excess iron deposition. If this is detected, most patients will tolerate therapeutic venesection to remove iron from the body.¹⁴⁶

Splenectomy should be avoided, as it is associated with a high incidence of thromboembolism and persistent postoperative thrombocytosis.

Acquired sideroblastic anemias

Those occurring in childhood have been described above in the differential diagnosis of the inherited sideroblastic anemias.

Primary acquired idiopathic sideroblastic anemia/refractory anemia

Primary acquired idiopathic sideroblastic anemia is one of the myelodysplastic syndromes, refractory anemia with ringed sideroblasts (RARS).¹⁴⁷ RARS is usually a disease of the elderly and is seen only rarely in childhood. However, with the increasingly successful use of powerful chemotherapy and radiotherapy to treat pediatric malignancies, secondary forms of RARS may begin to be seen in pediatric practice.

In adults, RARS has a relatively benign course, with a 50-month median survival and about a 10% incidence of leukemic progression.¹⁴⁸ The more malignant forms are associated with marrow clonal chromosomal abnormalities other than trisomy 8, which has no adverse prognostic significance. However, monosomy 7 or partial deletion of the long arm of chromosome 7 in particular have a poor prognosis with an increased risk of leukemic transformation. Other factors associated with a poorer outcome are anemia requiring regular transfusions and hence early iron overload and the presence of associated neutropenia and/or thrombocytopenia. It is likely that the same factors are relevant to children as well.

In general, myelodysplasias occurring in children should be treated aggressively (see Chapter 4). If differentiation from inherited sideroblastic anemia is certain, and particularly in the presence of poor prognostic indicators, bone marrow transplantation should be considered early in the course of the disease. If a conservative approach is taken, patients must be closely monitored for iron overload and progression to more advanced types of myelodysplasia or frank leukemia.

Iron overload

Acute overdose

Accidental overdose is not uncommon, particularly in pre-school children. A 1990 study of 339 cases found that 83.9% occurred in children under 6 years old.¹⁴⁹ This is because iron tablets look like sweets and are often available in the home because the child's mother is pregnant and has been prescribed iron supplements. Toxicity is directly related to the dose ingested. Doses > 60 mg/kg are likely to induce serious toxicity and ingestion of > 180 mg/kg may prove fatal.

Acute iron poisoning can be divided into four phases.

1 The patient experiences nausea and vomiting, abdominal

pain, and diarrhea due to irritation of the gastrointestinal tract. In some cases, ulceration can occur in the upper gastrointestinal tract during this phase with hematemesis and melena.

2 The patient appears to be well. Most recover at this stage but a minority progress to the third phase.

3 The patient develops iron encephalopathy, with fits and fluctuating conscious level, shock, metabolic acidosis, and acute renal tubular and hepatic necrosis.

4 Those that recover may go on to develop high intestinal obstruction with strictures, usually in the pyloric region. This fourth phase most often occurs in children 2–6 weeks after apparent recovery.

Treatment also depends on the amount of iron ingested. Where there is doubt about how many tablets, if any, have been taken, plain abdominal radiography may help to confirm significant overdose because iron tablets are radiopaque.

Serious toxicity occurs when the ability of TF and apoferitin to mop up the excess iron is exceeded. This is usually seen when serum iron is $> 90 \mu\text{mol/L}$ and the TIBC is overwhelmed and toxic free iron oxy-radicals are generated. Guidelines suggest that when $> 20 \text{ mg/kg}$ has been ingested, gastric lavage should be performed.¹⁵⁰ If the patient is too young or cannot tolerate this procedure, an emetic should be administered. Patients who have taken $> 40 \text{ mg/kg}$ or an intentional overdose should be admitted for observation following lavage. In cases of significant overdose, deferoxamine should be given orally to prevent further absorption from the gastrointestinal tract and parenterally to remove iron already absorbed.

Chronic iron overload

The effects of chronic iron overload are most often seen in patients who have increased dietary iron absorption and/or are receiving regular blood transfusions. The extent of tissue damage is related to the total amount of iron absorbed, the speed of iron accumulation, and the distribution of iron in the body tissues. Iron stored in tissue macrophages appears to be relatively innocuous, whereas deposits in parenchymal cells are often associated with extensive tissue damage.

The mechanism producing cellular damage appears to be the same irrespective of the underlying cause of the iron overload. As tissue stores build up, the excess iron overwhelms the protective iron-binding proteins TF and ferritin. This allows increasing amounts of free non-TF-bound iron to exist as ionic iron in the plasma and tissues,¹⁵¹ which promotes the production of free hydroxyl radicals. These oxy-radicals damage intracellular lipids, nucleic acids and proteins, disrupting intracellular organelles and breaking down intracellular lysosomes, which release hydrolytic enzymes into the cytosol and thereby cause further intracellular destruction. Cell death follows accompanied by pericellular necrosis and fibrosis.^{152,153}

Table 5.10 Etiology of iron overload.

<i>Increased gastrointestinal absorption</i>
Hereditary hemochromatosis

Congenital dyserythropoietic anemias
Pyruvate kinase deficiency
Sideroblastic anemias
Atransferrinemias and other rare disorders of iron transport
<i>Repeated red cell transfusions</i>
<i>Perinatal iron overload</i>
Hereditary tyrosinemia (hypermethioninemia)
Zellweger syndrome (cerebrohepato-renal syndrome)
Neonatal hemochromatosis
<i>Focal iron sequestration</i>
Idiopathic hemochromatosis
Hallervorden–Spatz syndrome
Chronic hemoglobinuria

Etiology and distribution of abnormal iron deposition in the body

The clinical manifestations of iron overload differ according to the underlying disease process (Table 5.10).

In hereditary hemochromatosis, increased oral absorption causes a gradual increase in tissue iron and symptoms do not usually develop until middle age or later when total body iron stores have increased by 15–20 g.¹⁵⁴ Iron deposition is predominantly in parenchymal cells, initially in the liver but eventually affecting other organs.¹⁵⁵ In the rare cases presenting in childhood, the pattern of iron deposition is often more marked in the heart and thyroid.¹⁵⁶ In both the adult and pediatric forms, bone marrow macrophage iron deposition is unimpressive and may be absent.¹⁵⁷

Excessive oral absorption of iron is also seen in the iron-loading anemias. These are the group of anemias associated with erythroid hyperplasia and ineffective erythropoiesis and include β -thalassemia major and intermedia, the congenital dyserythropoietic anemias, chronic hemolytic anemias, and some of the sideroblastic anemias. The iron distribution is similar to that seen in hereditary hemochromatosis and is predominantly in the parenchymal cells of the liver, spreading later to other organs. In some conditions such as β -thalassemia major, the increase in dietary iron absorption is of secondary importance to the iron deposition caused by the need for regular blood transfusions. In those conditions not requiring regular blood transfusions, increased oral iron absorption is the primary mechanism of iron overload. Although occurring more slowly than transfusion-related siderosis, this will eventually cause clinically significant

tissue damage. Even patients with mild anemia can develop significant iron overload because the rate of iron deposition is not related to the severity of the underlying anemia.¹⁴⁵

In transfusional iron overload, iron deposition occurs more quickly. Each unit of blood contains 200–250 mg of iron and most patients require >200 mL/kg of blood annually, equivalent to about 200 mg/kg of iron each year.¹⁵⁸ Clinical symptoms usually appear when >15 g of excess iron has been transfused. Initially, iron is stored in the marrow and reticuloendothelial macrophages, which have a storage capacity of about 10–15 g. When this storage capacity has been exceeded, parenchymal iron deposition occurs and tissue damage follows. Transfusional iron toxicity occurs relatively quickly. Iron-induced hepatic fibrosis has been detected in children under 3 years old.¹⁵⁹

In the early stages of iron accumulation, histologic assessment of the pattern of iron deposition in the liver and bone marrow can help in differentiating the underlying cause. In advanced iron overload, however, the differences in tissue distribution disappear as iron deposition becomes more widespread.

Perinatal iron overload

Perinatal iron overload is rare and presumably occurs where the normal but poorly understood mechanisms for transferring iron from the maternal blood to the fetus via the trophoblast basement membrane and fetal endothelium fail to control entry of iron into the fetus.¹⁶⁰ Two distinct inherited disorders have been described. In hereditary tyrosinemia (hypermethioninemia), iron deposition is restricted to the liver, which is usually cirrhotic.¹⁶¹ Pancreatic islet cell hyperplasia and renal abnormalities are also present. In Zellweger syndrome (cerebrohepatorenal syndrome), iron is deposited in the parenchymal cells of the liver, spleen, kidney, and lungs.¹⁶²

The syndrome of neonatal hemochromatosis is less well defined and the underlying defect has not been identified.¹⁶³ In affected infants, iron is deposited in the parenchymal cells of the liver, heart, and endocrine organs but not in the bone marrow or spleen. Death usually occurs in the neonatal period from liver disease, which in some cases may precede widespread iron deposition.¹⁶⁴ The disorder may represent the common end stage of a group of disorders with different etiologies. In some cases an infective agent may be responsible; in others there is evidence of abnormal fetomaternal iron transport.

Focal iron overload

Focal sequestration of iron into the pulmonary alveolar macrophages occurs in idiopathic pulmonary hemosiderosis and in the basal ganglia of patients with the rare neurodegenerative disorder Hallervorden–Spatz syndrome.¹⁶⁵ In idiopathic pulmonary hemosiderosis, the iron sequestered in the

pulmonary macrophages is unavailable for iron metabolism and eventually iron deficiency anemia develops. The pathogenic role of the iron deposited in the central nervous system in Hallervorden–Spatz syndrome is uncertain. Renal hemosiderosis can occur in patients with chronic hemoglobinuria but is not associated *per se* with any renal dysfunction.

Clinical effects

Prior to the introduction of chelation therapy the clinical effects of iron overload presented in late childhood and the early teenage years in most regularly transfused patients. In hereditary hemochromatosis the slow rate of tissue iron overload usually delayed significant tissue damage until middle age or later. Generally, children developed normally during the first decade of life as long as adequate amounts of blood were transfused. In the second decade, patients often presented with growth failure and delayed or absent pubertal development. In the early teenage years, heart disease and abnormalities of liver function were commonly seen and a minority of patients developed hypothyroidism.¹⁶⁶ In the late teenage years, abnormalities of glucose tolerance and even diabetes mellitus occurred but the clinical picture was most often dominated by deteriorating heart disease that was frequently fatal before the age of 20.¹⁶⁷

Iron chelation therapy has dramatically altered the clinical picture of iron overload. However, chelation regimens need to be strictly adhered to if they are to be effective, but unfortunately many patients fail to do so. In a study following variably chelated but regularly transfused thalassemic patients over a period of 21 years, the incidence of iron overload complications was still significant at 20 years of age; 30% had heart disease, 43% diabetes mellitus, 28% hypothyroidism, and 22% hypoparathyroidism. In patients older than 20, 60% had one or more iron-related, life-threatening complications.¹⁶⁸ The consequences of iron overload and the potential benefits of chelation therapy are shown in Table 5.11.

Heart

When total body iron is >1 g/kg, significant amounts begin to be deposited in the myocardium and the conducting system of the heart.¹⁵⁸ In transfusional iron overload, the ECG changes of left ventricular hypertrophy and conduction defects may be detected by 10–12 years of age. Echocardiographic changes occur late in the disease process.¹⁶⁹ In inadequately chelated patients, cardiac disease is the commonest cause of death and may occur in the late teens.¹⁶⁷ Except in the rare childhood forms of hereditary hemochromatosis,¹⁵⁴ the cardiac effects of excessive iron deposition are only seen at a late stage of the illness in about 10–15% of the most seriously affected patients.

Liver

In hereditary hemochromatosis, iron is primarily deposited

Table 5.11 Complications of iron overload and the effect of chelation therapy.

Complication	Effect of chelation therapy	
	Protection	Reversibility of established disease
Liver	Yes	Yes
Heart	Yes	Yes
Endocrine		
Growth	Yes	Yes
Hypogonadism	Yes	No
Diabetes mellitus	Yes	No
Hypothyroidism	Yes	No
Hypoparathyroidism	Yes	No
Arthropathy	Unknown	
Infections	No (<i>Yersinia</i> seen with chelation therapy)	

in the parenchymal cells and so liver cell damage is initiated early and becomes clinically significant when the liver contains iron concentrations of about 5000 µg/g dry weight of liver.¹⁷⁰ However, because the development of iron overload in hemochromatosis is slow, liver disease usually takes decades to develop. In transfusional iron overload, iron is first deposited in the protective liver reticuloendothelial storage cells and about twice as much iron needs to be deposited in transfusional iron overload as in hereditary hemochromatosis before clinical problems develop.¹⁷¹ Nevertheless, the rate of iron deposition in transfusional siderosis is so rapid that liver abnormalities can be detected within 2 years of initiating transfusion therapy.¹⁷²

Hepatomegaly is detectable early followed by abnormal liver function tests. With further deposition parenchymal damage induces fibrosis, which may be present before 3 years of age.¹⁵⁹ Eventually, macronodular or mixed macronodular/micronodular cirrhosis develops. In adults with hemochromatosis the incidence of development of hepatoma in the cirrhotic liver is high.

In transfusional siderosis, liver disease was often multifactorial due to a high incidence of hepatitis B and C. Immunization of patients against hepatitis B and the introduction of effective screening tests for hepatitis B and C by the blood transfusion services have greatly reduced the incidence of viral hepatitis in these patients.

Endocrine system

Even well-transfused patients develop growth failure and hypogonadism in the second decade of life.¹⁷³ Poor pubertal growth in unchelated patients is probably caused by a combination of central hypogonadism¹⁷⁴ and reduced production

of insulin-like growth factor (IGF)-1.¹⁷⁵ Failure or delay of sexual development remains a problem for patients who do not fully comply with chelation regimens.

In one study a high incidence of abnormalities of glucose tolerance was demonstrated but frank diabetes mellitus only occurred in 6.5% of transfused unchelated thalassemics and usually not before 17 years of age. The incidence was higher in patients with a family history of diabetes.¹⁷⁶

Hypothyroidism occurs in about 6% of unchelated thalassemics¹⁶⁶ and hypoparathyroidism in a similar number. Minor abnormalities of adrenal androgen secretion have also been described.

Joints

Arthropathy, particularly of large joints, is relatively common in older patients with hemochromatosis. It can also be seen at a younger age in a minority of patients with transfusional siderosis.¹⁷⁷

Infections

The increased availability of iron may predispose to infection with a variety of bacteria and fungi, particularly *Yersinia enterocolitica* but also *Listeria monocytogenes*, *Escherichia coli*, *Vibrio vulnificus* and some *Candida* species.¹⁷⁸

Management of iron overload

Iron chelation therapy

The introduction of effective iron chelation therapy has revolutionized the management of patients with iron overload disorders, and the problems of management of multiply transfused patients have shifted from detection and treatment of iron-induced organ damage to early detection and control of the unwanted effects of chelation. Modern pediatric practice is increasingly involved with the prevention rather than the management of iron overload (see Chapter 13 for details of iron chelation therapy).

Iron-loading anemias

Any condition associated with erythroid hyperplasia and ineffective erythropoiesis can be complicated by significant iron overload caused by increased gastrointestinal absorption. The degree of iron overload is not related to the degree of anemia and can occur even in those patients with little or no reduction in their hemoglobin concentration. The excess iron tends to be deposited in the parenchymal cells and so, as in hereditary hemochromatosis, tissue iron damage is initiated at an early stage of iron overload. Therefore, any patient with an iron-loading anemia needs to be monitored throughout life with intermittent estimations of serum ferritin. Any patient with a sustained significant rise in serum ferritin, especially if levels are continuing to increase,

needs to be considered for treatment with therapeutic phlebotomy. Once significant iron overload has been confirmed, treatment should begin promptly as delay will only increase parenchymal tissue damage. For every 2 mL of blood venesected, approximately 1 mg of iron is removed from the body.

Despite being well tolerated by most patients with absent or mild anemia, phlebotomy should be initiated carefully. Between 5 and 10 mL/kg, up to a maximum of 500 mL, should be withdrawn per week, with the hemoglobin concentration and hematocrit checked prior to each venesection. As therapy continues there should be a progressive fall in serum ferritin. Eventually, serum iron and TIBC will return to normal when body iron stores become nearly depleted. Occasionally, serum iron may fall and the anemia become more severe in the presence of a persistently high serum ferritin. In this situation, suspending phlebotomy for a few weeks may allow iron to be mobilized from long-term iron stores, and then reintroduction of phlebotomy will be followed by further reductions in serum ferritin. When serum ferritin has become normal, weekly therapeutic phlebotomy should be discontinued. Thereafter, maintenance phlebotomy will be required every few weeks with the aim of keeping serum ferritin below 50 µg/L and TIBC normal.

A minority of patients cannot tolerate regular venesection, usually because of worsening anemia. They require regular transfusion to suppress erythropoiesis and hence reduce dietary iron absorption to normal and regular chelation therapy to remove the excess iron introduced by the transfused blood.

Patients on regular transfusion regimens

A regular transfusion regimen should not be introduced without proper consideration of the potential benefits for the patient and the risks involved. Iron chelation therapy is the crucial factor. Parents and patients must be educated about the effects of iron overload and the critical need for compliance with chelation. The physician in charge needs to have a comprehensive plan for the management of regular transfusion therapy and be able to carefully monitor the patient for the effects of iron overload and deferoxamine toxicity (see Chapter 13 for details of iron chelation therapy). The UK Thalassaemia Society has recently published the guideline document "Standards for the clinical care of children and adults with thalassemia in the UK: a full review of the necessary resources".¹⁷⁹ Although aimed at patients with β-thalassemia major, the basic principles are relevant to any child on long-term transfusion therapy.

Pretransfusion considerations (Table 5.12)

In all patients, the ultimate goal of transfusion therapy is to ensure normal growth and development and promote well-being.

Table 5.12 Preparations for the introduction of regular transfusion therapy.

Baseline virology
Immunize against hepatitis B

In the hypoerythroblastic anemias, such as Diamond–Blackfan anemia, the only aim of therapy is to achieve the minimum hemoglobin concentration that ensures normal growth and development while preventing dyspnea and the other symptoms of clinical anemia. The appropriate level of pretransfusion hemoglobin will vary from patient to patient but in most at least 8 g/dL is necessary.

Those patients with anemias associated with erythroid hyperplasia and concomitant increase in iron absorption from the gastrointestinal tract also need regimens that promote normal growth and development. However, the regimen chosen for these patients must also adequately suppress marrow expansion and hypersplenism in order to prevent skeletal deformity and extramedullary hemopoiesis and at the same time reduce the excess absorption of dietary iron. In rare conditions such as pyruvate kinase deficiency, in which the oxygen dissociation curve is shifted to the right, relatively low levels of posttransfusion hemoglobin concentration may be adequate.¹⁸⁰ However, in the majority of patients, maintenance of a near-normal mean hemoglobin concentration is required.

Hypertransfusion regimens that aim for a trough hemoglobin of 9–10 g/dL are undoubtedly effective in preventing the physical effects of anemia and at the same time adequately suppress dietary iron absorption.¹⁸¹ Supertransfusion regimens that aim for a higher pretransfusion hemoglobin of > 11 g/dL have been developed¹⁸² but have not proven to be any more effective than hypertransfusion.¹⁸³

Transfusions should aim to raise the patient's hemoglobin by about 4 g/dL and are given at 3 or 4 weekly intervals. Appropriately matched packed red cells with as long an expiry date as possible should be transfused. Attempts to improve the lifespan of transfused blood and hence increase the interval between transfusions by selecting out younger

red cells from blood donations have been developed,¹⁸¹ but in clinical practice these "neocytes" have been shown to prolong transfusion interval by only 13–16%.^{184,185} Neocytes are about three times more expensive per unit and they increase donor exposure considerably. Leukocyte-depleted blood should be transfused to reduce the incidence of non-febrile transfusion reactions and to prevent the production of HLA antibodies, which is particularly important in patients who may at a later date be considered for bone marrow transplantation.

Logistic considerations are particularly important in pediatric patients. Children tolerate regular transfusion regimens better if they are treated in familiar surroundings by medical and nursing staff well known to them and who are skilled in the insertion of intravenous cannulae and the management of blood transfusions. Much of the pain associated with cannula insertion can be avoided by the use of topical anesthetic cream. Interference with schooling can be minimized with appropriate timing of outpatient appointments and by planning hospital visits well in advance. Schoolwork can be performed during hospitalization for transfusions.

The timing of the introduction of deferoxamine and the dose used is important. The side-effects of chelation therapy are most often seen when high doses are given before iron stores have significantly increased. A practical approach is to introduce deferoxamine when the serum ferritin is confirmed to be > 1000 µg/L. The serum ferritin should be maintained between 1000 and 2000 µg/L. The ratio of daily deferoxamine dose to serum ferritin should be assessed three to four times a year and should not exceed 0.025.

Prior to first transfusion, the patient's own red cell antigens should be identified, including full Rhesus genotype and Kell, Ss, Kidd, and Duffy types. It is not possible to transfuse fully matched red cells but units with the appropriate Rhesus and Kell type should be selected for routine use. If at a later date red cell antibodies develop, prior knowledge of the patient's own red cell antigens makes their identification much easier. Antibodies to these blood groups are particularly likely to complicate regular red cell transfusions in patients with sickle cell disease or β-thalassemia.¹⁸⁶

Patients receiving regular blood transfusions need to be assessed at intervals to ensure that the aims of transfusion are being met and that the side-effects of iron overload or deferoxamine toxicity have not developed.

Hereditary hemochromatosis

The pediatrician is mainly involved with the screening of children for the possible inheritance of hemochromatosis rather than in treating established cases. However, hereditary hemochromatosis can in rare instances present in childhood, even in those as young as 2 years old.^{157,187} Males and females are equally affected. The illness has a different clinical pattern in childhood from that seen in adults; the cardiac

and gonadal consequences of iron overload predominate rather than the hepatic and pancreatic effects seen in adults.

Screening is best carried out using a combination of serum ferritin and TF saturation. If either or both of these are elevated, a confirmatory liver biopsy should be performed. Children presenting with idiopathic cardiomyopathy, hypogonadism, amenorrhea, diabetes mellitus, or arthritis should be tested to exclude hereditary hemochromatosis. Screening may need to be repeated at intervals in children at risk, as initial results may be normal in early childhood because the rate of iron overload occurs so slowly in most cases. Most often screening will be initiated following the diagnosis of hemochromatosis in an older relative. The gene for hereditary hemochromatosis has been mapped to the HLA class I region on chromosome 6,¹⁸⁸ and homozygotes and heterozygotes can be confidently diagnosed from HLA class I typing. Recently, a candidate gene, *HFE* (or HLA-H), has been identified and two FIFE mutations described.^{189,190}

The treatment of iron overload in hereditary hemochromatosis is similar to that described above for the iron-loading anemias. The introduction of phlebotomy should not be delayed once diagnosis has been made. In cases where significant organ damage has occurred, iron chelation therapy may be required as well. When treatment is instituted at an early stage before significant organ damage has taken place, patients should have a normal life expectancy.¹⁵⁵

Megaloblastic anemia and disorders of cobalamin and folate metabolism

Eric J. Werner

Megaloblastic anemia in childhood is most often due to either deficiency of vitamin B₁₂ (cobalamin) or folate or to defects in their metabolism. It is the goal of this chapter to briefly discuss the metabolic pathways in which these vitamins play critical roles and the known defects in their absorption, transportation and metabolism. In addition, some defects in cobalamin metabolism that are not associated with megaloblastic anemia are also described here. For more complete discussion of cobalamin and folate metabolism, the reader is referred to recent reviews of various aspects of cobalamin and folate.^{1,2} In this chapter, the terms “cobalamin” and “vitamin B₁₂” are used interchangeably.

Cobalamin (vitamin B₁₂)

The cobalamins share the same structure: a planar corrin ring with a central cobalt atom, attached to a nucleotide structure, 5,6-dimethyl benziminazole, attached to ribose 3-phosphate (Fig. 6.1). The two main natural compounds have a methyl (CH₃) or a 5-deoxyadenosyl group attached to the cobalt atom. Cyanocobalamin was the form in which the vitamin was first isolated and this compound has been radioactively labeled with ⁵⁷Co or ⁵⁸Co for diagnostic uses. Hydroxocobalamin, which has the cobalt atom in the oxidized stable Co(III) state, is also used in therapy.

In nature, cobalamin is synthesized by microorganisms and is only present in foods of animal origin.³ The steps of cobalamin absorption in the gastrointestinal tract are illustrated in Fig. 6.2. Cobalamin is released by enzymatic digestion from protein complexes in food in the acid pH of the stomach, where it binds to R binder present in saliva and gastric juice. This binder is closely related to transcobalamin (TC) I present in plasma, and is similar to a binder in milk and other fluids. After release from R binder in the duodenum by pancreatic proteases, cobalamin binds to intrinsic factor (IF), a 45-kDa glycoprotein synthesized by gastric parietal cells. Cobalamin in bile is also attached to R binder and complexes with IF in the duodenum.⁴ The IF-cobalamin complex

Fig. 6.1 Structure of cobalamin. A cobalt atom is at the center of a planar corrin ring. This is attached to a nucleotide, 5,6-dimethyl benziminazole ribose 3-phosphate. Attached to the cobalt atom at “X” may be a methyldeoxyadenosyl-, hydroxo- or cyano-moiety.

attaches to its receptor cubulin on the ileal brush border. The absorption of cobalamin by ileal receptors is limited to 1.5–2.5 µg from a single meal, although larger amounts have been documented.⁵ A small fraction (<1%) of a large oral dose can be absorbed passively through the buccal, gastric and small intestinal mucosa.

Fig. 6.2 Steps in cobalamin (Cbl) absorption.

(1) Food-bound cobalamin is released from protein in stomach. (2) Cobalamin binds to R binder (haptocorrin) in the stomach. (3) Cobalamin is released from R binder in the proximal small intestine and binds to intrinsic factor (IF) produced by gastric parietal cells. (4) The IF–cobalamin complex is transported intracellularly through the cubilin receptor in the ileum. (5) Cobalamin is released into the plasma bound to transcobalamin II (TCII).

Within the enterocyte, the IF–cobalamin complex is digested, probably within lysosomes, and the cobalamin appears in portal blood attached to TCII, a 38-kDa polypeptide. The cobalamin–TCII complex has a rapid metabolic turnover with a half-life of about 6 min.³

In the plasma, cobalamin can bind to either TCI or TCII. TCI-bound cobalamin has a much slower turnover. The function of TCI and its bound cobalamin is unclear. Because 70–90% of cobalamin is bound to TCI, deficiency of TCII may be present with normal serum cobalamin levels.⁶ The cobalamin bound to TCII is transported into various tissues where it is available for its metabolic function.

Fig. 6.3 Structure of folic acid. Natural folates may contain a single carbon unit, i.e., methyl (CH_3 –), methylene (CH_2 –), methenyl ($\text{CH}=\text{}$), formyl (CHO –), formimino (CHNO –), attached at the N_5 or N_{10} position. A chain of glutamic acid residues attached by peptide bond linkage are reduced to dihydro or tetrahydro forms at positions 7, 8 or 5, 6, 7, 8 in the pteridine portion respectively.

Folate

Folic acid (Fig. 6.3) is the parent compound of natural folates with the same vitamin activity, which are:

- reduced to tetrahydrofolate (THF) forms at positions 5, 6, 7 and 8;
- have single carbon units: methyl (CH_3 –), formyl (CHO –), methylene (CH_2 –), methenyl ($\text{CH}=\text{}$) or formimino (CHNO –) attached to nitrogens N_5 , N_{10} or both;
- have a chain of four to six glutamate moieties attached by γ -peptide bonds (polyglutamates). These are the active folate coenzymes whereas the monoglutamates are transport forms.

Folates are present in most foods, with especially high amounts in liver, leafy vegetables, fruits and yeast.⁷ Cows' milk contains about 50–120 $\mu\text{g/L}$ and human milk about 85 $\mu\text{g/L}$.⁸

Beginning in 1998, the Food and Drug Administration (FDA) approved fortifying cereal-grain products with levels of folic acid at 140 μg per 100 g of cereal.⁹ Cooking, especially in large volumes of water for prolonged periods, destroys folates, especially if vitamin C and other reducing agents that protect folates are first destroyed.¹⁰ The first phase in the absorption of natural folates involves digestion of polyglutamates to monoglutamates. Absorption occurs in the small intestine via a saturable carrier process for relatively low intestinal concentrations of folate and by diffusion for high concentrations of folate or folic acid.⁷ Folate is transported across cell membranes by one of at least two systems. Human reduced folate carrier-1, the gene for which has been localized to chromosome 21q22.3,¹¹ functions as a high-capacity low-

Reproduced with permission from Ref. 12.

affinity system.¹² In the second known system, folates bind to folate-binding proteins or folate receptors on the cell membrane and are internalized by a process called potocytosis.¹³ Folate receptors are coded for by genes on chromosome 11q13.3–13.5.¹² Folic acid (pteroylglutamic acid) can be absorbed largely unchanged, especially when given in large, pharmacologic doses. It is converted to natural folates in the liver quite rapidly.¹⁴ Bile contains about 100 µg/day¹⁵ and interruption of the enterohepatic circulation leads to a fall in serum folate within 6 hours.¹⁶ Total body folate stores in adults have been estimated to be 5–10 mg,¹⁵ with some estimates as high as 12–28 mg,⁸ which should be sufficient for about 1–4 months, especially if the enterohepatic circulation is intact.⁸ Absence of dietary intake may lead to a fall in serum folate within 2–3 weeks.¹⁵

Folate in plasma is mostly either free or loosely and non-specifically bound to proteins such as albumin. Specific folate-binding proteins occur in small amounts in plasma. Their exact function is unclear.¹⁵

Cobalamin and folate metabolism

Cobalamin is known to have a role in two reactions in humans:

1 With a methyl group attached to the cobalt atom (methylcobalamin or MeCbl) it is a required cofactor for the

enzyme methionine synthase in the conversion of homocysteine to methionine. This reaction requires 5-methyl-THF as a cofactor.

2 With 5'-deoxyadenosine attached to the cobalt atom (5'-deoxyadenosylcobalamin or AdoCbl) in the conversion of methylmalonyl-CoA to succinyl-CoA by the enzyme methylmalonyl-CoA mutase.

Folate takes part in intracellular biochemical reactions in its polyglutamate forms. As shown in Fig. 6.4, these coenzymes are involved in three amino acid interconversions: homocysteine to methionine, serine to glycine and formiminoglutamic acid to glutamic acid; and in three reactions in DNA synthesis: formylation of the purines 5-phosphoribosylglycinamide (GAR) and 5-phosphoribosyl-5-aminoimidazole carboxamide (AICAR) and methylation of the pyrimidine deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP, thymidylate). This last reaction is rate limiting for DNA synthesis. Thymidylate synthesis also causes oxidation of the folate coenzyme from the THF to dihydrofolate (DHF) state. The enzyme DHF reductase, inhibited by methotrexate for example, is required to return folate to the active THF state. Deficiency of folate reduces DNA replication by inhibiting thymidylate synthesis. The mechanism by which deficiency of cobalamin reduces DNA synthesis and causes megaloblastic anemia is also probably a result of reduced thymidylate synthesis. Plasma folate

(5-methyl-THF) entering cells is first “demethylated” to THF through the homocysteine–methionine reaction. Cobalamin deficiency reduces this reaction and so decreases cell THF concentration. Folate polyglutamate synthase, the intracellular enzyme needed to synthesize folate polyglutamates, requires THF (or formyl-THF) as substrate but cannot use methyl-THF as substrate.¹² Thus, cobalamin deficiency results in reduction in synthesis of all intracellular folate (polyglutamate) coenzymes. Total cell folate is reduced, plasma folate (methyl-THF) rises, and the intracellular folate reactions in DNA synthesis and amino acid conversion are impaired.

Inborn errors of vitamin B₁₂ transport and metabolism

Transport disorders

Intrinsic factor deficiency

This inherited form of pernicious anemia results from an absence of effective IF. Evidence of vitamin B₁₂ deficiency usually appears in early childhood after the first year of life, but may not appear until adolescence or adulthood. Patients typically show megaloblastic anemia, developmental delay and myelopathy.^{17–20} They have normal gastric acid secretion and gastric cytology. In some cases, immunologically active but nonfunctional IF is produced, whereas in others none is found. An IF that is labile to destruction by acid and pepsin and with a low affinity for vitamin B₁₂ has also been reported.²¹ Absorption of cobalamin is abnormal in children with IF deficiency, but is normalized when the vitamin is mixed with a source of normal IF. Inheritance is autosomal recessive and the gene for human IF has been localized to chromosome 11q13. Recently, a 4-bp deletion in the IF gene was described in a child with apparent congenital IF deficiency.²²

Imerslund–Gräsbeck syndrome (defective vitamin B₁₂ transport by enterocytes)

Imerslund–Gräsbeck syndrome causes clinical manifestations of vitamin B₁₂ deficiency in childhood. Patients usually present within the first 2 years, although later presentation may occur.^{23,24} Findings include pallor, weakness, anorexia, failure to thrive, recurrent infections and gastrointestinal symptoms.²⁰ Over 250 cases have been described and reports of patients predominate from Norway, Finland and the Middle East.²⁴ Patients with Imerslund–Gräsbeck syndrome have normal IF, no evidence of antibodies to IF, and normal intestinal morphology. They have a selective defect in vitamin B₁₂ absorption that is not corrected by treatment with IF. Proteinuria of the tubular type is a common feature and systemic vitamin B₁₂ corrects the anemia but not the proteinuria.²⁰

Defects in two proteins have recently been described that

account for Imerslund–Gräsbeck syndrome. Linkage studies from Finland documented a defect in the cubulin gene on chromosome 10. Cubulin appears to function as a receptor for IF on the ileal mucosa. Norwegian patients were subsequently found to have a defect in the AMN (amnionless) gene.²⁵ Recently, Fyfe *et al.*²⁶ have presented evidence that AMN complexes with cubulin and plays a critical role in its ability to bind and transport cobalamin. Deficiency or dysfunction of either protein appears to prevent absorption of cobalamin.

Transcobalamin (haptocorrin, R binder) deficiency

A deficiency or complete absence of TCI has been found in the plasma, saliva and leukocytes of very few individuals, but it is not clear if this deficiency is the cause of disease in any of these patients.^{27–33} Zittoun *et al.*³² described a boy with combined deficiency of R binder (TCI) and IF who had severe megaloblastic anemia and neurologic dysfunction. His father, who also had R-binder deficiency, was asymptomatic. TCI carries the majority of cobalamin in the plasma. However this percentage varies by location and with certain disease states.³⁴ Patients with severe deficiency of TCI may have a benign course.²⁹ Cobalamin levels are low, but TCII–vitamin B₁₂ (holotranscobalamin II) levels are normal, and the affected individuals may not be clinically cobalamin deficient. Carmel³³ found that of 567 samples referred for low cobalamin levels, three had undetectable TCI. Only one patient was available for study and she did not have abnormal neurologic findings, megaloblastic anemia or elevated levels of methylmalonic acid. Typically, individuals with TCI deficiency will have normal values for homocysteine and methylmalonic acid, will not show megaloblastic hematologic features and will have a normal Schilling test. Their plasma cobalamin levels should not respond to cobalamin supplementation. However, several patients with TCI deficiency have had neurologic sequelae, some of whom carried a diagnosis of multiple sclerosis.^{6,29} The physiologic function of TCI is not known; roles as a scavenger of cobalamin analogs that may be toxic³⁵ or protection of methylcobalamin from photolytic degradation have been proposed.³⁶

Transcobalamin II deficiency

TCII deficiency is a rare autosomal recessive disorder.^{20,37} Because TCI binds larger amounts of cobalamin in blood than TCII, serum cobalamin levels are often normal in TCII-deficient patients, but subnormal values have been reported.^{34,38} Even though TCII in cord blood is of fetal origin,³⁹ infants with undetectable TCII in their plasma are usually born healthy but then demonstrate signs of cobalamin deficiency over the first several days of life. Usually, patients develop severe megaloblastic anemia in the first few months of life, but others present with pancytopenia or even

isolated erythroid hypoplasia.⁴⁰ The presence of immature white cell precursors in an otherwise hypocellular marrow can result in the misdiagnosis of leukemia. Other symptoms include failure to thrive, weakness and diarrhea. Neurologic disease typically appears later, especially in untreated or undertreated patients.^{41–44} The neurologic manifestations are more associated with diagnosis outside the neonatal period.⁴⁵ Severe immunologic deficiency with defective cellular and humoral immunity has been seen, as has defective granulocyte function. Long-term follow-up has documented persistence of neurologic deficits despite adequate therapy, although in some patients the neurologic damage may have occurred prior to diagnosis.⁴⁶ Laboratory findings should include macrocytic anemia, hyperhomocysteinemia and elevated levels of methylmalonic acid.⁴⁷

The defect in TCII can be absent protein,^{42,48} an inability to bind to cobalamin⁴⁹ or an inability to mediate cobalamin uptake into cells.⁵⁰ An abnormal Schilling test is usually found in TCII deficiency. This suggests that the TCII molecule may play a role in the IF-mediated transport of cobalamin across the ileal cell.

The TCII gene is located on chromosome 22.^{51,52} The molecular basis of some of the variants has been defined. The first mutant alleles in TCII deficiency have included deletions⁵³ and nonsense mutations.⁵⁴ TCII is synthesized by amniocytes and prenatal diagnosis is possible even in the absence of known mutations in a family at risk.^{55,56}

The mainstay of treatment for TCII deficiency has been high-dose cobalamin. Both oral treatment and systemic treatment have been used, although at least one patient redeveloped pancytopenia when transitioned to oral treatment,⁴⁶ and caution has been raised about using oral therapy.⁵⁷ Serum cobalamin levels must be kept very high (1000–10 000 pg/mL) in order to treat TCII-deficient patients successfully and this has been achieved with twice-weekly doses of hydroxocobalamin orally (500–1000 µg) or of systemic hydroxocobalamin (1000 µg) weekly or more often.^{20,44,46}

Early and regular high-dose cobalamin therapy may lead to a favorable outcome.⁵⁸ Folate in the form of folic acid or folinic acid in milligram doses has been successful in reversing the hematologic findings in most patients. However, folate should not be given alone to patients with TCII deficiency as hematologic relapse and neurologic damage can occur when folate supplementation is given without cobalamin.^{42,43}

Disorders of utilization

Methylmalonic acidurias

Disorders causing methylmalonic aciduria (MMA) are characterized by severe metabolic acidosis and the accumulation of large amounts of methylmalonic acid in blood, urine and cerebrospinal fluid (CSF). Patients with MMA have a defect in the nuclear-encoded mitochondrial matrix protein L-methylmalonyl-CoA mutase (mutase), which requires AdoCbl as a cofactor, and catalyzes the conversion of L-methylmalonyl-CoA to succinyl-CoA. The failure of this reaction to occur may be a result of a defect in the mutase enzyme itself or a defect in AdoCbl synthesis. The intracellular pathways and the potential defects are shown in Fig. 6.5. Defects that cause isolated abnormalities in mutase or AdoCbl will cause only MMA without homocysteinemia, while those that lead to abnormalities of both AdoCbl and MeCbl cause both MMA and homocysteinemia. Classification of the defects of cobalamin metabolism has been made largely on the basis of somatic cell complementation studies in cultured fibroblasts. The incidence of all forms of MMA determined by neonatal screening in Massachusetts is about 1 in 48 000.⁵⁹ Of 12 infants diagnosed in that state with MMA, three had mutase deficiency (two mild), six had defects in cobalamin synthesis (not further defined) and three were undefined. However, not all infants with elevated methylmalonic acid on newborn screen have disease, especially with mild elevations (<1400 µmol/mmol creatinine).⁶⁰

Fig. 6.5 Intracellular cobalamin metabolism and defects. Cbl^I, Cbl^{II} and Cbl^{III} refer to the oxidation state of the central cobalt atom of cobalamin. A–G refer to the sites of blocks that have been identified by complementation analysis. The site of block for Cbl^{II}H has not been identified. AdoCbl, adenosylcobalamin; MeCbl, methylcobalamin; TC, transcobalamin; OH-Cbl, hydroxocobalamin. The mitochondrial, lysosomal and cytoplasmic compartments are indicated. Modified from Ref. 198.

Deficiency of methylmalonyl-CoA mutase (*mut*⁰, *mut*⁻)

Mutations in the mutase apoenzyme result in MMA that is not responsive to cobalamin therapy.^{20,37} Mature mutase purified from human liver is a dimer with a molecular weight of 150 000–160 000.⁶¹ There are at least two types of mutase deficiency as defined in cultured fibroblasts from patients with MMA. Cell lines having no detectable mutase activity are designated *mut*⁰; those with residual activity are called *mut*⁻. Some cell lines synthesize no detectable protein, whereas others synthesize unstable proteins, and at least one has a mutation that interferes with transfer of the mutase to the mitochondria.^{62,63} Variable levels of mRNA have been demonstrated in different *mut*⁰ lines. Intragenic (interallelic) complementation has been seen between some *mut* lines.^{64,65}

Patients with severe mutase deficiency rapidly become symptomatic with protein feeding. In a retrospective questionnaire study of patients with MMA, Matsui *et al.*⁶⁶ found lethargy (88%), recurrent vomiting (89%), failure to thrive (67%), dehydration (71%) and respiratory distress (50%) in patients with either *mut*⁰ or *mut*⁻ defects. Of note, while the numbers were quite small (13 *mut*⁰ and 5 *mut*⁻), and not all patients were evaluated for each item, there were differences between these two disorders in the incidence of developmental delay (69% vs. 25%) and hepatomegaly (57% vs 0%). For normal children, urinary excretion of methylmalonic acid is < 0.04 mmol/24 hours and plasma concentrations are virtually undetectable. In contrast, in children with MMA, urinary excretion can exceed 2.1–49 mmol/24 hours and plasma concentrations range from 0.2 to 2.9 mmol/L (2.6–34 mg/dL).⁶² Patients with MMA often have ketones and glycine in both blood and urine, hypoglycemia and hyperammonemia.^{20,66} Matsui found leukopenia in about 60% and thrombocytopenia in 40% of patients with mutase deficiency. About half of the infants with *mut*⁰ had anemia and methylmalonic acid has been shown to inhibit bone marrow stem cells in a concentration-dependent manner.⁶⁷ Interestingly, follow-up of children identified by newborn screening^{59,60,68} has identified a number of individuals who excrete methylmalonic acid, have mutase deficiency by complementation analysis, and yet are clinically well and have never developed acidosis. Limited intellectual ability has been noted in several patients with *mut*⁻ disease; however, Varvogli *et al.*⁶⁹ described a 12 year old with the *mut*⁻ defect who scored in the 99th percentile on the National Achievement Test and had a full-scale IQ of 129 on the Wechsler Intelligence Scale.

The cDNA for human mutase has been cloned and the gene localizes to chromosome 6p12–p21.2.⁷⁰ Over 50 mutations have been identified in human mutase,⁷⁰ including a large number near the carboxyl terminus which appear to alter AdoCbl binding to the enzyme.^{65,71} A premature stop codon in the mitochondrial leader sequence has been described.⁷² A common mutation (G717V) was found in five black patients who had a similar phenotype; of these, four were African-American and one was from Ghana.^{73,74} In Japan, 6 of

16 patients studied shared one mutation (G425T),⁷⁵ while another mutation (N219Y) was identified in five unrelated Caucasian families from Turkey and France.⁷⁶

Treatment consists of handling immediate issues such as hypoglycemia, acidosis and hyperammonemia and protein restriction using a formula deficient in valine, isoleucine, methionine and threonine, with the goal of limiting the amino acids that use the propionate pathway. While patients in the *mut* complementation class are not clinically responsive to vitamin B₁₂, a therapeutic trial of daily intramuscular hydroxocobalamin should be administered as soon as a diagnosis of MMA is considered until other cobalamin-responsive disorders have been excluded. Therapy with carnitine has been advocated.^{77,78} Metronidazole may improve the clinical status of patients by reducing enteric propionate production by anaerobic bacteria.^{79,80} A 7 year old with *mut*⁻ MMA and acute metabolic crisis and multiorgan dysfunction was found to have very low glutathione levels. Clinical and laboratory improvement were noted with ascorbate 2 g (120 mg/kg) daily.⁸¹ Even with therapy, prognosis is guarded at best, with reports of brain infarctions and renal dysfunction as late complications.⁸² Renal dysfunction was noted in two-thirds of patients with cobalamin-unresponsive MMA. In these patients the reduction of glomerular filtration rate correlated with age and the severity of the disease.⁸³

Adenosylcobalamin deficiency (CblA, CblB, CblH)

Vitamin B₁₂-responsive MMA is caused by an intracellular deficiency in AdoCbl in both CblA and CblB. These two disorders are distinguished by complementation analysis. Recently, a gene called *MMAA* (for methylmalonic acidemia linked to the CblA complementation group) has been identified that is responsible for the CblA complementation group.⁸⁴ *MMAA* maps to chromosome 4q31.21. At least 22 mutations in *MMAA* have been identified.⁸⁵ The function of the protein product is not well understood, but appears to function within the mitochondria. In a single patient, fibroblasts behaved like those from CblA patients, but complementation was seen with CblA cells.⁸⁶ The defect in CblB lies in the cob(I)alamin adenosyltransferase enzyme, which participates in the final step in the synthesis of AdoCbl.⁸⁷ A gene for this protein (*MMAB*) has been mapped to chromosome 12q24 and several mutations have been identified from CblB patient cell lines.⁸⁸ Recently, a patient with clinical and biochemical features of CblA was found to have a new defect (CblH) by complementation analysis. The causative protein and/or gene product have not been identified.⁸⁹

Most patients with CblA and CblB become sick early in the first year of life with symptoms that are similar to those seen in mutase deficiency.⁶⁶ The principal difference between defects in *MMAA* and *MMAB* as opposed to those in mutase is the clinical response to cobalamin treatment: 90% of CblA patients respond to vitamin B₁₂, with nearly 70% still well at up to 14 years of age. However, only 40% of patients with

CblB respond to therapy and only 30% show long-term survival. Therapy has been with systemic hydroxocobalamin or cyanocobalamin. Initial therapy also includes protein restriction avoiding proteins that utilize the propionate pathway.²⁰ Therapy with AdoCbl has not been successful, perhaps because of the inability of administered drug to get into the mitochondria.^{90,91}

Both CblA and CblB are presumed to be inherited in an autosomal recessive manner. Roughly equal numbers of patients of both sexes have been reported, and obligate heterozygotes of CblB patients show decreased adenosyltransferase activity. Although prenatal therapy with vitamin B₁₂ has had a good therapeutic result in a CblA patient, it is not certain whether therapy from birth would be equally effective.^{92,93} In one patient, dosing of vitamin B₁₂ to the mother was adjusted based on maternal methylmalonic acid levels.⁹⁴

Combined deficiencies of adenosylcobalamin and methylcobalamin (CblC, CblD, CblF)

These three disorders result in failure of the cell to synthesize both MeCbl and AdoCbl.⁶² Because these patients have a functional deficiency in both methionine synthase and mutase, homocystinuria, hypomethioninemia and MMA can develop. The metabolic defects occur after both endocytosis of TCII-vitamin B₁₂ and hydrolysis of the TCII-vitamin B₁₂ complex in the lysosome. In CblF disease, the defect appears to block the exit of vitamin B₁₂ from the lysosome. In CblC and CblD disease, the defect is presumed to be in a cytosolic cob(III)alamin reductase or reductases.⁹⁵ Partial deficiencies of cyanocobalamin β -ligand transferase and microsomal cob(III)alamin reductase in CblC and CblD fibroblasts have been described.⁹⁶ When incubated with labeled cyanocobalamin, fibroblasts from CblC and CblD accumulate very little intracellular vitamin B₁₂ and virtually no AdoCbl or MeCbl. In contrast, CblF fibroblasts accumulate excess vitamin B₁₂ but it is all unmetabolized, nonprotein bound, and localized to lysosomes.^{12,97} The definitive gene and protein abnormalities have not been identified.

Over 100 patients have been reported with CblC disease.^{20,62} Most present in the first year of life, with a median age of onset of 1 month. Clinical features include poor feeding, failure to thrive, microcephaly, developmental delay and lethargy.^{62,98,99} Most, but not all, have macrocytic megaloblastic anemia, and some have hypersegmented neutrophils and thrombocytopenia. Plasma homocysteine levels and urinary methylmalonic acid levels are increased while plasma methionine is decreased. There appears to be an early- and late-onset form of the disorder. Newborns may be difficult to recognize due to the nonspecific nature of their presenting symptoms and potential lack of laboratory features of metabolic disease.¹⁰⁰ Neurologic disorders such as poor cognitive function, dementia, delirium, myelopathy and tremor predominate in late-onset disease and hemato-

logic abnormalities may be absent.^{62,101} An unusual pigmentary retinopathy with perimacular degeneration has been described,^{98,102} as have cor pulmonale, hepatic failure and hemolytic-uremic syndrome.^{62,103} It is likely that inheritance of CblC is autosomal recessive. Prenatal diagnosis has been successfully accomplished in CblC disease, using amniocytes, and the diagnosis has been ruled out using chorionic villus biopsy material and cells.^{104,105}

Five patients with CblD have been reported. A pair of siblings presented at age 14 years and 1 year. The older child had neuromuscular and psychiatric disorders as well as mental retardation. He developed recurrent thrombosis in his late teens. The younger was clinically normal initially, but was developing academic problems by 13 years of age.¹⁰⁶ They did not have megaloblastic changes, but later abnormalities of the deoxyuridine suppression test that corrected with hydroxocobalamin were documented. This suggests the presence of a cobalamin-related defect in marrow DNA synthesis.¹⁰⁷ Recently, three additional patients were diagnosed with CblD by complementation group analysis. Two had significant neurologic problems, macrocytic red blood cells, elevated plasma homocysteine and low methionine levels. Neither had elevated urinary methylmalonic acid. The third patient was a premature infant who had several perinatal problems and a markedly elevated urinary methylmalonic acid but normal homocysteine. Early treatment with cobalamin was instituted. Because of the differing clinical picture associated with this complementation group result, the authors propose that mutations of different epitopes of the involved protein may lead to the disparate clinical presentations.¹⁰⁸

Only five patients with CblF have been described so far. One died suddenly at 5 months of age despite a good clinical and biochemical response to cobalamin. Other findings in some patients have been small-for-gestational-age birthweight, growth retardation, stomatitis, dermatitis, hepatomegaly, hypoglycemia and arthritis.^{20,109–111} Laboratory features may include megaloblastic anemia, thrombocytopenia, neutropenia, elevated homocysteine and decreased cobalamin absorption.⁶² The defect is probably inherited as an autosomal recessive.²⁰

Treatment of these disorders can be difficult, particularly in cases with early onset. Many patients with onset in the first month of life die.^{62,99} Suggested therapy includes high-dose systemic hydroxocobalamin with a recommended dose of up to 1 mg daily,^{20,62} although the need for daily therapy is unproven.¹¹² Two patients were recently documented to respond much more favorably to hydroxocobalamin than to cyanocobalamin.¹¹³ Bartholomew *et al.*¹¹² found that systemic hydroxocobalamin was more effective than oral therapy and that betaine appeared to be helpful in combination with hydroxocobalamin in two patients. Neither folic acid nor carnitine had any effect in these patients. The result of therapy with daily oral betaine and twice-weekly injections of

hydroxocobalamin was reduced methylmalonic acid, normal serum methionine and homocysteine concentration, and resolution of lethargy, irritability and failure to thrive. However, complete reversal of the neurologic and retinal findings did not occur. Early diagnosis and treatment hopefully will improve outcome, but thus far surviving patients usually have moderate-to-severe developmental delay.²⁰ The patients with CblF disease responded to systemic therapy with hydroxocobalamin; the first patient responded to oral cobalamin.^{62,109,111} The disease has been excluded in twins and in a single pregnancy by studies on amniocytes.⁶²

Methylcobalamin deficiency (CblE, CblG)

Two groups of patients have been identified through complementation analysis with defects in methionine synthase activity but normal mutase activity, designated CblE and CblG. CblG is due to defects in methionine synthase while CblE is due to defects in the methionine synthase reductase enzyme that reduces cobalamin to its cob(I)alamin form necessary for function.¹² Clinically, patients with CblE and CblG present in the first few months of life with vomiting, poor feeding and lethargy.¹² Common findings include developmental delay, cerebral atrophy, feeding difficulty, seizures and megaloblastic anemia. Long-term neurologic damage is noted, but may be improved with early treatment. Although patients usually come to medical attention in the first 2 years of life, in one case the patient was diagnosed at age 21 years with findings resembling multiple sclerosis.¹¹⁴ Other findings include electroencephalographic abnormalities, nystagmus, hypotonia, hypertonia, seizures, blindness and ataxia.¹¹⁵ MMA is usually not present, but was transiently noted in one patient.¹¹⁶ Both disorders are inherited in an autosomal recessive fashion. Visual abnormalities may be due to microvascular retinal damage.¹¹⁷

Following incubation in labeled cyanocobalamin, fibroblasts from both CblE and CblG patients show decreased intracellular levels of MeCbl in the presence of normal levels of AdoCbl.¹¹⁸ The finding that in CblE extracts a relative deficiency in methionine synthetase activity can be seen when the assay is performed under suboptimal reducing conditions suggested that the defect was in a reducing system associated with the enzyme.^{119,120} This has been confirmed with the identification of the methionine synthase reductase enzyme and its gene *MTRR*. This gene is localized to chromosome 5p15.2–15.3 and codes for a protein with 38% identity with human cytochrome P450 reductase.¹²¹ Multiple defects in *MTRR* have been described in patients with CblE,¹²² including one that appears to code for a less severe variant of the disorder.¹²³ CblG is due to defects in the methionine synthase enzyme. The gene for methionine synthase has been cloned and localized to chromosome 1q43.¹²⁴ Gene mutations that cause CblG have been identified.^{124–126} Both CblE and CblG are inherited in an autosomal recessive pattern.

Systemic hydroxocobalamin, 1 mg administered at first daily and then decreased to once to three times weekly, has been recommended¹² and usually results in correction of the anemia and metabolic abnormalities. The neurologic changes are more reticent to treatment, but may improve gradually. A mother carrying an affected fetus was treated with twice-weekly hydroxocobalamin from the second trimester.¹²⁷ Long-term follow-up showed the child to be well at 14 years of age with a speech impediment.¹²

Inborn errors of folate metabolism and transport

Metabolic disorders

Methylenetetrahydrofolate reductase deficiency

Methylenetetrahydrofolate reductase (MTHFR) deficiency is the most common inborn error of folate metabolism and more than 40 cases are known.¹² The enzyme leads to the formation of 5-methyl-THF, a key component of the methionine synthase pathway for the conversion of homocysteine to methionine (see Fig. 6.4). Defects lead to neurologic manifestations similar to those of methionine synthase or cobalamin deficiency. Unlike cobalamin deficiency, megaloblastic anemia is rare in MTHFR deficiency.

The clinical manifestations of MTHFR deficiency are quite varied. Clinically asymptomatic but biochemically affected individuals have been reported.^{128,129} In general, clinical severity is related to the proportion of methyl-THF in cells. In a review of 68 patients with MTHFR deficiency, 19% had clinical onset in the neonatal period, 49% between 3 months and 10 years of age and the remainder after age 10.¹⁰² Neurologic abnormalities are the predominant finding, with developmental delay, hypotonia, lethargy, seizures and encephalopathy being frequently described.¹⁰² Psychosis has also been described. Breathing disorders and microcephaly are often present along with motor and gait abnormalities.¹⁰² The report of reversible psychiatric disturbances leads to speculation on the role of MTHFR deficiency in psychiatric disease.¹³⁰ Clinical manifestations of thrombotic disease, including stroke and retinal vein thrombosis, are also seen with MTHFR deficiency.^{12,102,131,132} Thrombosis has been a prominent finding at autopsy in some patients.²⁰

MTHFR-deficient patients have elevated urine homocysteine levels, although the amounts are less than seen in cystathionine synthase deficiency.¹² More than one determination of homocysteine excretion may be needed to eliminate the possibility of a false-negative value. Serum folate levels are generally but not always reduced while cobalamin levels are normal. Serum methionine levels are low or low-normal.

Kanwar *et al.*¹³³ described the autopsy findings in a patient

with MTHFR deficiency. The neurologic findings included perivascular demyelination and astrocytosis. Arterial vascular injury with intimal hyperplasia and extensive thrombosis was prominent. In the brain, the degree of demyelination was felt to be out of proportion to the vascular changes. Other post-mortem studies have also shown thrombosis and leukoencephalopathy.^{134,135} There have been reports of patients with classic findings of subacute combined degeneration of the spinal cord similar to those described for vitamin B₁₂ deficiency.^{135,136}

The diagnosis of severe MTHFR deficiency has been made by direct measurement of enzyme activity in liver, leukocytes, cultured fibroblasts and lymphocytes. The specific activity of MTHFR in cultured fibroblasts is dependent on the stage of the culture cycle, being several fold higher in confluent cells than in cells in logarithmic growth. Therefore, it is important to compare activities of unknown samples and control cell lines in confluent cells. There is a rough correlation between residual enzyme activity and clinical severity.¹³⁷ In cultured fibroblasts, the proportion of total folate that is methyl-THF and the extent of labeled formate incorporated into methionine provide better correlations with clinical severity.^{137,138} The gene for human MTHFR has been localized to chromosome 1p36.3. More than 30 mutations have been identified and there does not appear to be a predominant mutation in the families studied to date.¹³⁹ Prenatal diagnosis may be possible.^{140–142} The inheritance appears to be autosomal recessive.¹²

The mechanism by which MTHFR and indeed cobalamin deficiency cause neuropathy is not well known. It may be due to undermethylation of proteins in the CNS caused by methionine deficiency, as betaine : homocysteine transferase, an alternative pathway for methionine production, is absent in the brain.¹⁴³ Since MTHFR is present in the mammalian brain and only methyl-THF can cross the blood–brain barrier, MTHFR deficiency may result in functionally low levels of folate in the brain.²⁰

The prognosis is poor in severe MTHFR deficiency once there is evidence of neurologic involvement. Again, early recognition and treatment may improve the long-term neurologic outcome. Folic acid is given to maximize residual enzyme activity; and methyl-THF to replace the missing product of MTHFR.¹² Newborns should be given a trial of folic acid to assess responsiveness. Betaine appears to have improved the prognosis in patients both biochemically and developmentally.^{102,144–146} Psychiatric symptoms also improved with betaine.¹³⁰ Other suggested agents include methionine to correct the deficiency of this amino acid; pyridoxine, which as a cofactor for cystathionine synthase may lower homocysteine levels; vitamin B₁₂ because MeCbl is a cofactor for methionine synthetase; and carnitine, because of its requirement for adenosylmethionine.^{12,102}

More than one case has been described in several families,

both affected males and females have been born to unaffected parents, and consanguinity has been reported, all features consistent with autosomal recessive inheritance.

Methylenetetrahydrofolate reductase polymorphisms

Two common polymorphisms have been identified in the MTHFR gene. The C677T (Ala to Val) transition when present in the homozygous form yields a thermolabile variant of MTHFR that has decreased activity at 37°C.¹⁴⁷ The 677T allele occurs with a higher frequency in whites compared with African-Americans or Africans. The frequency of this allele ranges from 0.17–0.19 in Asia to 0.27–0.36 in Western Europe.¹⁴⁸ Homozygous 677TT has about 30% of the activity of the wild-type enzyme¹⁴⁷ and individuals with this variant have about 22% and 24% higher homocysteine levels compared to persons with the 677CT and 677CC genotypes respectively.¹⁴⁹ Of note, the effect of the 677TT genotype on homocysteine levels may be more significant for people with relatively low folate levels.^{149,150} Folate levels are reduced in children over 10 years of age with this genotype.¹⁵¹ A second polymorphism has been described at position 1298 (A1298C) substituting a glutamine for alanine at that position. This mutation does decrease MTHFR activity but its effect on homocysteine levels is unclear.¹⁵² These two mutations occur in linkage disequilibrium, with the combination of 677TT and 1298CC being extremely uncommon.¹⁴⁷

While some studies have shown that hyperhomocysteinemia is a risk factor for both coronary artery disease and venous thromboembolism,¹⁵² a recent metaanalysis revealed the correlation between MTHFR genotype and coronary artery disease to be weakly positive, with a 16% increase for those with the 677TT genotype.¹⁵³ Of interest, the increased risk was present in European but not North American populations, perhaps due to differences in folate status. While conflicting results have been obtained, it appears that no clear increased risk for venous thromboembolism can be assigned to the 677TT genotype.¹⁵⁴ In addition to risk of thrombotic disease, the 677TT genotype in the mother may increase the risk of neural tube defects in the newborn.

Several studies have documented a decreased rate of acute lymphoblastic leukemia in children and adults with the 677TT genotype.^{155–157} Some studies have also shown a protective effect for the 1298C allele as well.¹⁵⁸ The story is less clear for non-Hodgkin lymphoma. Matsuo *et al.*¹⁵⁹ documented a decreased odds ratio for either the 677T or the 1298C alleles in adults with non-Hodgkin lymphoma. However, Skibola *et al.*¹⁶⁰ found an increased proportion of patients with subtypes of non-Hodgkin lymphoma to have the 677TT genotype and Stanulla *et al.*¹⁶¹ found the representation of this genotype to be high in children with lymphoblastic lymphoma. Krajcinovic *et al.*¹⁵⁸ found that the protective effect of the 677TT and 1298CC alleles was only

present for Canadian children born before 1996, following which folate supplementation was recommended in Canada. Furthermore, one study documented decreased risk of childhood acute lymphoblastic leukemia if mothers received folate supplementation when pregnant.¹⁶² The mechanism for the decreased risk of leukemia has not been proven, but it has been theorized that decreased MTHFR activity leads to increased levels of 5,10-methylenetetrahydrofolate available for purine and pyrimidine synthesis.¹⁴⁷

Glutamate formiminotransferase deficiency

Histidine catabolism is associated with the transfer of a formimino group to THF, followed by the release of ammonia and the formation of 5,10-methylenetetrahydrofolate (see Fig. 6.4). The two steps in this reaction are carried out through a single bifunctional enzyme, formiminotransferase cyclodeaminase (FTCD) with two domains, glutamate formiminotransferase and formiminotetrahydrofolate cyclodeaminase.¹⁶³ Defects lead to build-up of formiminoglutamate (FIGLU). While rare, genetic defects in FTCD are the second most common genetic defect in folate metabolism, with more than 20 cases described.¹²

The clinical picture in patients with FTCD defects is quite inconsistent. Patients have been identified by elevation of FIGLU in the urine with or without histidine loading.¹² Some patients have had significant mental retardation, cortical atrophy, hypotonia, seizures and speech delay, while others do not appear to have significant neurologic problems.^{12,164,165} Hematologic abnormalities including hypersegmented neutrophils and macrocytosis have also been described.^{12,166} Decreased glutamate formiminotransferase activity in liver extracts (14–54% of control) and erythrocytes (35–37% of control) was seen in three patients,¹⁶⁵ although the ability to detect enzyme activity in erythrocytes is unclear.¹² Of note, three patients with malignancies were found to have increased urinary FIGLU and hydantoin propionic acid (HPA) excretion that persisted after treatment.¹² This suggests that congenital FTCD deficiency may predispose to malignancy. In addition to elevated urinary excretion of FIGLU, serum folate levels are normal to increased and vitamin B₁₂ levels are normal.^{165,167}

As both males and females have been described, autosomal recessive inheritance is the probable means of transmission. The gene for FTCD has been cloned and maps to chromosome 21q22.3.¹⁶⁸ Gene abnormalities have been identified in patients with FTCD deficiency.¹⁶⁹ The gene is predominantly expressed in the liver with weak expression in the kidney. Of interest, FTCD appears to be the target antigen in type 2 autoimmune hepatitis.^{170,171}

Treatment for this disorder is limited. Perry *et al.*¹⁷² described two siblings who had massive urinary FIGLU excretion, speech delay and normal folate levels but whose FIGLU excretion decreased significantly with folate 5 mg

every 8 hours for 3 days or folinic acid 6 mg i.m. every 8 hours. However, others have not shown a response to folate treatment.^{167,173} Methionine was not effective either clinically or biochemically in one patient.¹⁶⁷ As the relationship between clinical expression and FIGLU excretion is unclear, it is uncertain that reducing FIGLU excretion has clinical utility.

Transport disorders

Hereditary folate malabsorption

The process of folate absorption and transport is described above. Hereditary folate malabsorption (HFM) has also been called congenital malabsorption of folate; 18 patients have been described in the literature and the topic has been reviewed.¹⁷⁴ These children usually present in infancy with megaloblastic anemia, diarrhea, mouth ulcers, failure to thrive and usually progressive neurologic deterioration. Immunodeficiency is common and several infants had *Pneumocystis carinii* pneumonia either at diagnosis or shortly after treatment was initiated.^{174,175} The neurologic disorders include mental retardation/developmental delay, seizures, intracranial calcifications and peripheral neuropathy.¹⁷⁴ The hematologic picture consists of megaloblastic anemia appearing in the first few months of life. The serum and red blood cell folate levels are low. Of significance, the folate level in the CSF is low, and lower than the serum level in folate-supplemented patients with HFM.¹⁷⁴ Excretion of FIGLU and orotic acid may be found in patients with HFM. All patients have a severe abnormality in the absorption of oral folic acid or reduced folates.

The defect in HFM remains to be identified. Malatack *et al.*¹⁷⁵ suggested that for HFM to occur defects must be present in both the high-capacity, pH-dependent active transport mechanism for folate and the low-capacity, pH-independent facilitated diffusion mechanism. Hence they propose that either there is a common component of both mechanisms or that the defects in the active transport system are more common than previously recognized. Even when blood folate levels are raised sufficiently to correct anemia, levels in the CSF remain low and the CSF/plasma folate ratio is reversed (normal > 3 : 1).^{174–176}

The treatment of HFM requires maintaining adequate plasma and CSF folate levels. Folinic acid appears to be preferable to folic acid for obtaining adequate CSF levels, although the two may be used simultaneously.¹⁷⁶ Poncz and Cohen¹⁷⁷ reported that long-term folinic acid, initially 1.5 mg daily then decreased at age 6 years to five times weekly and then to three times weekly as a teenager, produced an excellent outcome in a single patient. Close monitoring of developmental functioning is important in addition to measurement of plasma and CSF folate concentrations. Many medications, such as anticonvulsants, antacids, histamine H₂ blockers and oral contraceptives, may further affect folate absorption and

transport. This may lead to changes in the adequacy of oral folic acid treatment for patients with HFM.

There is a preponderance of females with HFM,¹² and the first reported male had atypical features,¹⁷⁸ including lack of mental retardation and correction of CSF folate levels in conjunction with correction of serum folate levels. Presumably affected siblings who died were noted in several of the families.¹⁷⁴ Consanguinity has been reported in several families, and the father of one patient has intermediate levels of folate absorption. These findings make autosomal recessive inheritance probable but unproven.

Cellular uptake defects

Although patients have been described with well-characterized abnormalities of folate uptake into cells, it is not clear that any of these represent primary defects. Branda *et al.*¹⁷⁹ reported an individual with severe aplastic anemia in whom folate treatment led to a dramatic recovery. There was an extensive family history of pancytopenia and leukemia. Studies revealed decreased uptake of 5-¹⁴CH₃-THF in lymphocytes and bone marrow cells, but normal uptake, polyglutamate formation and apparent function in thymidylate synthetase in mature erythrocytes and intestinal cells. This appeared to represent an inherited defect in folate cellular uptake in certain cells. In another family, the proband and three daughters had dyserythropoiesis without anemia.¹⁸⁰ There was abnormal methyl-THF uptake in red blood cells and bone marrow cells but not in lymphocytes. There was no clear correlation in the family between clinical findings and the disorder of cellular uptake.

Cerebral folate deficiency

5-Methyl-THF is actively transported into the CNS through binding to folate receptor protein 1 (FR1) attached to choroidal epithelial cells.¹⁸¹ Wevers *et al.*¹⁸² described an 18-year-old man with cerebellar symptoms, distal spinal muscular atrophy, pyramidal tract dysfunction and perceptive hearing loss who had severely low CSF but normal plasma and red blood cell folate levels. They suspected a defect in a folate-binding protein in the CSF leading to an isolated defect in the choroid plexus transport of folate. Subsequently, Ramaekers and Blau¹⁸¹ reported 20 children who developed progressive neurologic findings beginning in infancy with deceleration of head growth, psychomotor retardation, cerebellar ataxia, spastic paraplegia, dyskinesia, visual disturbances and sensorineural hearing loss. Seven patients had seizures and seven had autistic features. CSF folate levels were low. The folate-binding affinity of FR1 was significantly reduced in four patients. Treatment with folic acid 0.5–1 mg/kg daily or higher in some patients led to clinical improvement, especially in patients treated before 6 years of age.

Other inherited disorders associated with megaloblastic anemia

Thiamine-responsive megaloblastic anemia

Thiamine-responsive megaloblastic anemia, also known as Rogers syndrome, is a rare autosomal recessive disorder characterized by megaloblastic anemia, thrombocytopenia, diabetes mellitus, and sensorineural deafness.¹⁸³ The disorder is caused by abnormalities in the thiamine transporter protein THTR-1, encoded by the *SLC19A2* gene mapped to chromosome 1q23.2–23.3.^{184,185} The THTR-1 protein has significant homology with the human reduced folate carrier protein.¹⁸⁵ Mutations in this gene have been reported in patients with thiamine-responsive megaloblastic anemia.^{186–188} Other reported manifestations include retinitis pigmentosa, hypothyroidism, cardiac rhythm and structural abnormalities, optic nerve atrophy, and retinal dystrophy.^{186,189,190} Villa *et al.*¹⁹¹ reported an 18-year-old girl with thiamine-responsive megaloblastic anemia who suffered a stroke. The pathogenesis of the megaloblastic anemia appears to be related to decreased ribose formation.¹⁹² Thiamine treatment improves the megaloblastic anemia and decreases insulin requirements.^{183,193}

Hereditary orotic aciduria

Hereditary orotic aciduria is an autosomal recessive disease due to a defect in the last two enzyme activities of the pyrimidine *de novo* synthetic pathway: orotate phosphoribosyltransferase and orotidine-5'-monophosphate decarboxylase.¹⁹⁴ These two enzyme activities reside in a single bifunctional polypeptide, UMP synthase. The UMP synthase gene is localized to chromosome 3q13 and is approximately 15 kb in length.¹⁹⁴

There have been 15 patients described with hereditary orotic aciduria and these patients have been recently reviewed.¹⁹⁴ Anemia is a consistent finding, with severe anisocytosis and macrocytosis. Hypochromia may be apparent. Leukopenia and neutropenia occur but thrombocytopenia has not been seen. Megaloblastic changes in the marrow are noted. Large amounts of orotic acid excreted in the urine may crystallize, causing urethral or ureteral obstruction. Orotic aciduria has also been noted in a patient with FTCD deficiency.¹⁹⁵ Malformations have been identified in several of these patients, including four individuals with congenital heart disease. Other abnormalities may include muscle weakness, strabismus, skeletal deformities and developmental delay, although these are not uniformly present. With treatment the prognosis is good, although the presence of malformations or immune deficiency may adversely affect prognosis. In addition, one patient had long-term neurologic degeneration.¹⁹⁴ The mainstay of treatment is uridine sup-

plementation usually at a dose of 100–200 mg/kg daily, but dosing needs to be individualized.¹⁹⁴

Acquired disorders of cobalamin metabolism (Table 6.1)

Nitrous oxide

It is well established that nitrous oxide (N₂O) is able to reversibly oxidize cobalamin from the cob(I) to cob(III) state. Because methionine synthase requires cobalamin in the fully reduced cob(I) state it is inactivated by nitrous oxide.¹⁹⁶ Myeloneuropathy has been reported in patients with vitamin B₁₂ deficiency exposed to nitrous oxide.¹⁹⁷ Chronic nitrous oxide exposure has also resulted in myeloneuropathy.¹⁹⁸ Felmet *et al.*¹⁹⁹ described an 8-month-old infant who developed hypotonia, tremor and athetoid movements in association with macrocytic anemia 6 days after exposure to nitrous oxide. Three days later the infant had severe pancytopenia and megaloblastic changes in the bone marrow. Methylmalonic acid and homocysteine levels were markedly elevated. McNeely *et al.*²⁰⁰ described an infant with a similar presentation 3 weeks after exposure to nitrous oxide anesthesia. Both infants had normal folate and very reduced cobalamin levels, responded well to cobalamin injections, and had evidence of maternal cobalamin deficiency. Selzer *et al.*²⁰¹ reported an infant with MTHFR deficiency who died after exposure to nitrous oxide anesthesia. Autopsy revealed asymmetric cerebral atrophy and severe demyelination. Transient elevated FIGLU excretion has been noted in some patients after nitrous oxide exposure.²⁰² While these case

Table 6.1 Acquired causes of cobalamin deficiency.

<i>Nutritional</i>	
Maternal deficiency	
Vegan	
<i>Malabsorption</i>	
Gastric	Pernicious anemia
	Total or subtotal gastrectomy
Intestinal	Stagnant loop syndrome
	Ileal resection
	Fish tapeworm
	Chronic tropical sprue
Malabsorption of cobalamin occurs in the following conditions but the deficiency is not usually sufficiently severe to cause megaloblastic anemia	
Gluten-induced enteropathy	
Cystic fibrosis and chronic pancreatitis	
Crohn disease uncomplicated by resection or stagnant loop	
Drugs: slow K, phenformin, metformin, cholestyramine	

reports illustrate the potential for nitrous oxide to induce symptoms in at-risk individuals, the frequency of this problem appears to be very low.

Nutrition

Adult cobalamin stores are about 2000–3000 µg;⁵ hence with a daily adult requirement of < 3 µg, it should take years for cobalamin deficiency to become symptomatic in the initially replete adult with an intact enterohepatic circulation. Adequate daily vitamin B₁₂ intakes have been estimated to be 0.4 µg for infants < 6 months of age and 0.5–0.6 µg for those aged 6–12 months.⁵ After infancy, the recommended dietary allowance (RDA) for cobalamin in children increases from 0.9 µg/day (1–3 years old) to 1.2 µg/day (4–8 years old) to 1.8 µg/day (9–13 years old) to 2.4 µg/day (14–18 years old). The RDA for pregnant women is 2.6 µg/day, with 2.8 µg/day during lactation. These figures assume normal absorption of this amount of the vitamin (approximately 50%) and an intact enterohepatic circulation.⁵ The average American diet contains a mean of 4.6 µg/day (5.4 µg/day for males, 3.8 µg/day for females and 3.4 µg/day for adolescent females).²⁰³ Vegan and macrobiotic diets contain little vitamin B₁₂. Holotranscobalamin II levels were reduced and homocysteine and methylmalonic acid levels were increased in a majority of nonsupplemented individuals who followed strict vegan or ovo-lacto diets,²⁰⁴ although symptomatic changes or megaloblastic anemia appear to be uncommon in these people. Pregnant and lactating women have increased requirements for cobalamin.^{5,205} Adolescents on vegetarian or macrobiotic diets may develop cobalamin deficiency with symptoms or cognitive changes.^{206,207} There is a high incidence of cobalamin deficiency in developing countries such as Latin America.^{208–210} It is unclear if this is entirely due to nutritional factors.²⁰⁸

Infants born to cobalamin-deficient mothers may become cobalamin deficient because of reduced placental transfer of cobalamin and, if breast-fed, because of cobalamin-deficient milk.^{5,211,212} Several infants have been described who developed symptomatic cobalamin deficiency in infancy. Most were breast-fed infants of mothers who followed vegan diets.^{213–217} These infants developed symptoms before the age of 18 months. Infants of mothers with pernicious anemia are rare because the disorder usually strikes after childbearing age and is associated with sterility.²¹⁸ Nevertheless, Lampkin *et al.*²¹⁹ reported an exclusively breast-fed 4-month-old infant who developed cobalamin deficiency. The mother had pernicious anemia and low levels of cobalamin in her milk. For older children, evidence of cobalamin deficiency has been noted in children and adolescents who follow vegetarianism without supplementation. Miller *et al.*²²⁰ found that children fed a macrobiotic diet were more likely to have growth delay that correlated with elevations in methylmalonic acid.

Malabsorption

Pernicious anemia

Pernicious anemia is an autoimmune disorder caused by antibodies against gastric parietal cells or intrinsic factor and is generally a disease of older adults. Pernicious anemia in children is quite rare, but has been reported in association with polyglandular autoimmune syndrome type I. Neufeld *et al.*²²¹ identified nine cases of pernicious anemia in 71 patients with this disorder. Typically, juvenile pernicious anemia presents in the first or second decade of life and is associated with other signs of endocrinopathy and atrophic gastritis.²²² As in adults, it may occur in any ethnic group and affects both sexes. Dahshan *et al.*²²³ describe a case who presented at 17 years with prior history of diabetes mellitus at age 6, Graves disease at age 13 and schizophrenia at age 14. Many cases of polyglandular autoimmune syndrome type I are now classified as autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED). Features of APECED include candidiasis, alopecia, keratopathy, and multiple endocrine disorders including hypoparathyroidism, adrenal failure and insulin-dependent diabetes.²²⁴ Multiple autoantibodies are described in this syndrome. Abnormalities of the *AIRE* gene, mapped to chromosome 21q22.3, may be responsible for this disorder.²²⁵

Other causes

Total or subtotal gastrectomy, intestinal stagnant loop syndrome and ileal resection may all cause severe cobalamin deficiency with megaloblastic anemia or neuropathy in children as in adults. Vitamin B₁₂ deficiency has been seen in long-term follow-up of infants who had ileal resection for necrotizing enterocolitis.^{226–228} In one report vitamin B₁₂ absorption improved after several years.²²⁹ Vitamin B₁₂ deficiency has also been noted after neonatal subtotal gastrectomy.²³⁰ Cobalamin absorption is decreased in children with cystic fibrosis,^{231,232} perhaps due to impaired digestion of haptocorrins in the small intestine.²³³ However, clinically significant cobalamin deficiency has been rarely reported in cystic fibrosis patients and one study found elevated cobalamin levels in these children.²³⁴ The elevated levels may be due to liver disease and binding of cobalamin to TCI, and may not reflect the functional cobalamin status of these children. Supplemental cobalamin has been suggested for children with cystic fibrosis.²³⁵ Other gastric illness such as infestation with *Diphyllobothrium latum* can deplete vitamin B₁₂.²³⁶ *Helicobacter pylori* infection may play a role in cobalamin malabsorption.²⁰⁸ A number of drugs, including proton pump inhibitors,²³⁷ slow K, cholestyramine,²³⁸ H₂ blockers,¹⁹⁶ and biguanides (metformin and phenformin),^{239–241} have been reported to cause cobalamin malabsorption.

Food-cobalamin malabsorption

Food-cobalamin malabsorption has been described mainly in adults. It is manifested by an inability to absorb food-bound cobalamin with an intact ability to absorb free cobalamin. The Schilling test is normal. The disorder has been associated with atrophic gastritis, *Helicobacter* infection or partial gastrectomy.^{196,242} The treatment is oral or systemic cobalamin supplementation.²⁴³ It is likely that this disorder is due to an inability to remove cobalamin from R binders in food.

Folate deficiency (Table 6.2)

Nutrition

In the absence of clear data, the adequate folate intake for infants was estimated by determining the average intake of children fed predominantly human milk (~85 µg/L) and was found to be 65 µg/day or about 9.4 µg/kg daily for infants aged 0–6 months and 80 µg/day or about 8.8 µg/kg daily for those aged 7–12 months. The RDA for total folates in children increases from 150 µg/day (1–3 years old) to 200 µg/day (4–8 years old) to 300 µg/day (9–13 years old) to 400 µg/day (14–18 years old).⁸ The RDA for pregnant women is

Table 6.2 Acquired causes of folate deficiency.

600 µg/day, with 500 µg/day during lactation.⁸ Beginning in 1998, in the USA cereal-grain products have been fortified with 140 µg folic acid for every 100 g of cereal-grain.⁹ This mandated folate supplementation of cereal-grain products has increased the American daily folate equivalent intake by about 200 µg to over 400 µg.²⁴⁴

Folate deficiency is common in children in underdeveloped countries. Villalpando *et al.*²⁴⁵ found the incidence of severe folate deficiency to range from 2.8 to 13% for children < 4 years of age in Mexico, but was lower in those of higher socioeconomic status or higher vegetable intake.

Newborn infants have higher serum and red cell folate levels than adults but these fall in the first few weeks of life.^{246,247} In premature infants the fall is steeper, folate reaches lower levels and folate deficiency with megaloblastic anemia may develop, especially if there are feeding difficulties, hemolytic disease, diarrhea or infection.²⁴⁸ Goats' milk contains only 6 µg/L and infants fed only on this may develop clinically symptomatic deficiency.^{249,250}

Pregnancy

Folate requirements are increased in pregnancy by about 200 µg/day to a total of 600 µg/day.⁸ Folate is preferentially transferred to the fetus in a two-step process that involves placental folate-binding proteins.^{20,251} Megaloblastic anemia may develop if the diet is inadequate and prophylactic folic acid is not given. Bone marrow examination showed that 25% or more of unsupplemented pregnant women had megaloblastic changes.²¹⁸ Folate deficiency can also lead to premature and low-birthweight infants.²¹⁸ Neonatal neural tube defects (spina bifida, meningocele, anencephaly) are associated with periconceptual folate deficiency.²⁵² In a randomized clinical trial, folate supplementation of 4 mg/day given to women with a previously affected child decreased the rate of neural tube defects by 72%.²⁵³ In another trial, periconceptual folic acid supplementation of 400 µg/day decreased the rate of neural tube defects by 79% in a high-risk region.²⁵⁴ Folic acid supplementation has also been shown in some studies to decrease the rate of cleft lip and palate,^{255–257} and possibly conotruncal abnormalities.²⁵⁸ Folate antagonists increase the rate of these deformities.²⁵⁹ Similarly, the 677TT polymorphism in the MTHFR gene has been associated with increased neural tube defects.^{260,261}

Malabsorption

Folate deficiency is very common in celiac disease (gluten-sensitive enteropathy).^{262,263} The majority of patients with untreated celiac disease have anemia.²⁶³ The anemia can be due to both iron and folate deficiency, hence a dimorphic picture may be seen. Anemia secondary to iron and folate deficiency may be present even in the absence of gastrointestinal symptoms.²⁶⁴ Virtually all affected children have sub-

normal serum and red cell folate levels.²⁶³ Malabsorption of cobalamin is frequent but cobalamin deficiency is generally not sufficiently severe to be the main cause of megaloblastic anemia.²⁶³ While the presence of IgA anti-endomysial antibodies and transglutaminase antibodies have a high sensitivity and specificity for celiac disease, the diagnosis is confirmed by endoscopy and biopsy. The intestinal lesion responds to withdrawal of gluten (glutamine-rich protein) from the diet. There is an increased risk of intestinal non-Hodgkin lymphoma as well as cancers of the mouth, pharynx and esophagus in adults.^{265,266} Withdrawal of gluten also reduces the risk of subsequent development of cancer.²⁶⁶

Tropical sprue occurs in the local population and visitors to areas in the tropics where the condition is endemic. Generalized small intestinal malabsorption occurs. Folate and cobalamin deficiency are very common in tropical sprue.²⁶⁷ In the chronic disease, cobalamin deficiency may become severe and cause megaloblastic anemia or neuropathy, even in the absence of gastrointestinal symptoms.²⁶⁸ The cause of tropical sprue is likely to be an infection and antibiotic therapy is indicated. Therapy should also include folate and cobalamin (the latter especially for chronic cases).²⁶⁸ Other acquired causes of folate malabsorption occasionally seen in childhood include inflammatory bowel disease^{269,270} and gastric bypass.²⁷¹

HIV infection²⁷² or systemic bacterial infections can cause folate deficiency.²⁷³ Many medications are associated with folate deficiency and/or megaloblastic anemia. Phenytoin, carbamazepine, valproic acid and oral contraceptives may in some instances cause low folate levels.^{274,275} Tobacco use has been associated with lower red blood cell folate levels.^{274,276} Alcohol abuse is a common cause of folate deficiency for a number of reasons.^{277,278}

Excess utilization

In a wide range of inflammatory and malignant diseases, folate requirements are increased (see Table 6.2). These include chronic hemolytic anemias, severe chronic infections and widespread skin diseases. Folate may also be lost by dialysis.²⁷⁹ Conditions of increased folate need, e.g., sickle cell anemia, HIV infection, hepatitis and malaria, may increase the risk of the deficiency. In sickle cell disease, varying results have been seen. For instance, van der Dijs *et al.*²⁸⁰ found elevated homocysteine levels in sickle cell patients that decreased by 50% with folate supplementation. In contrast, Rodriguez-Cortes *et al.*²⁸¹ found normal plasma homocysteine levels as well as serum and red cell folate values in unsupplemented sickle cell patients.

Antifolate drugs

Inhibitors of human dihydrofolate reductase (DHFR) include methotrexate, pyrimethamine and, to a much lesser degree,

trimethoprim. Methotrexate causes megaloblastosis in humans whereas the main action of pyrimethamine is against malarial parasite DHFR. Trimethoprim acts against the bacterial enzyme and is at least 1000-fold less able than methotrexate to bind human DHFR.²⁸² Methotrexate is converted to polyglutamate forms in cells and this may result in prolonged inhibition of DNA synthesis. Alcohol, which may be the commonest cause of folate deficiency in the USA, has a variety of effects on folate metabolism, including decreased intestinal absorption and decreased hepatic storage as well as a direct effect on the bone marrow causing vacuolated normoblasts or megaloblasts.²⁸²

Tissue effects of cobalamin and folate deficiencies

The characteristic morphologic abnormalities of megaloblastic anemia are noted on the peripheral blood smear and bone marrow morphology. Anemia is usually but not always present and may be accompanied by neutropenia and thrombocytopenia. The mean cell volume is increased and erythrocyte morphology reveals macrocytosis and misshapen red blood cells. Neutrophil hypersegmentation, defined as > 5% of neutrophils with five clearly distinct lobes or the presence of any neutrophils with six clear lobes (Fig. 6.6). The bone marrow findings include dyserythropoiesis with less tightly condensed nuclear chromatin than appropriate for the degree of cytoplasmic maturation (nuclear–cytoplasmic dyssynchrony). There are giant bands and metamyelocytes. Of note, there is a relative decrease in late hematopoietic precursors due to ineffective hematopoiesis. This ineffective hematopoiesis also causes elevations in serum bilirubin and lactate dehydrogenase. The detailed mechanisms by which inhibition of DNA synthesis leads to the morphologic and biochemical features of megaloblastic anemia are unclear. One explanation has proposed that the intracellular

Fig. 6.6 Neutrophil hypersegmentation.

accumulation of uracil due to the inhibition of thymidylate synthetase leads to the formation of dUTP, which in turn is misincorporated into DNA. Excision of these uracil molecules can lead to breaks in the DNA.¹⁴³ Apoptosis appears to be increased in hematopoietic progenitors.²⁸³

As noted above, neuropathy due to cobalamin deficiency is seen in children with severe cobalamin deficiency as well as defects in cobalamin metabolism. Permanent mental retardation may result.^{284,285} In older children and adults, features of a peripheral neuropathy mainly affecting the legs with, in severe cases, posterior column and pyramidal features are characteristic (subacute combined degeneration of the spinal cord). Paresthesiae, loss of sensation in the feet and unsteadiness in the dark are typical symptoms. Psychiatric and ophthalmic features may be present. The mechanism is not well understood, but may be related to undermethylation of myelin.¹⁴³ Neutrophil function defects have been described in cobalamin deficiency.^{286,287}

The deficiencies affect epithelial surfaces. Glossitis, manifested as a painful, smooth, red tongue, may be a presenting feature.²⁸⁸ Pathologically, squamous cells in the oral mucosa show nuclear and cytoplasmic enlargement.²⁸⁹ Intestinal and other epithelial cells also show changes with folate or vitamin B₁₂ deficiency.²⁹⁰

Serum bone alkaline phosphatase is reduced due to an effect on osteoblasts.²⁹¹ Reversible, diffuse hyperpigmentation due to hypermelanosis has been described in both children and adults with cobalamin deficiency.^{292–294}

Diagnosis

Measurement of serum cobalamin and serum and/or red cell folate are the most commonly used techniques. Both serum and red blood cell levels for folate and cobalamin can be measured by radiodilution, microbiological and chemiluminescence assays. Red blood cell assays are less affected by recent changes in diet or medications.²⁹⁵ Typically, both serum and red blood cell folate levels will be reduced in folate deficiency and serum cobalamin levels are reduced in cobalamin deficiency. TCI levels exceed TCII levels in the plasma, although as previously noted the cobalamin attached to TCI is not in the metabolically active pool.³⁴ Elevations of TCI, as can occur in myelodysplastic syndrome or with oral contraceptive use, can cause normal serum cobalamin values in the presence of cobalamin deficiency. Similarly, deficiency of TCI can cause low serum cobalamin levels without disease.^{33,296} Low red blood folate levels and normal to elevated serum folate levels are seen in cobalamin deficiency.²⁹⁵ The mechanism for this “methylfolate trap” phenomenon is not clearly established.¹⁴³

Metabolic assays may be helpful in diagnosing patients with mild deficiencies or who have false-positive results for serum folate or cobalamin. Serum methylmalonic acid

is elevated in cobalamin but not folate deficiency and is sensitive for CblA, CblB, CblC, CblD and CblF.¹⁹⁶ It is also elevated in renal failure, thyroid disease, hemoconcentration, small bowel bacterial overgrowth and pregnancy.^{196,297} Serum homocysteine is elevated in both folate and cobalamin deficiency.¹⁹⁶ Homocysteine is elevated in CblC, CblD, CblE, CblF and CblG, MTHFR deficiency and can also be elevated with the 677TT MTHFR polymorphism, especially when folate levels are suboptimal.¹⁹⁶ Homocysteine levels are less specific and are elevated in renal dysfunction, hypothyroidism, vitamin B₆ deficiency and with certain medications such as cholestyramine, carbamazepine and valproic acid.^{196,297} Hence, patients with suspected cobalamin or folate deficiency and normal serum levels should be investigated with plasma or serum methylmalonic acid and homocysteine levels.²⁹⁵ Recently, low levels of holotranscobalamin II have been shown to be another sensitive method for diagnosing cobalamin deficiency.²⁰⁴ Holotranscobalamin II may be an early marker of cobalamin deficiency, with levels decreasing before there are other manifestations of the disorder.^{298,299} The deoxyuridine suppression test is an indirect test of thymidylate synthesis. Deoxyuridine is added to bone marrow cells followed by exposure to ³H-thymidine. In normal cells, deoxyuridine is rapidly converted to TTP and incorporated into DNA, suppressing the incorporation of ³H-thymidine. In cells deficient in cobalamin or folate, there is a relative inability to convert deoxyuridine to thymidylate triphosphate, hence less suppression of ³H-thymidine uptake into DNA. The test is corrected in cobalamin deficiency by cobalamin or 5-formyl-THF, but not by 5-methyl-THF. In folate deficiency, 5-formyl-THF and 5-methyl-THF both correct the test but cobalamin does not.²⁹⁵ While the test is quite sensitive to early deficiency and can exclude other refractory macrocytic anemias such as myelodysplastic syndrome,²⁹⁵ the test is only performed in specialized laboratories.

Tests of cobalamin absorption

The Schilling test is used to diagnose defects in cobalamin absorption. Fasting patients who are at least 3 days out from cobalamin exposure ingest a dose of ⁵⁷Co-labeled cobalamin. Thereafter, this labeled cobalamin is excreted into the urine, flushed by a large parenteral dose of unlabeled cobalamin. A 24-hour urine collection is analyzed for radioactivity. If subnormal amounts are excreted, a defect in cobalamin absorption is likely. The test can be repeated days later, administering exogenous IF with the ⁵⁷Co-labeled cobalamin. Correction of the defect confirms IF deficiency as occurs in congenital IF deficiency or pernicious anemia, but failure to correct with IF is not uncommon in patients with pernicious anemia.²⁹⁵ In another modification of this test, ingested cobalamin is given with food such as eggs to investigate food-cobalamin malabsorption.²⁹⁵

Treatment

The treatment of disorders of cobalamin and folate metabolism and absorption has been previously discussed. Patients with severe anemia should be monitored closely for signs of heart failure. Transfusion should be given very slowly to avoid worsening the patient's cardiovascular status. In patients with severe anemia, close attention should be paid to electrolyte status to look for hypokalemia following initiation of treatment. High-dose folate may reverse the hematologic features of cobalamin deficiency, but the neurologic manifestations can progress. Hence, it is important to ensure that cobalamin deficiency is excluded before treating solely with folate.

Cobalamin deficiency is first treated by a series of intramuscular or subcutaneous injections of hydroxocobalamin (1000 µg in adults); usually six are given over a few weeks at intervals of a few days. Low doses of cobalamin (10 µg/day or 0.2 µg/kg daily subcutaneously for 2 days) may stimulate reticulocytosis and partially improve the metabolic state of the patient. Despite earlier reports of frequent mortality with treatment of severe cobalamin deficiency, Carmel³⁰⁰ reported only a single death secondary to a coexisting disease in 219 patients with pernicious anemia of whom 101 had a hemoglobin ≤ 80 g/L. There is no comment on dosing of cobalamin treatment for these patients.³⁰⁰ Maintenance is 1000 µg of hydroxocobalamin every 3 months. Vegans with cobalamin deficiency are also initially loaded with cobalamin and they may then be advised to eat food supplemented with cobalamin. Prophylactic cobalamin therapy is given to patients with an ileal resection or total gastrectomy.

Folate deficiency is initially corrected by giving folic acid 5 mg (100 µg/kg) daily for 4 months. The treatment is continued if the underlying condition causing folate deficiency cannot be reversed and daily folate dietary intake is not improved. Folinic acid (5-formyl-THF) is used to reverse the effect of methotrexate. Prophylactic folic acid is often given to children with severe hemolytic anemias, e.g., sickle cell anemia, thalassemia major and severe autoimmune hemolytic anemia, although as previously noted folate deficiency appears to be uncommon in patients with sickle cell disease. Periodic check of serum cobalamin levels may be advisable to avoid masking unsuspected cobalamin deficiency.³⁰¹ Folate (0.1 mg/day) and cobalamin (100 µg/month) supplementation to premature infants increased hemoglobin concentration in a randomized controlled trial.³⁰²

Other causes of megaloblastic and macrocytic anemia

Megaloblastic changes can be seen in the marrow in the

absence of disorders of cobalamin or folate. Drugs inhibiting synthesis of purine or pyrimidine DNA precursors at various points in DNA synthesis cause megaloblastic anemia. These drugs include hydroxycarbamide (hydroxyurea), mercaptopurine, 5-fluorouracil, cytosine arabinoside, zidovudine and others.²⁸² Erythropoiesis may also be megaloblastic in acute myeloid leukemia and myelodysplasia but the site of the presumed block in DNA synthesis is unknown. Congenital dyserythropoietic anemia types 1 and 3 have megaloblastic erythropoiesis.³⁰³ These disorders are discussed elsewhere in this book.

Pappo *et al.*³⁰⁴ reviewed the causes of macrocytosis in 146 children with a mean corpuscular volume > 90 fL; 35% were due to medications, principally anticonvulsants, zidovudine and immunosuppressive agents. Other causes were congenital heart disease (14%), Down syndrome (8%), reticulocytosis (8%) and marrow failure/myelodysplasia (4%). Neither cobalamin nor folate deficiency was identified, although extensive studies were not performed to rule them out. Macrocytic anemia has also been seen with hypothyroidism³⁰⁵ and selenium deficiency.³⁰⁶

Acknowledgments

I would like to recognize the excellent work of Dr D.S. Rosenblatt and Dr A.V. Hoffbrand, who authored the chapter on this topic in the second edition of this book and which served as the backbone for this chapter.

Nonimmune neonatal anemias

Brenda E.S. Gibson and Christina Halsey

Anemia is the commonest hematologic abnormality in newborn babies and this chapter concentrates on the nonimmunologic causes of neonatal anemia. A careful history and examination combined with a few key investigations will help identify the cause of anemia in the majority of affected neonates.

Hematopoiesis in the neonatal period

Appreciation of the unique features of neonatal anemia requires an understanding of the many differences between fetal and adult hematopoiesis.

Erythropoiesis is switched off at birth

Although born with a hemoglobin (Hb) level significantly higher than that of the older child and adult, the rate of red cell production and hemoglobin synthesis in the neonate falls dramatically after birth.¹ At this time erythropoietin levels are virtually undetectable, which is thought to result from both the sudden increase in tissue oxygenation that occurs at birth and the switch from hepatic to renal erythropoietin production. Red cell production reaches a nadir at 2 weeks of age. Although bone marrow erythropoiesis gradually increases thereafter, there is a time lag before mature red cells appear in the circulation. Hence the hemoglobin is lowest at around 8 weeks of age and only attains more normal childhood values at 3–4 months of age.²

Neonatal red cells have a short half-life

The average lifespan of the red cells of the term and preterm neonate is 60–70 and 35–50 days respectively,³ both considerably shorter than the 120-day lifespan of the adult red cell. The exact cause of the shortened red cell lifespan in neonates is unknown but probably reflects differing red cell membrane lipid composition in neonatal cells.

The major hemoglobin at birth is HbF ($\alpha_2\gamma_2$)

Fetal hemoglobin (HbF) comprises 70–80% of the total hemoglobin at birth. It remains static at this level until about

2 weeks of age when erythropoiesis recommences, and thereafter falls steadily to reach a level of less than 2% by the end of the first year of life. Although adult-type HbA ($\alpha_2\beta_2$) is produced in the embryo from 6–8 weeks gestation onwards, it remains at low levels until about 32 weeks' gestation. It gradually rises thereafter, reaching levels of 20–30% at birth and becomes the predominant hemoglobin by 3 months of age. This switch from fetal to adult hematopoiesis may be delayed in the sick premature infant. Small amounts of HbA₂ ($\alpha_2\delta_2$) and Hb Barts (γ^4 tetramers) are detectable in healthy neonates at birth. An understanding of the pattern of hemoglobin production, particularly when the switch from fetal to adult hematopoiesis occurs, explains the clinical manifestations of hemoglobinopathies in the neonatal period and in particular why α -chain abnormalities cause problems from early fetal life and why β -chain abnormalities may be difficult to diagnose in the neonatal period.

The neonatal red cell membrane is different from the adult red cell membrane

The neonatal red cell membrane shows many different properties to that of adult red cells. It has an altered lipid profile with increased total lipid content, increased mechanical fragility but relative resistance to osmotic lysis, and reduced expression of the blood group antigens A, B and I.

Neonatal red cell metabolism is different from adult red cell metabolism

There are many subtle differences between neonatal and adult red cell metabolism involving both the glycolytic and pentose phosphate pathways. This may increase the susceptibility of red cells to oxidant injury although the significance *in vivo* is unclear.

Hematologic values at birth

The diagnosis and treatment of neonatal anemia requires a knowledge of normal hemoglobin values for age and gestation

and an awareness of factors that may produce artifactual results. Tables of age- and gestation-related reference values are given in Chapter 37. The following should be considered when assessing an infant with possible anemia.

Site of sampling

Blood samples collected by capillary sampling give consistently higher hemoglobin values than those collected simultaneously by the venous or arterial route. Studies have shown that capillary samples taken around the time of birth give an average hemoglobin value 2.3–3.5 g/dL higher than simultaneous venous samples.^{4,5} The discrepancy is most marked in sick and premature infants and sample site differences should be taken into account when interpreting results, especially borderline results, in infants.

Quality of the sample

Neonatal sampling is difficult and samples may be small or partially clotted and collection tubes underfilled, all of which may produce false results. Capillary sampling from a good blood flow in a well-warmed extremity minimizes the recognized discrepancy between capillary and venous results. Because of the potential for artifactual error, a result suggesting a sudden or unexpected drop in hemoglobin should be repeated, if possible, before any other action is taken.

Timing of cord clamping at delivery

The average blood volume at birth in the healthy full-term infant is 86 mL/kg (range 69–107 mL/kg) and is higher in small-for-gestational-age and preterm infants.⁶ The placental vessels contain approximately 150 mL of blood (range 50–200 mL). An increase in the hemoglobin concentration occurs uniformly in the first few hours after birth in all healthy newborns, because about one-quarter of the placental blood volume transfuses into the infant in the first 15 s after birth and 50% of the placental blood volume in the first minute. A delay in cord clamping allows more complete emptying of the placental vessels and can increase the infant's blood volume by 50–60%.⁷ The rate of placental transfusion is increased in women who receive ergotamine derivatives at the onset of the third stage of labor and is decreased in placenta praevia, multiple pregnancies and after cesarean section. The advantages of late clamping of the umbilical cord may be greatest for premature infants in whom the red cell mass and total iron stores are decreased.⁸ A hemoglobin concentration of less than 15 g/dL in the first week of life has been shown to be a significant predictor of severe refractory anemia of prematurity. The placental transfusion in preterm infants may also facilitate postnatal lung adaptation.⁹

Table 7.1 gives examples of how the variable management of the umbilical cord at birth can result in differences in blood volume, hematocrit and hemoglobin concentration; these can take up to 3 months to equalize.

Table 7.1 Effect of cord clamping on blood volume, hematocrit (Hct) and hemoglobin concentration (Hb).

	Early clamping	Late clamping
Blood volume at birth (mL/kg)	82	93
HCT (%) at 2 hours of age	0.47	0.63
HCT (%) at 24 hours of age	0.43	0.59
HCT (%) at 120 hours of age	0.44	0.59
Hb (g/dL) at 20–30 hours	15.6	19.3
Hb (g/dL) at 72–96 hours	18.1	19.7
Hb (g/dL) at 3 months	11.1	11.1

Gestational age

There is little variation in hemoglobin levels at birth between preterm and term infants but premature infants experience a more rapid and profound drop in hemoglobin postnatally (see below). The normal mean cell volume (MCV) is higher in preterm than term infants. The nucleated red cell and reticulocyte counts fall in inverse proportion to gestational age up until term, after which they rise again so that babies born after 40 weeks have higher reticulocyte counts than those born at term.¹⁰ Red cell morphology also varies considerably with gestation, with increasing numbers of echinocytes (spiculated/burr like cells) seen with increasing prematurity. The gestational age is therefore very important when interpreting neonatal blood films.

Postnatal age

Postnatal age is also important in the interpretation of hematologic values. As already stated, erythropoiesis is effectively shut off at birth and this is followed by a steady decline in hemoglobin values to a nadir at around 8 weeks. This fall in hemoglobin is most marked in preterm infants. The reticulocyte count declines rapidly in nonanemic infants and is less than 1% by the end of the first week of life. Nucleated red blood cells also fall rapidly, usually disappearing from the circulation by 3 days of age, although small numbers may persist in premature infants until the end of the first week of life. The persistence of a reticulocytosis or of nucleated red cells can be a useful pointer to the cause of neonatal anemia (see Fig. 7.1).

Classification of neonatal anemia

There are three principal mechanisms that produce neonatal anemia:

- impaired red cell production;
- increased red cell destruction due to hemolysis;
- blood loss due to hemorrhage.

A stepwise approach to diagnosis should help identify the cause of the anemia and simplify management. However, in

Table 7.2 Hematologic causes of hydrops fetalis.

<i>Impaired red cell production</i>
Parvovirus B19 infection
Diamond–Blackfan anemia
Congenital dyserythropoietic anemias
Congenital leukemia
<i>Increased red cell destruction</i>
Immune hemolysis: Rh and Kell
α-Thalassemia major
Pyruvate kinase deficiency
Glucose phosphate isomerase deficiency
γβ-thalassemia
Rare unstable α-chain variants
<i>Blood loss</i>
Twin-to-twin transfusion syndrome
Fetomaternal hemorrhage

most cases, particularly anemias associated with prematurity and infection, the pathology may be multifactorial.

The timing of the onset of anemia can be helpful in identifying the likely cause.

- *Onset prior to birth.* Hydrops fetalis may be detected on antenatal ultrasound or be an unexpected finding at the time of birth. This condition has hematologic and nonhematologic causes but is characterized in the fetus and neonate by gross edema, ascites, pleural effusions, cardiac failure and profound anemia. The hematologic causes are listed in Table 7.2.
- *Onset in first 24 hours.* Severe anemia (hemoglobin < 8.0 g/dL) that presents around the time of birth is usually due to immune hemolysis or hemorrhage. Hydrops fetalis can result if either process has been chronic.
- *Onset after first 24 hours.* Anemia that becomes apparent after 24 hours is most often due to internal or external hemorrhage or nonimmune hemolytic disorders. Anemia due to impaired red cell production often manifests relatively late due to the boost in hemoglobin given to the baby by placental transfusion at birth, but if sufficiently severe, anemia due to impaired red cell production may lead to hydrops fetalis (see Table 7.2).

The causes of nonimmune neonatal anemia are listed in Table 7.3 and will be discussed in more detail; those which are immune-mediated are discussed in Chapter 8.

A diagnostic approach to neonatal anemia

The anemic fetus/neonate can present in one of four ways:

- 1 symptomatic anemia;
- 2 coincidental finding of a low hemoglobin;
- 3 hydrops fetalis detected before or at the time of birth;
- 4 jaundice/unconjugated hyperbilirubinemia.

Table 7.3 Causes of anemia in the neonate.

<i>Anemia secondary to blood loss</i>
Concealed hemorrhage prior to birth or during delivery
Fetomaternal
Fetoplacental
Twin-to-twin
Obstetric accidents, malformations of the cord or placenta
Internal hemorrhage
Extracranial
Intracranial
Intraabdominal
Pulmonary
Iatrogenic blood loss
<i>Anemia as a result of a hemolytic process</i>
Immune
Alloimmune
Autoimmune (passively acquired)
Drug-induced
Infection
Acquired (bacterial sepsis)
Congenital: rubella, cytomegalovirus, etc.
Macroangiopathic and microangiopathic hemolytic anemias
Hereditary disorders of the red cell membrane
Hereditary spherocytosis
Hereditary elliptocytosis
Other rare membrane disorders
Red cell enzyme deficiencies
Glucose 6-phosphate dehydrogenase deficiency
Pyruvate kinase deficiency
Glucose phosphate isomerase deficiency
Other rare enzyme deficiencies
Abnormal/unstable hemoglobins
<i>Anemia due to impaired red cell production</i>
Congenital red cell aplasia: Diamond–Blackfan anemia
Anemia of the preterm infant
Infection
Bacterial sepsis
Congenital infections
Parvovirus B19 infection
Nutritional deficiencies
Congenital leukemia
Osteopetrosis

The hematologic causes of hydrops fetalis are listed in Table 7.2. The presence of significant jaundice suggests a hemolytic process as a cause for the anemia.

The initial assessment of any anemic neonate should include the following.

Maternal history

- Preexisting medical conditions: bleeding disorders, hemoglobinopathies, red cell membrane defects, red cell enzymopathies.
- Antepartum conditions: drugs, maternal infection, trauma or vaginal bleeding.

- Helpful maternal investigations that may be available: full blood count during pregnancy, serologic tests, amniocentesis and ultrasound.

Birth history

- Method of delivery.
- Evidence of maternal hemorrhage.
- Fetal distress.
- Multiple pregnancies.
- Placental or umbilical cord pathology.

Family history

- Red cell membrane defects, hemoglobinopathies, red cell enzymopathies.
- Carrier status.
- History of consanguinity.

Neonatal history

- Gestation.
- Postnatal age at presentation of anemia.
- Ethnicity.
- Gender.

Examination

- Evidence of acute or chronic blood loss (see Table 7.4), organomegaly, congenital malformations and congenital infection.

Investigations

- Initial investigations: blood count, blood film, reticulocyte count and direct Coombs test.
- Subsequent investigations: dependent on results of initial assessment.

A diagnostic algorithm for the initial assessment and investigation of neonatal anemia is presented in Fig. 7.1.

Anemia secondary to blood loss

Bleeding can occur antenatally, during labor, or within the first few hours or days after birth. Neonates have a limited capacity to tolerate acute hemorrhage and prompt diagnosis and management are therefore essential for survival. The causes of blood loss can be considered in the following categories:

- concealed or occult hemorrhage prior to or during delivery;
- internal hemorrhage in the fetus or neonate;
- obstetric accidents;
- bleeding due to umbilical cord or placenta malformations;
- iatrogenic blood loss due to excessive sampling.

The clinical signs and symptoms of hemorrhage depend on the site, volume and rate of blood loss. It is usually relatively simple to distinguish acute from chronic blood loss on clinical grounds (Table 7.4). While life-threatening hemorrhage occurs in otherwise hematologically normal neonates, an

Table 7.4 Characteristics of acute and chronic blood loss in the neonate.

Acute blood loss

Pallor
Shallow tachypnea
Tachycardia
Poor peripheral perfusion
Hypotension
No organomegaly
Normochromic, macrocytic anemia (may have normal hemoglobin initially)
Reticulocytosis (may not be seen acutely)

Chronic blood loss

Pallor
Signs of cardiac failure
 Cardiac enlargement
 Tachypnea
 Hepatomegaly
 Ascites
Hypochromic, microcytic anemia
Reticulocytosis and nucleated red cells at birth

underlying bleeding diathesis should be considered in any infant presenting with unusual, unexplained or severe hemorrhage. It is important to remember that in acute blood loss the hemoglobin may initially be normal before falling rapidly in the subsequent few hours and therefore blood counts taken early may not reflect the degree of blood loss.

Concealed hemorrhage in the fetus prior to or during delivery

Occult hemorrhage can occur into the maternal circulation (fetomaternal), the placental circulation (fetoplacental) or, in the case of multiple pregnancies, into the fetus sharing the same placental blood supply (twin-to-twin).

Fetomaternal hemorrhage

Small numbers of fetal red cells (0.01 mL or more of blood) pass through the placental trophoblastic lining and enter the maternal circulation in more than 75% of normal pregnancies. Although this passage of red cells has been demonstrated from as early as 4–8 weeks' gestation, most significant spontaneous fetomaternal bleeding occurs in the third trimester or during labor and delivery. The risk in terms of both the frequency and magnitude of fetomaternal hemorrhage is increased by the use of invasive procedures during pregnancy and in a number of maternal conditions (Table 7.5).¹¹

Clinical manifestations

Clinical manifestations vary with the size, rapidity and chronicity of the hemorrhage and the time at which the bleeding occurs with respect to delivery. In fetomaternal hemorrhage occurring at delivery, the volume of fetal blood

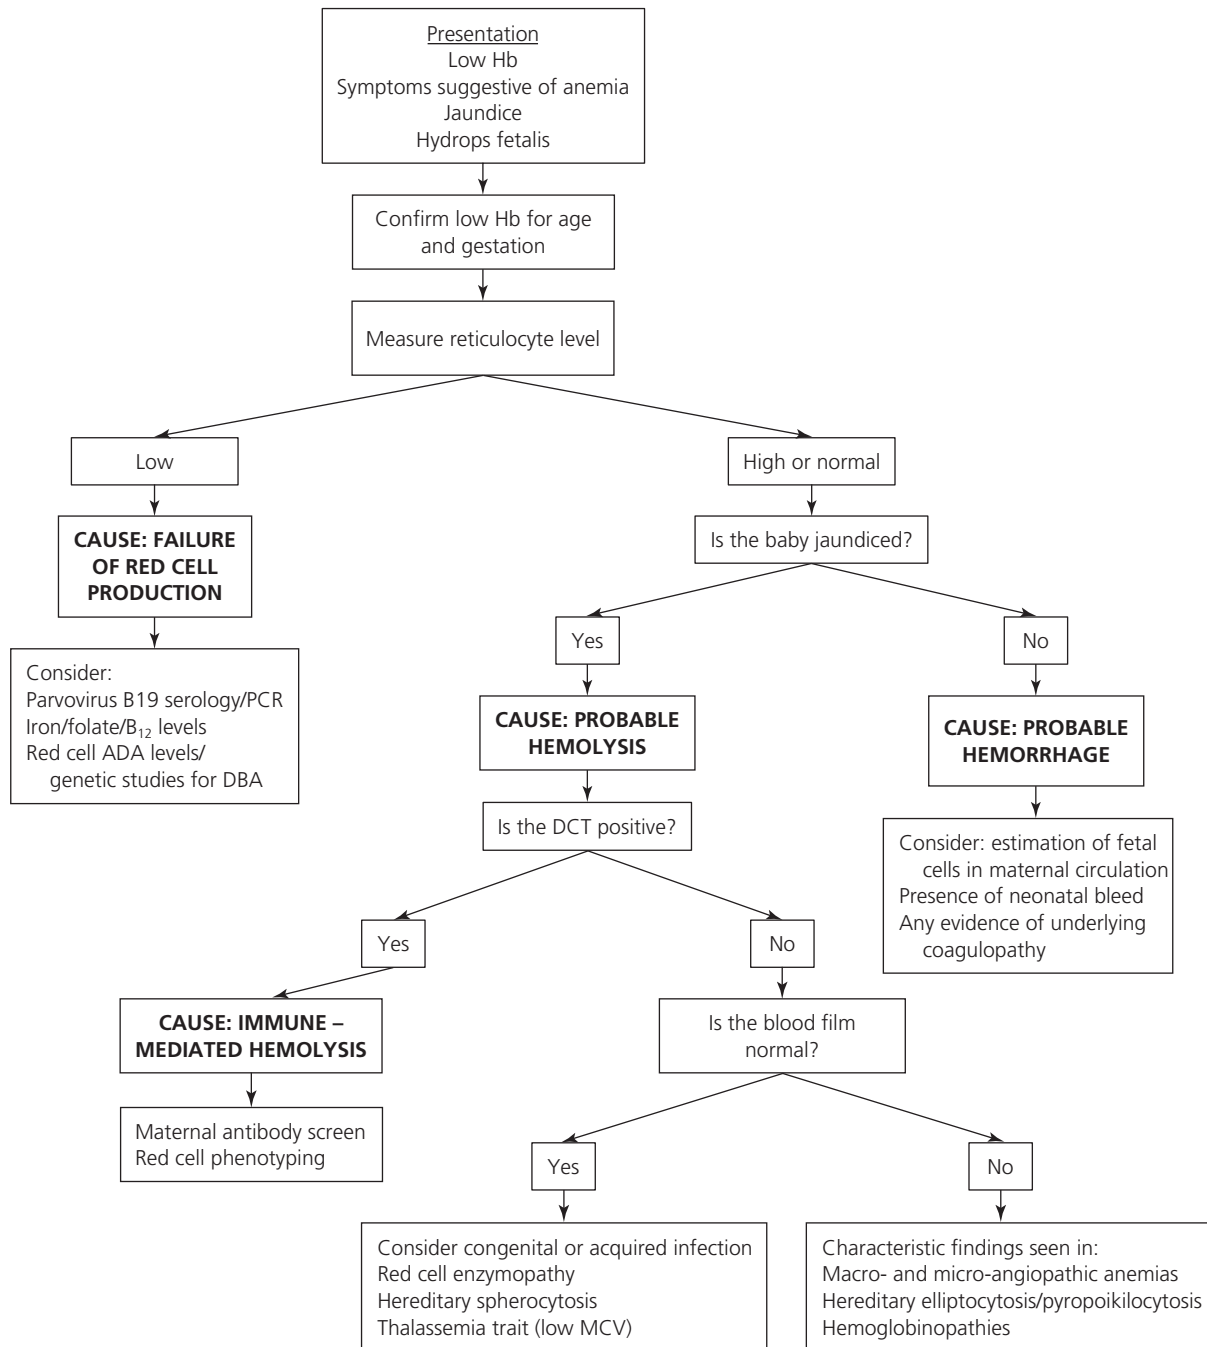

Fig. 7.1 A diagnostic algorithm for neonatal anemia. ADA, adenosine deaminase; DBA, Diamond–Blackfan anemia; DCT, direct Coombs test; MCV, mean cell volume; PCR, polymerase chain reaction.

detected in the maternal circulation is usually less than 0.5 mL but is greater than 15 mL in 0.3% of cases. Prior to delivery the acute loss of more than 20% of the fetal blood volume can lead to hydrops fetalis and stillbirth in the absence of intrauterine transfusion. Infants who survive will be clinically shocked, apneic and severely anemic. The same degree of blood loss over a more prolonged period of

time may allow the fetus to compensate hemodynamically. Symptomatology is dependent on the degree of anemia: if mild it may go undetected, but if the hemoglobin is less than 12.0 g/dL the infant will usually display some signs of anemia such as pallor, tachypnea or poor feeding. Surviving infants with hemoglobin levels less than 4.0 g/dL at delivery have been reported.

Table 7.5 Conditions associated with increased risk and magnitude of fetomaternal hemorrhage.

Amniocentesis
Termination of pregnancy
Abdominal trauma
Chorioangioma or choriocarcinoma of placenta
Fetal blood sampling
Intrauterine transfusion
External cephalic version
Antepartum hemorrhage
Obstetric instrumentation
Manual removal of the placenta
Cesarean section
Pregnancy-induced hypertension

Laboratory diagnosis

The blood film is useful in distinguishing between acute and chronic blood loss. In acute blood loss, the red cells are normochromic and normocytic; in chronic blood loss, hypochromic and microcytic with anisopoikilocytosis. The reticulocyte count and nucleated red blood cell count are initially normal in acute blood loss but rise within the first few hours. A negative direct Coombs test and normal bilirubin will help distinguish anemia secondary to acute blood loss from that secondary to immune hemolysis.

A definitive diagnosis can only be made by demonstrating the presence of fetal red cells in the maternal circulation. The most widely used method is the Kleihauer–Betke technique of acid elution, although flow cytometer methods using fluorescent antibodies are increasingly employed.¹²

The Kleihauer test is based on the fact that at acid pH adult cells lose their hemoglobin whereas fetal hemoglobin resists elution and remains within erythrocytes. After appropriate staining, fetal cells appear pink and adult cells are seen as empty “ghosts”. The ratio of fetal to adult cells can be determined by light microscopy. Evaluation of 6000 cells allows detection of bleeds greater than 0.4 mL. This technique is unreliable when maternal levels of fetal hemoglobin are increased as occurs in some hemoglobinopathies, in hereditary persistence of fetal hemoglobin, and in some normal women in whom pregnancy induces a rise in fetal hemoglobin, particularly in the first and second trimester.

Flow cytometric analysis permits the rapid, objective and reproducible evaluation of 50 000–100 000 red blood cells and is able to detect as little as 0.03 mL of fetal red cells in the maternal circulation.

If ABO incompatibility exists between maternal and fetal cells, the latter may be agglutinated and removed within hours from the maternal circulation by maternal antibody. It is therefore very important for an accurate assessment of the volume of fetomaternal hemorrhage that a maternal blood sample is taken as soon as a fetomaternal hemorrhage is suspected.

Fetoplacental hemorrhage

Rarely a transfusion of blood from the fetal circulation can accumulate within the placental tissue or retroplacentally rather than passing to the maternal circulation. If the infant is inadvertently held above the level of the placenta before the umbilical cord is cut at delivery, this can result in direct transfusion of blood from the fetus into the placenta.

Twin-to-twin transfusion

Approximately 70% of identical twin (monozygous) pregnancies share a placenta (monochorion). Vascular anastomoses within the placenta allow transfer of blood between the two fetuses. In about 15% of these monochorionic pregnancies the flow is sufficiently unbalanced to cause one fetus to become fluid overloaded with evidence of polyhydramnios and cardiac dysfunction, and the other to become anemic with evidence of poor renal function and oligohydramnios. This so-called twin-to-twin transfusion syndrome was previously diagnosed by a significant weight and hemoglobin discordance (>5 g/dL) at birth. Nowadays it is usually diagnosed antenatally by detection of markedly discrepant amniotic fluid volumes in the second trimester. Severe forms have a poor prognosis.¹³ Several *in utero* interventions are employed to try to minimize the morbidity and mortality associated with this condition. A recent randomized trial showed some benefit for laser ablation of vascular anastomoses compared with serial removal of amniotic fluid from the polyhydramniotic twin.¹⁴ However neither method was shown to be convincingly superior in all cases and further trials of intervention are indicated.

Obstetric accidents and malformations of the umbilical cord or placenta**Umbilical cord**

In precipitous unattended or traumatic forceps deliveries, a normal umbilical cord can rupture and result in fetal hemorrhage. In normal deliveries, rupture can occur if the cord is abnormally short, entangled around the fetus or if it has vascular abnormalities such as venous tortuosity or an aneurysm.¹⁵ Inflammation of the cord by meconium can weaken the vessels within it and predispose to rupture. If the hemorrhage is contained within the cord, a hematoma can form which can contain a large percentage of the fetal blood volume. In 1% of pregnancies there is a “velamentous” insertion of the cord into the edge of the placenta. This is more common in twin pregnancies and in pregnancies in which the placenta is low-lying (see below). In an estimated 1–2% of these pregnancies, fetal blood loss is significant and results in perinatal mortality of more than 60%.

Table 7.6 Classification of cranial bleeds in neonates.

	Clinical features	Risk factors	Timing	Outcome
Extracranial	<i>Subgaleal</i> : boggy swelling extending from orbital ridge to nape of neck (no limitation to spread) <i>Subaponeurotic/cephalhematoma</i> : swelling usually confined to one skull bone, i.e., does not cross sutures (extension limited by periosteal attachments)	Instrumental delivery, especially vacuum-assisted delivery, but 25% seen after normal vaginal delivery and 9% after cesarean section	Early: swelling apparent in first day of life	Can cause life-threatening hemorrhage. Once acute phase complete, recovery is usual. If large bleed, may see late hyperbilirubinemia, which is occasionally severe enough to require exchange transfusion
Intracranial (intraventricular, subarachnoid)	Diverse presentation from clinically asymptomatic to sudden collapse. Usually combination of bulging fontanelle, with neurologic signs: apnea, seizures, hypotonia. However, presentation may be with unexplained anemia alone	Prematurity, low birthweight, respiratory distress syndrome	Prenatal: very rare unless associated with hemorrhagic disorder such as NAIT 60% within first 24 hours 95% within first week	Depends on severity but can be associated with long-term neurologic sequelae

NAIT, neonatal alloimmune thrombocytopenia.

Placenta

Placenta previa and large placental abruptions can result in hemorrhage from both the fetal and maternal sides of the placenta and lead to neonatal anemia in surviving fetuses.¹⁶ Fetal blood vessels in vasa previa are supported by the umbilical cord or placental tissues and traverse the amniotic sac in the lower segment of the uterus. If these vessels precede the presenting part during vaginal delivery they are at high risk of occlusion or laceration and this can result in life-threatening hemorrhage. The incidence of this condition is around 1 in 6000 pregnancies and is thought to be commoner with *in vitro* fertilization. The diagnosis is initially suspected on antenatal ultrasound and confirmed by Doppler studies. Hemorrhage is prevented by elective cesarean section before the onset of natural labor.

Massive fetal hemorrhage can be associated with accidental incision of the placenta at cesarean section; this complication is more likely if the placenta is anterior and low-lying.

Internal hemorrhage

Internal hemorrhage following a traumatic delivery is a well-recognized cause of neonatal anemia, although improvements in obstetric care and the increasing use of cesarean section for potentially difficult deliveries has resulted in a considerable decline in this complication. Nevertheless, all deliveries carry a risk of fetal hemorrhage, particularly if the fetus is large, small or abnormal, if the delivery is instrumental, or if antenatal care has been poor. A coincidental coagulopathy in the neonate, such as vitamin K deficiency or hemophilia, is likely to worsen the extent of any traumatic hemorrhage.

The clinical signs of anemia due to internal hemorrhage often

present within 24–72 hours after birth, although with brisk hemorrhage their onset may be immediate, and are those of a shocked neonate with poor Apgar scores at delivery.

Cranial bleeds

Table 7.6 highlights the clinical features of extracranial and intracranial hemorrhage in neonates.^{17–20} Severity of hemorrhage is variable but can be severe.

Intraabdominal hemorrhage

Breech deliveries of large-for-gestational-age infants are at particular risk of intraabdominal hemorrhage, although this complication has been described following normal deliveries. The hemorrhage can involve the adrenals, kidneys, liver and spleen or the retroperitoneal space. Retroperitoneal hemorrhage can present with bluish discoloration of the skin of the flank and sometimes a palpable mass and has been described following traumatic perforation or rupture of an umbilical artery by catheterization.

Rupture of the liver was previously reported in 1.2–9.6% of post-mortems carried out for investigation of stillbirth or neonatal death.²¹ Despite improvements in obstetric care over the last few decades, small subcapsular hemorrhages probably occur more frequently after traumatic births than is clinically appreciated, particularly in low-birthweight infants. The severity depends on whether the hemorrhage is confined within the capsule of the liver (abdominal swelling and anemia but potential recovery) or whether the capsule ruptures. This complication usually presents 24–48 hours after delivery, with free blood in the peritoneal cavity and rapid onset of shock. Radiography of the abdomen reveals free fluid, and paracentesis confirms the presence of blood in the peritoneum.

The prognosis is typically poor but infants do survive with prompt resuscitation, blood transfusion and surgical repair.

Splenic rupture secondary to extreme splenic distension associated with severe hemolytic disease of the newborn is now an exceedingly rare event in countries with anti-D prophylactic programs, but splenic rupture can occur after apparently normal deliveries, most often in large-for-dates infants.²²

Other sites

Pulmonary hemorrhage can occur in infants on ventilatory support, particularly in those born prematurely. Rarely, hemangiomas of the skin,²³ gastrointestinal tract²⁴ and thymus²⁵ can present with significant neonatal blood loss.

Iatrogenic blood loss

Despite the use of micromethods in modern neonatal practice, blood sampling losses in preterm babies is the commonest cause of neonatal anemia.²⁶ Blood sampling should be kept to a minimum and routine daily testing avoided if at all possible.

Anemia as a result of hemolysis

A hemolytic process is defined as a pathologic state that results in shortening of the normal red cell lifespan. Recognition of hemolysis, even if initially mild, is extremely important in the neonate as careful clinical monitoring and early intervention may prevent kernicterus and its sequelae. Neonatal hemolysis may be the first indication of an inherited red cell disorder, such as a red cell enzymopathy, a red cell membrane defect or a hemoglobinopathy, which will have consequences for the affected neonate throughout life. Neonatal anemia secondary to alloimmune hemolysis may have implications for future siblings.

In the neonate with hemolysis, hyperbilirubinemia may be a more prominent feature than anemia. The degree of anemia will depend on the rate of red cell destruction and the ability of the bone marrow to compensate by increasing red cell production. In addition, in some children, genetic variation in bilirubin conjugating mechanisms may lead to a disproportionately greater degree of hyperbilirubinemia than would be expected for the degree of red cell destruction (see discussion of G6PD deficiency below).

Laboratory results suggestive of hemolysis include:

- 1 the presence of persistently increased numbers of reticulocytes and/or nucleated red blood cells; although elevated at birth, these should normally be very low (<1%) by day 3 of life;
- 2 unconjugated hyperbilirubinemia especially in the first 48 hours after birth or an unusually high level;

- 3 a positive direct Coombs test (if immune in etiology);

- 4 characteristic red cell morphology (in some cases).

A Coombs test should be performed on any neonate suspected of having hemolytic anemia. A positive Coombs test suggests immune-mediated hemolysis (discussed in Chapter 8).

The major causes of nonimmune hemolysis are (i) red cell membrane disorders, (ii) red cell enzymopathies, (iii) hemoglobinopathies, (iv) infections (both congenital and acquired) and (v) macroangiopathic and microangiopathic processes.

Red cell membrane disorders

These may be suspected by a positive family history or characteristic red cell morphology on a blood film. The commonest inherited red cell membrane defect is hereditary spherocytosis, which has an incidence of 1 in 5000 births. Hereditary pyropoikilocytosis is significant in that it may result in a severe transfusion-dependent anemia during the neonatal period. Red cell membrane disorders are discussed in more detail in Chapter 12.

Hereditary spherocytosis

This is a group of disorders caused by various mutations in proteins that comprise the red cell cytoskeleton. The cytoskeleton is responsible for the maintenance of red cell shape, deformability and elasticity, and hence patients with hereditary spherocytosis (HS) have fragile abnormally shaped cells that are particularly susceptible to extravascular hemolysis in the spleen. The inheritance pattern is usually autosomal dominant and most mutations are private, i.e., unique to each affected family. This explains the clinical heterogeneity and similar course within families.^{27,28}

HS is commonly symptomatic in the neonatal period. In published series, 20–50% of affected individuals have a history of jaundice with or without anemia and mild splenomegaly in the newborn period.²⁹ Presentation is usually within the first 48 hours of life, but in 20% of neonates it is delayed beyond the first week. Severe anemia due to neonatal HS is rare, and the anemia is usually mild to moderate.

In the absence of a family history of HS the diagnosis is infrequently made in the neonatal period, when it is more difficult to confirm than later in childhood. The reticulocytosis and degree of splenomegaly can be variable and the number of spherocytes in the peripheral blood may not be significantly increased over the normal for this age group until the infant is 2–3 months of age. The haptoglobin level is an unreliable indicator of hemolysis in neonates. The osmotic fragility test, which is most commonly used to diagnose HS, is unreliable in the neonate, as the increased lipid content of the membrane of neonatal red cells renders them osmotically resistant. It is therefore important to perform an incubated

osmotic fragility test and to include a control neonatal sample. It is often more practical to make a presumptive diagnosis of HS based on the blood film features and clinical findings and to defer formal testing until the baby is 6–12 months of age. Examination of parental blood films, one of which may show the typical morphologic features of HS, can be diagnostically rewarding.

Newer tests, such as the eosin-5-maleimide (EMA) binding dye test, have a higher predictive value but are not yet routinely available. Protein electrophoresis of the membrane proteins may be informative where there is diagnostic difficulty.

The main differential diagnosis is with ABO incompatibility, where spherocytosis is a striking feature, but spherocytes can also be seen in bacterial sepsis, hemolytic transfusion reactions and oxidative red cell injury. Morphologically, ABO incompatibility and HS may be indistinguishable. Maternal and infant blood groups and a Coombs test may be helpful, but if not, family studies may help differentiate HS from acquired conditions, as will the passage of time.

Management

The management is that of hyperbilirubinemia, which can usually be controlled with phototherapy, although kernicterus is a risk and exchange transfusion may be required. Hyperbilirubinemia may appear late and therefore babies born to parents with known HS should be carefully observed for jaundice during the first few days of life. Similarly it is important to monitor for the development of anemia, especially in those infants who do not mount an adequate reticulocyte response. Anemia may be more common in HS in the neonatal period than previously recognized. The hemoglobin is usually normal at birth but can drop precipitously during the first 5–30 days.²⁹ Transfusion is sometimes necessary but continued transfusion dependence is unusual. In these rare severe cases, erythropoietin may reduce or prevent the need for red cell transfusions.³⁰

Supplementary dietary folic acid is recommended.²⁷ There is no evidence that children with HS who are symptomatic as neonates have a more severe form of the disease in later life.

Hereditary elliptocytosis and hereditary pyropoikilocytosis

These are a heterogeneous group of membrane disorders characterized by defective horizontal interactions between membrane proteins. There is some confusion with the nomenclature of these disorders, with “infantile poikilocytosis”, “pyropoikilocytosis” and “pyknocytosis” all being used in the literature. There is no merit in this subclassification and all these disorders can be generically classified as hereditary pyropoikilocytosis (HPP). The diversity is not surprising as the genetic basis is complex, with hereditary elliptocytosis (HE) and HPP coexisting in the same families. HPP can be seen in homozygotes for HE mutations, in compound

heterozygotes for two different HE mutations, or in individuals who inherit one HE mutation and a low expression spectrin allele such as α LELY.²⁸

The commonest form of this condition, HE, is inherited in an autosomal dominant manner and other than the finding of 25–75% elliptocytes on the blood film, is generally a benign condition which does not cause any clinical symptoms.

In contrast, HPP results in a moderate to severe hemolytic anemia and jaundice and is morphologically characterized by marked red cell budding, fragmentation and variation in red cell shape (poikilocytosis). The blood film is very characteristic and HPP is one of the few causes of a low MCV (<70 fL) in neonates, the others being α -thalassemia and chronic iron deficiency. The correct diagnosis may be confirmed by examination of parental blood films when one or both may show features of classical HE.

The reason for the particularly severe phenotype seen in neonates is not well understood but may be related to the elevated free 2,3-diphosphoglycerate (2,3-DPG) levels in fetal cells, which may weaken spectrin–actin bonds leading to increased fragility.³¹

Management of HPP

In its milder forms, red cell fragmentation and subsequent hemolysis decline in the infant and the benign clinical picture of mild HE emerges by 6 months to 2 years of age. Supportive care with folic acid supplements and the judicious use of red cell transfusion is indicated. Investigations such as membrane protein analysis, osmotic fragility or EMA binding dye tests should be performed prior to transfusion.

In more severe cases, the red cell abnormalities do not improve with time and hemolysis persists with severe anemia, splenomegaly and early gallstone formation. Regular transfusion is necessary. Splenectomy is often effective at reducing or abolishing the transfusion requirement but is usually deferred until at least 3 years of age to reduce the risk of postsplenectomy sepsis.

Infantile pyknocytosis

This describes the association in early infancy of hemolytic anemia with unusual red cell morphology. The red cells are distorted, irregular and small with many projections. Spontaneous resolution is usual by 4–6 months of age. This disorder is probably heterogeneous and results from a number of different pathologies and has been described in association with HPP, glucose 6-phosphate dehydrogenase (G6PD) deficiency, and electrolyte disturbance. The term is therefore not useful and should probably be abandoned.³²

Rare membrane defects

Dehydrated hereditary stomatocytosis is an inherited hemolytic anemia characterized by increased membrane

permeability to sodium and potassium ions. It may be confused with HS. Although rare, it is associated with neonatal hepatitis and is a cause of perinatal ascites and therefore should be included in its differential diagnosis.³³

Red cell enzyme deficiencies

Inherited disorders of red cell metabolism are an important cause of hemolytic anemia in early life (see also Chapter 9). Most enzymopathies have no distinct red cell morphology and their diagnosis depends on their inclusion in the differential diagnosis of hemolytic anemia in this age group. A family history and awareness of ethnicity may be helpful. Jaundice is again the prominent clinical finding but anemia can arise if the hemolysis is severe.

Glucose 6-phosphate dehydrogenase deficiency

This is the commonest of the red cell enzyme deficiencies. It is an X-linked disorder seen in individuals from the Mediterranean, Africa and Asia, and over 150 variants have been identified.³⁴ Female carriers are affected only if the normal gene on one X chromosome is inactivated by extreme lyonization.

G6PD is the first enzyme in the hexose-monophosphate shunt and is important in NADPH generation and in the regeneration of reduced glutathione, which protects the red cell from oxidative damage. Exposure to oxidant drugs, infection, acidosis or ingestion of fava beans can lead to denaturation of hemoglobin and extravascular hemolysis.

In global terms, G6PD deficiency is the commonest cause of severe neonatal jaundice. A family history or the ethnic origin may suggest the diagnosis. The onset of jaundice is often delayed until the second or third day of life and can be confused with “physiologic” jaundice, although the peak bilirubin is usually much higher. The degree of jaundice is often disproportionally high for the rate of hemolysis. Recent evidence suggests that decreased bilirubin conjugation and elimination play a major role in the pathogenesis of neonatal jaundice. There is an association between the degree of hyperbilirubinemia and the coinheritance of Gilbert syndrome due to a polymorphism in the promoter of the gene uridine diphosphate glucuronyltransferase (UGT1A).³⁵ Other genetic polymorphisms may also be involved.³⁶

Although rare, massive acute hemolysis can occur, with or without obvious exposure to oxidant compounds, and may be fatal.³⁷

The blood film is usually normal, although microspherocytes may be seen in severe cases. The diagnosis may be confirmed by enzyme assay but this may be within normal limits in the presence of a brisk reticulocytosis because reticulocytes have higher G6PD levels than mature red cells and in such circumstances the assay should be repeated when the acute hemolytic episode has subsided. Preterm infants

have higher G6PD levels than term infants but this does not usually preclude the diagnosis.

Management

Early phototherapy is indicated and exchange transfusion may be necessary in severe cases. Parents and medical staff should be educated about avoidance of exposure to oxidant drugs and compounds. Maternal exposure to oxidant drugs may cause hemolysis in the neonate via transplacental transfer and has been reported for methylene blue and maternal ingestion of fava beans. Naphthalene, a major component of mothballs, is the most common domestic trigger for acute hemolysis. A list of drugs to be avoided can be found in the British National Formulary. Fat-soluble preparations of vitamin K (phytomenadione) are safe and all babies should receive vitamin K prophylaxis either intramuscularly or as an oral colloidal formulation. In contrast, water-soluble preparations of vitamin K (menadiol sodium phosphate) have been reported to cause severe hemolysis and are contraindicated. Folic acid supplements are not generally indicated except in severe variants associated with chronic hemolysis.

Pyruvate kinase deficiency

This is the second commonest red cell enzyme deficiency associated with neonatal hemolysis and the commonest red cell enzyme deficiency of the Embden–Meyerhof pathway. However, pyruvate kinase deficiency is relatively uncommon.³⁸ It is autosomal recessive in inheritance, and is primarily seen in northern Europeans, in whom there is wide variation in expression of the disorder although the severity remains fairly constant within a family. The block in the glycolytic pathway caused by pyruvate kinase deficiency results in an increase in 2,3-DPG levels. This improves oxygen delivery to the tissues and helps alleviate the clinical and biochemical effects of the anemia. However, in the neonate the hemolysis can be particularly severe, with jaundice developing within the first 24 hours of life associated with anemia, reticulocytosis and splenomegaly. Hydrops fetalis has been reported in severely affected families. Exchange transfusion is frequently required to avoid the risks of kernicterus. Infants who present at birth appear to have more severe hemolysis in later life. The blood film shows features of non-spherocytic hemolysis with a reticulocytosis and nucleated red blood cells. Irregularly contracted cells are seen in some but not all cases. Diagnosis can usually be made by direct enzyme assay or by demonstrating the carrier state in both parents. Although affected individuals usually have enzyme levels of about 5–40% of normal, there is not a good correlation between enzyme activity as measured *in vitro* and clinical severity and occasional patients with severe pyruvate kinase deficiency have completely normal enzyme activity when assayed by conventional methods. In these individuals, measurement of metabolic intermediates may demonstrate

blockade at the pyruvate kinase step. Later, if multiple transfusions are required, splenectomy may lessen the transfusion requirement.

Glucose phosphate isomerase deficiency

This is the third commonest red cell enzymopathy and one-third of affected individuals develop symptoms in the neonatal period. Hydrops fetalis has been described.³⁹ Inheritance is autosomal recessive and the clinical manifestations and morphologic features are similar to those of the other congenital nonspherocytic anemias.

Other enzymopathies

Other enzymopathies should be considered. Neonatal hemolysis may be the only presenting feature of conditions such as triose phosphate isomerase deficiency that have severe sequelae later in infancy and childhood. Clinical features and appropriate tests are discussed in Chapter 9.

Hemoglobinopathies (see also Chapters 10, 11 and 13)

As previously discussed, red blood cells contain approximately 80% HbF ($\alpha_2\gamma_2$) and 20% HbA ($\alpha_2\beta_2$) at birth. Therefore hemoglobinopathies presenting in the neonatal period involve abnormalities of the α or γ chains. Abnormalities affecting γ -globin may be associated with severe clinical manifestations at birth which subside when the switch from fetal to adult hemoglobin occurs. The α -chain defects may behave differently in neonates compared with older infants and children, because in the neonatal period the α -chain is predominantly paired with a γ -chain to form HbF, whereas in later infancy onwards it is paired with a β -chain to form HbA. Because β -globin synthesis is limited in the newborn, defects involving the β -globin gene rarely manifest in the first weeks of life.

Neonatal screening for hemoglobinopathies is now routinely performed in some countries and will lead to the increased detection of these disorders in the neonatal period, allowing early intervention.⁴⁰

Globin-chain structural abnormalities

Most α -chain structural abnormalities have no clinical consequences in neonates or adults and most infants with these mutations are detected only by routine neonatal screening programs. Occasionally, an α -chain variant may be clinically significant in the neonate, but not in the adult. Hb Hasheron ($\alpha_2^{14\text{Asp}\rightarrow\text{His}}\beta_2$) can present as a transient hemolytic anemia in the newborn period because this α -chain variant is unstable when it associates with γ -globin but not β -globin chains. The hemolysis in the neonate resolves with transition from the fetal to the adult form of Hb Hasheron trait. Other rare α -

chain variants include Hb Taybe, which may be sufficiently unstable to cause hemolysis of a degree that can lead to hydrops fetalis.

Structural variants of the γ -chain also rarely cause clinical problems; if they do, these resolve as the γ to β switch occurs. HbF Poole is an unstable γ -chain variant that can be associated with a significant hemolytic anemia in the neonatal period.

Neonatal sickle cell disease

Although β -chain abnormalities can be detected at birth using sensitive electrophoretic techniques, they do not usually cause clinical problems. The newborn with the commonest β -chain variant, sickle cell disease, is usually asymptomatic in the first few months of life due to the presence of HbF, which interferes with HbS polymerization within the red cell. However, hyperbilirubinemia may be more common in neonates with sickle cell disease than in the normal population and there has been a report of fatal sickling in a 5-day-old baby.⁴¹ Despite the relative lack of symptoms in the majority of babies with sickle cell disease, it is important that they are started on penicillin prophylaxis and referred to a comprehensive care provider early for parental education, support and other preventive measures including pneumococcal vaccination. There is emerging evidence that such interventions reduce morbidity and mortality in this disease.^{42,43}

Defective hemoglobin synthesis: the thalassemia syndromes (see also Chapter 13)

α -Thalassemias

A reduced rate of α -globin chain synthesis characterizes the α -thalassemias, which usually arise from a deletion of one or more of the four α -globin genes. In the presence of α -globin gene deletions, excess γ chains accumulate within the red cell and form a tetramer called Hb Barts (γ_4). The amount of Hb Barts is proportional to the number of affected α -globin genes. Clinical and laboratory features depend on the number of genes deleted as described below.⁴⁴

- Silent carrier α -thalassemia (α^+ -thalassemia) occurs when one gene is deleted and is associated with a mild elevation of Hb Barts at birth (<2%) but no clinical manifestations.
- α -Thalassemia trait (α^0 -thalassemia) occurs when two genes are deleted. The diagnosis is simpler in neonates than adults. It is the commonest cause of microcytic red cell indices (MCV < 95 fL), which are otherwise very rare in this age group. The diagnosis is confirmed by detection of an elevated level of Hb Barts of around 3–10% at birth, which disappears by 3 months of age after which the diagnosis is more difficult to make. This disorder is common in Southeast Asia, with an incidence of about 20% compared with 2–5% in African populations. In the latter, the α -thalassemia gene mutations are almost invariably on different chromosomes, i.e., the abnormal gene is always linked to a normal gene.

Consequently, offspring from two African α -thalassemia trait individuals will not inherit more than two α -thalassemia genes.⁴⁵ In Southeast Asians, the two gene mutations are usually on the same chromosome and if both parents pass on their affected chromosome, a four-gene deletion results (see below).

- If three α genes are deleted, HbH disease results. HbH consists of β^4 tetramers, is unstable, precipitates within the red cell and can be demonstrated by incubation of the blood with supravital oxidizing stains such as methylene blue. It can also be detected on hemoglobin electrophoresis or high-performance liquid chromatography (HPLC). HbH disease presents in the neonatal period with a significant microcytic, hemolytic anemia and a level of Hb Barts ranging from 20 to 40%. By 3 months of age, when the γ to β globin switch occurs, Hb Barts disappears and is replaced by HbH. Infants with HbH disease may require transfusion for severe anemia at birth but outwith this period the severity of the anemia is variable but often mild. The combination of two α gene deletions on one chromosome and a nondeletional α gene mutation on the other chromosome (e.g., Hb Constant Spring) may produce a particularly severe form of HbH disease that may be associated with hydrops fetalis.

- When all four α genes are deleted, no α -chain synthesis occurs, no HbF or HbA are produced and homozygous α -thalassemia results. This is a common cause of fetal death throughout Southeast Asia. These fetuses invariably become hydropic due to severe intrauterine anemia in the second or third trimester and are stillborn or die soon after birth. Those who survive to birth have a hemoglobin level of around 6–8 g/dL, with severe thalassemic changes on the peripheral blood film: microcytosis, hypochromia, poikilocytosis, target cells and nucleated red cells. The hemoglobin consists of approximately 80% Hb Barts, with the rest being the embryonic hemoglobin Hb Portland ($\zeta_2\gamma_2$). Hb Barts has an oxygen dissociation curve like myoglobin and is therefore unable to deliver oxygen to tissues. Intrauterine transfusions followed by a postdelivery transfusion program or hematopoietic stem cell transplantation have been reported to result in occasional survivors.⁴⁶ This disorder must be distinguished from other causes of hydrops fetalis due to severe anemia. In future, it is possible that *in utero* stem cell transplantation or gene therapy may be curative.

β -Thalassemias

Homozygous β -thalassemia does not cause symptoms in the newborn but during the γ to β globin switch, a microcytic anemia develops, nucleated red cells appear on the blood film and high levels of HbF persist. Any disorder that significantly alters the survival of fetal red cells, such as intrauterine blood loss or blood group incompatibility, can unmask β -thalassemia clinically at a younger age. Although generally asymptomatic, patients with β -thalassemia major can be detected by newborn screening by the presence of HbF alone on

Hb electrophoresis or HPLC. This is not diagnostic and can be seen in patients with hereditary persistence of fetal hemoglobin (see Chapter 11) mutations or in premature neonates.⁴⁷

$\gamma\beta$ -Thalassemia

The β -globin cluster on chromosome 11 comprises closely linked genes that encode for embryonic (ϵ), fetal ($^G\gamma$ and $^A\gamma$) and adult (δ , β) globin chains. There are two γ genes on each chromosome termed $^G\gamma$ and $^A\gamma$ which differ in a single amino acid at position 136 (glycine and alanine respectively). Deletions of γ genes usually involve adjacent δ , β and sometimes ϵ genes also. Deletion of one γ gene is seen in $^G\gamma(^A\gamma\delta\beta)^0$ -thalassemia. Homozygotes may have thalassemia intermedia and heterozygotes have a thalassemia trait-like picture with high HbF levels. $(\epsilon\gamma\delta\beta)^0$ -Thalassemia involves deletion of both $^G\gamma$ and $^A\gamma$ on the same chromosome. Homozygous deletions have not been described, presumably because they would result in no fetal hemoglobin production and therefore be incompatible with *in utero* survival. Heterozygotes for $(\epsilon\gamma\delta\beta)^0$ -thalassemia have a variable clinical phenotype but neonates may have a severe transfusion-dependent microcytic hemolytic anemia, and hydrops fetalis has been reported.⁴⁸ The disorder often improves with time, resembling β -thalassemia trait after 6 months of age when the switch to adult globin chain synthesis has been completed.

Infection

Both intrauterine and postnatally acquired infections can be associated with anemia in addition to other hematologic abnormalities in the neonatal period. The anemia may be multifactorial and due in part to marrow suppression and decrease in red cell production and in part to hemolysis. In severe bacterial sepsis, the hemolysis develops because of infection-induced small vessel damage and fibrin deposition, which can damage red cells and result in disseminated intravascular coagulation (see below).

Infections acquired by hematogenous spread *in utero* and associated with hemolysis include toxoplasmosis, cytomegalovirus, congenital syphilis and rubella (Table 7.7).⁴⁹ Herpes simplex infections are generally acquired from the cervix and vagina during delivery. The hemolytic process is thought to arise from direct injury to the red cell membrane or reticuloendothelial hyperplasia. Occasionally, antibody produced in response to infection can cross-react with antigen on the surface of the red cell producing a positive direct Coombs test leading to immune-mediated hemolysis.

Clinical suspicion of intrauterine infection in the neonate with hemolysis is often triggered by the associated findings of jaundice, chorioretinitis, pneumonitis, central nervous system abnormalities, growth retardation, skin lesions or hepatosplenomegaly. If the spleen is enlarged, hypersplenism can increase the rate of red cell destruction. Laboratory features include thrombocytopenia, leukocytosis with

Table 7.7 Congenital infections that may be complicated by anemia in the neonatal period.

Infection	Proportion of babies with any symptom of the infection	Laboratory features of the anemia
Cytomegalovirus	<10%	Hb 8.0–120 g/dL in first week Hb 5–10 g/dL at 3– weeks with reticulocytosis Blood film: poikilocytes, NRBCs
Herpes simplex	>90% have generalized disease	Mild microangiopathic changes
Rubella	>90% if infected in first trimester, less in second trimester	Mild anemia in 15–30% of infected infants Exaggerated postnatal decline in Hb
Toxoplasmosis	30–50%	Anemia in 40–50% of infected infants. Can be severe (Hb < 8.0 g/dL) and cause hydrops fetalis Reticulocytosis NRBCs on blood film
Syphilis	15% if mother untreated	>90% of infected infants are anemic. Can be severe (Hb < 8.0 g/dL). Reticulocytosis and NRBCs on blood film
Malaria	10% in endemic areas	Can be severe and life-threatening Reticulocytosis Parasitemia on blood film
Parvovirus	<10%	Reticulocytopenic anemia which can be mild to severe and cause hydrops fetalis Giant pronormoblasts in bone marrow with general erythroid hypoplasia

NRBCs, nucleated red blood cells.

immature forms (left shift), reticulocytosis and large numbers of nucleated red cells. Hyperbilirubinemia may be both conjugated and unconjugated due to the coexistence of hepatitis and hemolysis. The diagnosis is confirmed by serology or direct isolation of the infective agent from blood or an alternative site.

Although malaria remains a major health hazard in many parts of the world, vertical transmission appears to be rare, but when it does occur it can cause severe fetal infection and stillbirth.⁵⁰ All four species can produce congenital infection. The placenta is a preferential site for reproduction and growth of the malarial parasite, but also acts as a relative barrier to fetal infection. Maternal IgG crosses the placenta and provides additional protection to the fetus, which explains why congenital malaria is much commoner in infants born to nonimmune mothers. If the parasites are not eradicated, they may enter a latent phase that can delay presentation of malaria in the infected neonate for several weeks. Features of malaria in the newborn include fever, irritability, hepatosplenomegaly and jaundice as well as anemia, which is usually severe with associated reticulocytosis.

The diagnosis of congenital malaria requires a high index of clinical suspicion. The blood film should be carefully examined following suitable staining and blood should be sent for serologic testing to a reference laboratory that specializes in tropical diseases. If the diagnosis is suspected at birth, usually because the mother has been treated for

malaria in pregnancy, the placental bed can be examined for the parasite and treatment instituted in the first days of life to prevent subsequent severe sequelae.

Parvovirus infection is discussed in the section on impaired red cell production.

Macroangiopathic and microangiopathic neonatal anemias

Macroangiopathic anemia

Severe cardiac defects, renal artery stenosis and large-vessel thrombi have been reported to cause hemolysis in the newborn by shear-related disruption to the red cell membrane and/or interaction of red cells with abnormal surfaces within the heart. The blood film may be very abnormal, with geometric red cell fragments. Thrombocytopenia and a coagulopathy may be present.

Disseminated intravascular coagulation

This is a common complication of neonatal infection, particularly bacterial infection. It can also be associated with severe birth asphyxia, respiratory distress syndrome, hypovolemia and hypothermia. A microangiopathic process results from red cell injury in partially occluded small blood vessels where red blood cells can be damaged by passage through

fibrin strands or by trapping by damaged endothelium. There is accompanying thrombocytopenia and coagulopathy (see Chapter 29).

Hemangiomas

A microangiopathic hemolytic anemia can also occur in association with a giant hemangioma, i.e., Kasabach–Merritt syndrome. This can present at birth or during infancy. The predominant findings are of profound thrombocytopenia with anemia, hypofibrinogenemia and coagulopathy. Early recognition is important because the syndrome can be associated with considerable morbidity and mortality.⁵¹

Congenital thrombotic thrombocytopenic purpura

This is an inherited form of thrombotic thrombocytopenic purpura due to deficiency of von Willebrand cleaving protease (ADAMTS13). It can present in the neonatal period with thrombocytopenia, severe hyperbilirubinemia and a microangiopathic hemolytic anemia.⁵²

Anemia secondary to impaired red cell production

With the exception of the physiologic anemia of prematurity, anemia secondary to impaired red cell production is relatively uncommon in the neonatal period. However, anemia due to inherited disorders associated with failure of red cell production, congenital infection and nutritional deficiencies or inborn errors of metabolism that affect absorption, transport or metabolism of heme precursors can present in the neonatal period. Rarer causes of impaired red cell production at this age include congenital leukemia, Down syndrome with transient abnormal myelopoiesis, and osteopetrosis.

Inherited disorders of failure of red cell production

Inherited disorders of red cell production are all rare. Even in the neonatal period, failure of red cell production may be part of a pancytopenia, suggesting involvement of the stem cell, or a single cytopenia, suggesting involvement of committed erythroid progenitors. Some disorders typically present in the neonatal period and others more commonly outwith. Some disorders are associated with congenital abnormalities and others are not.

Diamond–Blackfan anemia

Diamond–Blackfan anemia is an uncommon inherited condition characterized by failure of erythropoiesis that results in a normochromic and usually macrocytic anemia with reticu-

locytopenia. The white cell and platelet counts are usually normal in infancy. The bone marrow shows an absence or a marked reduction in erythroid precursors. About 10% of patients are anemic at birth, 25% by 1 month of age and 90% by the end of the first year of life.⁵³ Infants presenting with hydrops fetalis have been reported.^{54–56}

Approximately 10% of affected infants are of low birth-weight (<2500 g).⁵³ Physical anomalies are seen in about 30% of patients and those evident in the neonatal period include microcephaly, cleft palate, flat thenar eminence, thumb deformities, web neck and eye anomalies.

The majority (75%) of cases are sporadic, but both autosomal dominant and autosomal recessive inheritance is described. Multiple genes for the disease probably exist but only the RPS 19 mutation has been identified to date. In patients without an identified mutation, the finding of elevated erythrocyte adenosine deaminase levels (measured before transfusion) helps support the diagnosis.

Steroid therapy should be instigated when the diagnosis is confirmed and the majority respond, at least initially. However, steroids started in early infancy have the potential to impair growth at the time when it is maximal and interfere later with routine infant immunizations.

Congenital dyserythropoietic anemia

Congenital dyserythropoietic anemia (CDA) is an uncommon inherited cause of anemia characterized by ineffective erythropoiesis and dysplastic morphology. The anemia is usually mild to moderate, but can be more severe and transfusion dependent. Very rarely it is severe enough to result in hydrops fetalis.^{57,58}

CDA type 1 is characterized by macrocytic anemia, megaloblastic erythroid hyperplasia and nuclear chromatin bridging in bone marrow erythroid precursors with characteristic ultrastructural features on electron microscopy. In a retrospective review of 31 patients, about 50% had been investigated for anemia and early jaundice in the neonatal period, and had required blood transfusion during the first month of life.⁵⁹ Although the diagnosis of CDA type 1 is not usually made in the neonatal period, this study suggests that it should be considered in the differential diagnosis of neonatal anemia.

Hydrops fetalis has been reported secondary to profound anemia associated with atypical CDA characterized by peripheral blood, bone marrow and electron microscopy features resembling CDA type II, but with a negative acidified serum lysis test (Ham test).^{57,58} These infants had remarkably similar hematologic findings of binuclear erythroblasts in the peripheral blood and erythroid hyperplasia with binuclear to multinuclear erythroblasts in the bone marrow. Fetal loss and consanguinity were common. Infants who survived were transfusion dependent and some received intrauterine transfusion.⁵⁷

Pearson syndrome

Pearson syndrome, which is characterized by sideroblastic anemia and exocrine pancreatic dysfunction, results from a deletion of mitochondrial DNA. The anemia is usually macrocytic and presents before 1 month of age in 25% and by 6 months of age in 70% of affected individuals.⁵³ Hydrops fetalis has been reported.⁶⁰ Myeloid and erythroid precursors are vacuolated and sideroblasts, usually ring sideroblasts, are present in the bone marrow. Support with blood transfusion may be required.

Fanconi anemia

Fanconi anemia is characterized by increased chromosome breakage, progressive pancytopenia, predisposition to malignancy and an autosomal recessive pattern of inheritance. Associated congenital abnormalities include short stature (unhelpful diagnostically in the neonate), skin pigmentation, microphthalmia, genitourinary abnormalities and defects of the thumbs and radii. However some patients only have hematologic abnormalities and lack the congenital nonhematologic anomalies. Bone marrow failure generally starts during early school years, but hematologic presentation does occasionally occur in the neonatal period, and while this is most commonly with thrombocytopenia, there are reports of pancytopenia in this age group. Therefore Fanconi anemia should be considered as a cause of neonatal anemia and/or thrombocytopenia even in the absence of the typical congenital anomalies.⁶¹

Physiologic anemia of infancy/prematurity

The healthy term infant has a hemoglobin of around 16.5–18.5 g/dL; the level is influenced by a number of factors previously described, including the timing of cord clamping. The infant's hemoglobin remains reasonably stable during the first week of life and thereafter declines to reach a nadir of 10.5–12.5 g/dL by 8–10 weeks,² and this is referred to as the physiologic anemia of infancy. The hemoglobin concentration in the preterm infant is similar to that of the term infant at birth but the postnatal physiologic fall in hemoglobin, termed the physiologic anemia of prematurity, reaches its nadir earlier (4–8 weeks), is more profound (around 8 g/dL) and in both speed of onset and degree is directly related to the infant's gestation.

Pathophysiology of the anemia of infancy/prematurity

- Erythropoietin does not cross the placenta but is produced by the fetus. Levels rise with increasing gestation and are high in cord blood.¹ High erythropoietin levels are thought to be a physiologic response to low intrauterine oxygen tension and to be responsible for the infant's high hemoglobin at

birth. The increase in oxygen tension after birth results in marked erythropoietin suppression, leading to almost undetectable levels and a subsequent fall in red cell production. The decline in hemoglobin production in the term infant reaches a nadir at 2 weeks of age, but in preterm infants may happen soon after birth, which is the reason that their hemoglobin nadir occurs earlier.

- Erythropoietin levels fall after birth and remain inappropriately low for the level of hemoglobin associated with the anemia of infancy and prematurity. This blunted response may partly be due to the fact that at this age the switch from liver to kidney as the site of erythropoietin production is incomplete and the liver may be less sensitive than the kidney to hypoxia. The number of erythroid progenitor cells have been shown to be relatively low for the degree of anemia, presumably secondary to a lack of erythropoietin drive, but burst forming unit-erythroid (BFU-E) colonies retain normal responsiveness to erythropoietin.^{62,63}
- Pharmacokinetic studies in animal models and preterm infants have shown that preterm infants require higher doses of recombinant human erythropoietin (r-HuEPO) because of more rapid clearance and greater volume of distribution; this may contribute to the preterm's low erythropoietin levels.
- Other factors that contribute to the severity of the anemia include rapid growth in the first few weeks of life with an increase in blood volume but no increase in red cell mass, shortened red cell survival in neonates, iatrogenic blood losses from blood sampling, and hematinic deficiencies.

Treatment of the anemia of prematurity

r-HuEPO is widely used in the management of preterm infants to reduce their transfusion requirements associated with the anemia of prematurity. However, there are many unanswered questions about r-HuEPO therapy in premature infants, including which preterms benefit, the optimal dose and scheduling of r-HuEPO, the optimal dose and route of iron and folate supplementation, and the appropriateness and safety of parenteral iron supplementation.⁶⁴

The aim of r-HuEPO is to reduce both the number of infants who require any transfusion and the total number of transfusions required by those infants who cannot avoid transfusion because of their extreme prematurity. r-HuEPO has been shown to reduce the transfusion requirements of preterm infants weighing more than 1000–1250 g at birth,⁶⁵ although this is a group that less often requires transfusion and minimization of phlebotomy losses and stringent adherence to a transfusion policy is an attractive alternative.⁶⁶ The evidence for infants with a birthweight of less than 1000–1250 g is less convincing.

In a recent study, 172 preterm infants with a birthweight of 401–1000 g were randomized to receive r-HuEPO at a dose of 400 units/kg three times weekly or placebo supplemented with enteral and parenteral iron starting 4 days after birth.

There was no difference in the number of transfusions received by treated and control infants (4.3 ± 3.6 vs. 5.2 ± 4.2 respectively). Likewise, 118 infants with a birthweight of 1001–1250 g were similarly randomized and in this group there was no difference between treated and control infants in the number who received at least one transfusion (37% vs. 42% respectively). Hematocrits and reticulocyte counts were higher in treated infants and ferritin levels higher in controls. Therefore although r-HuEPO with iron supplementation stimulated erythropoiesis in infants weighing < 1250 g at birth, it did not impact on their transfusion requirements either by reducing the number of preterm infants who were exposed to allogeneic donor blood or the total number of transfusions required by preterm infants with a birthweight < 1000 g.⁶⁷

Anemia during the first 2 weeks of life results predominantly from phlebotomy losses and the use of r-HuEPO during this period remains controversial. A multicentre, randomized, placebo-controlled trial investigated whether early administration reduced the total number of transfusions and in particular those required during the first 2 weeks of life; 114 preterms with a birthweight < 1250 g were randomized to receive r-HuEPO 1250 units/kg i.v. weekly or placebo from day 2 to day 14 of life. Subsequently, all patients received 750 units/kg s.c. weekly for an additional 6 weeks. All infants received oral iron 6 mg/kg daily and folic acid 2 mg daily. The early administration of r-HuEPO resulted in a higher hematocrit and reticulocyte count but this did not translate into a reduction in the total number of transfusions required during the first 2 weeks of life. A subgroup of the most severely ill infants (birthweight < 800 g and phlebotomy losses > 30 mL/kg) who received early r-HuEPO required fewer transfusions after the second week of treatment. Thrombocytosis (platelet count > $500 \times 10^9/L$) and neutropenia (neutrophil count < $1.0 \times 10^9/L$) were observed in 31% and 13% of infants respectively during treatment with r-HuEPO, but both were transient and unassociated with adverse events.⁶⁸

Serum ferritin levels fall and red cells become hypochromic in infants who receive r-HuEPO. The optimal dose and route of iron supplementation to achieve the best response to r-HuEPO is not known or whether iron insufficiency limits the effectiveness of r-HuEPO. The American Academy of Pediatrics recommends a dose of 6 mg/kg daily,⁶⁹ but ferritin levels have fallen after even higher doses.⁷⁰ High oral doses may supply sufficient iron for erythropoiesis but storage iron may be depleted. Intravenous iron appears to maintain better serum ferritin concentrations and some have suggested that it be considered for patients with a low ferritin or those not established on enteral feeding.⁷¹ Consideration should be given to the use of vitamin E with parenteral iron for its antioxidant properties. In a recent study, 42 preterm infants (<33 weeks and birthweight < 1500 g) received r-HuEPO 600 units/kg weekly and

were randomized to receive oral ferrous lactate (12 mg/kg daily) or intravenous iron sucrose (6 mg/kg weekly). The hematocrit, reticulocyte count and number of transfusions were similar in both groups. Markedly higher ferritin levels ($P < 0.001$) were reported in the group receiving intravenous supplementation, the number of hypochromic cells was significantly greater ($P = 0.04$) in the group receiving oral supplementation, although present in both, and the mean daily weight gain greater ($P = 0.04$) in the group receiving intravenous supplementation.⁷¹

The aim of r-HuEPO is to reduce exposure to allogeneic blood. An alternative approach is to collect placental blood (PB), fractionate and store it in additive solutions in the same manner that would be applied to allogeneic donor blood. A recently reported study of 52 neonates showed no difference in efficacy and safety between autologous PB–RBC (red blood cell) transfusion and allogeneic RBC transfusion. All infants with a birthweight < 1000 g, but only 59% with a birthweight of 1000–2500 g and 58% of those infants who received surgery directly after delivery required allogeneic blood in addition to PB–RBCs. The mean hemoglobin increase after RBC transfusion of 10 mL/kg was 3 g/dL per kilogram of body weight following both allogeneic and PB–RBC blood; the posttransfusion fall in hemoglobin occurred faster in the PB–RBC group (0.32 vs. 0.24 g/dL daily; $P < 0.05$). The investigators concluded that preterm infants weighing less than 1000 g could not be supported by PB–RBC alone, but 40% of those with a birthweight of 1000–2500 g could be.⁷²

In summary, r-HuEPO should be targeted at preterm infants for whom reducing phlebotomy losses and strict adherence to a transfusion policy cannot avert transfusion. Infants with a birthweight of less than 1000–1250 g are those with the greatest potential to benefit from r-HuEPO, because this is the group most likely to require transfusion. The evidence from controlled randomized trials is inconsistent but suggests that while r-HuEPO may reduce their total number of transfusions, it does not protect them from exposure to allogeneic donor blood. Neither does the use of autologous placental blood. Pedi-packs dedicated to one recipient continue to be important in reducing donor exposure. Further studies on the optimal dose and route of iron administration are required. r-HuEPO has the potential to reduce the risk of transfusion-related infection and appears safe but if iron supplementation is not optimal carries the risk of precipitating iron deficiency. Cost-effective use is important.

Infection

Congenital infection with cytomegalovirus, rubella, toxoplasmosis, herpes simplex and congenital syphilis often present with anemia but while this may be contributed to by marrow suppression, hemolysis generally plays a more important role. Adenovirus and particularly human parvovirus cause anemia by suppression of erythropoiesis.

Primary maternal infection with human parvovirus B19 during pregnancy can lead to intrauterine fetal infection resulting in profound anemia and nonimmune hydrops fetalis.⁷³ The virus infects bone marrow erythroid precursors and inhibits erythropoiesis. A retrospective review of consecutive cases of hydrops fetalis referred to a tertiary maternal fetal medicine center in the UK over a 30-month period implicated human parvovirus in 14.5% of those cases with a non-immune cause.⁷⁴ Most maternal infections with human parvovirus B19 cause no harm to the fetus and are associated with delivery of a healthy infant.⁷⁵ Fetal loss is highest when the infection occurs during the first 20 weeks of gestation.^{76,77} The risk of transplacental transmission associated with primary maternal infection with human parvovirus B19 has variably been reported as 33–50%,^{76,78} with a less than 5–9% risk of adverse outcome in the fetus.^{76,79} Human parvovirus B19 virions can be demonstrated in the erythroid precursors of hydropic infants.

Diagnosis in the second trimester is by the ultrasound findings of a hydropic infant, the appropriate maternal serology and anemia on fetal blood sampling, if this is done prior to intrauterine transfusion, which has been used successfully to treat a number of infants with profound anemia and hydrops. Less severely affected infants who are delivered without transfusion will be anemic, reticulocytopenic and have giant pronormoblasts in their bone marrow which contain the viral particles. Viral DNA can be detected in the infant's serum and antibodies to human parvovirus B19 in maternal serum. The neonate generally requires only supportive care with red cell transfusions until the anemia resolves.

Transient pancytopenia secondary to bone marrow failure has been reported in a 5-day-old infant and attributed to echovirus type 11. Symptoms arose before 7 days of life, suggesting perinatal transmission. The infant was anemic (hemoglobin 7.1 g/dL), reticulocytopenic and had a hypocellular bone marrow. Echovirus type 11 was isolated from the infant's stool. The hemoglobin and neutrophil counts recovered but the infant received high-dose intravenous immunoglobulin for persistent thrombocytopenia.⁸⁰

Virus-associated hemophagocytic syndrome has been reported in infants associated with Epstein–Barr virus, herpes simplex, cytomegalovirus and bacteria, and more recently following enteroviral infection.⁸¹ The anemia is part of a pancytopenia and secondary to macrophage hemophagocytosis of red cells in the bone marrow. A previously affected sibling, a history of consanguinity and an early age at onset may suggest familial hemophagocytic lymphohistiocytosis, but both familial and sporadic forms can be associated with infection.

In infants born to mothers with HIV the perinatal prophylactic administration of zidovudine is associated with a rapidly reversible macrocytic anemia, thought secondary to marrow suppression. A placebo-controlled trial identified a significant reduction in hemoglobin concentration in new-

borns during the 6 weeks of treatment that normalized from 12 weeks of life onwards.⁸²

Nutritional deficiencies

Hematinic deficiencies are rare in the neonatal period because the fetus is a successful parasite and unless maternal stores are extremely low will accumulate adequate stores by birth. However, the rapid growth which takes place in the neonatal period, particularly in the preterm infant, may deplete these.

Iron deficiency

Iron sufficiency is critical for rapidly developing fetal and neonatal tissue. Available iron is prioritized to hemoglobin synthesis in red cells when iron supply does not meet demands. Nonheme tissues such as skeletal muscle, heart and brain will become iron deficient before signs of iron deficiency anemia appear. Early iron deficiency appears to adversely affect cognitive development in infants, and the preterm infant may be at greater risk because of the relative immaturity and rapid growth rate of the preterm brain.⁸³

Two-thirds of total body iron present in the term infant is acquired during the third trimester and the iron accumulated during fetal life is relatively independent of maternal iron stores. Iron stores are rarely depleted in the term infant before 6 months of age but this can occur earlier in the preterm infant who has a faster growth rate and less stored iron at birth. Multiple factors⁸³ can affect the infant's highly variable iron stores and preterm infants are more vulnerable:

- Antenatal and perinatal hemorrhage: fetomaternal hemorrhage, twin–twin transfusion, placenta previa or abruption, hemorrhage from the umbilical cord.
- Delayed clamping of the umbilical cord increases and early clamping decreases circulating hemoglobin and available iron.
- Gestational conditions: severe maternal iron deficiency, maternal hypertension with intrauterine growth retardation, maternal diabetes mellitus.
- Postnatal hemorrhage: phlebotomy losses, gastrointestinal blood loss.
- Erythropoietin without iron supplementation.

In addition to their lower iron stores and rapid growth rate with its attendant increase in blood volume and hemoglobin concentration, preterm infants are more likely to have significant phlebotomy losses and to receive r-HuEPO. r-HuEPO not only utilizes iron but if it reduces transfusion requirements, it deprives the preterm infant of a potential source of exogenous iron.

The early postnatal fall in hemoglobin concentration in the preterm infant is accompanied by an earlier (1–2 months of age) recovery of erythropoiesis. With the onset of erythropoiesis the serum ferritin level falls. Nontransfused infants

who receive no iron supplementation have sufficient stores to sustain effective erythropoiesis only until they have doubled their birthweight.⁸⁴ Breast milk, cows' milk and unsupplemented formula are low in iron, although the iron in breast milk is more available. The American Academy of Pediatrics recommends iron supplementation at a dose of 2–4 mg/kg daily, up to 15 mg daily for preterm infants exclusively breast-fed, starting at 2 months of age, or when the birthweight doubles, and continued throughout the first year of life. Supplementation is not recommended for preterm infants receiving iron-fortified formula unless they are in negative iron balance or are receiving r-HuEPO. An incremented dose of iron of 6 mg/kg daily is recommended for those who receive exogenous erythropoietin or have pre-existing iron deficiency.⁶⁹ Even this dose may be inadequate to meet the iron needs of an optimal erythropoietin response.⁷¹ Iron stores are depleted and red cells become hypochromic following r-HuEPO administration even with high-dose iron supplementation.^{65,70,71} Early iron supplementation does not prevent or ameliorate physiologic anemia.

The main cause of iron loss in the preterm infant is through phlebotomy. Minimizing phlebotomy losses is important. Conservative transfusion practices with agreed transfusion thresholds are now common (see Table 7.8) and while these are to be supported, they may increase the risk of iron deficiency.

Indiscriminate iron supplementation should be avoided because of the poor antioxidant capabilities of preterm infants and the potential role of iron in several oxidant-related perinatal disorders. Preterm infants who are transfused may not need early iron supplementation. It may be important to maintain adequate vitamin E and ascorbic levels in the serum to prevent oxidative damage.

Inborn errors of iron metabolism

Iron metabolism is strictly regulated. There are relatively few genetic disorders that affect it and most are rare. Mutations in human genes regulating membrane iron transport causing simple iron deficiency have not yet been described.⁸⁵

- *Congenital atransferrinemia*. This is a very rare autosomal recessive condition that usually presents in the first few months of life and is characterized by a virtual absence of transferrin, resulting in a severe hypochromic anemia and tissue iron overload.
- *Inherited sideroblastic anemia*. These anemias are characterized by a failure to utilize iron for heme synthesis. This results in hypochromic red cells, ineffective erythropoiesis with an increased demand for iron leading to increased iron absorption, ring sideroblasts in the bone marrow and tissue iron overload. The inheritance may be X-linked, associated with a mutation in the erythroid-specific 5-aminolevulinate synthase gene and be pyridoxine responsive or autosomal recessive and pyridoxine refractory. The latter has been described in the neonatal period.⁸⁶

Vitamin B₁₂ deficiency

Vitamin B₁₂ deficiency with megaloblastic anemia has been reported in infants born to mothers with pernicious anemia.⁸⁷ The neonate's cobalamin level is directly related to maternal cobalamin levels and indirectly related to maternal metabolite levels of methylmalonic acid and homocysteine.^{88,89} Infants of mothers with very low vitamin B₁₂ levels who are exclusively breast-fed are at particular risk.⁹⁰ If untreated these infants can develop neurologic problems as well as hematologic ones. Treatment is with vitamin B₁₂, which should be given intramuscularly if the cause is thought to be malabsorption.

Megaloblastosis associated with cobalamin C disease, a cobalamin-related metabolic disorder, has recently been reported in a 28-day-old infant.⁹¹ The infant presented with failure to thrive, neurologic impairment, pancytopenia, megaloblastosis and hemolytic-uremic syndrome. The possibility of an underlying vitamin B₁₂ disorder was prompted by evidence of megaloblastic changes on the peripheral smear. Homocysteine and methylmalonic acid levels were elevated and the diagnosis confirmed by complementation studies using skin fibroblasts. Treatment was with parenteral hydroxocobalamin, carnitine and folinic acid.⁹¹

Folate deficiency

Folate deficiency is common in the preterm infant unless folate supplements are given. The preterm's rapid growth places it at particular risk of folate deficiency, which may be contributed to by additional factors such as infection, hemolysis, r-HuEPO administration and malabsorption secondary to diarrhea. Preterm infants routinely receive folate supplements. Rarely folate deficiency in the infant may be secondary to inherited disorders of absorption, transport and intracellular metabolism.

Management of neonatal anemia

This involves (i) identifying the cause of the anemia, (ii) preventive/prophylactic measures to lessen the anemia and/or hyperbilirubinemia and (iii) treatment which should only include red cell transfusion if absolutely indicated.

Diagnosis

The approach to diagnosis has been covered in the preceding sections and specific problems or issues related to diagnosis in the neonatal period highlighted.

Preventive/prophylactic measures

- 1 Routine blood sampling, the major cause of iatrogenic

blood loss, should be kept to a minimum and laboratory tests ordered judiciously.

2 Iron supplementation should adhere to the recommendation previously stated. Iron supplementation should be given to preterm infants who are exclusively breast-fed and those who receive r-HuEPO. Infants who are fed an iron-fortified formula should not receive supplemental iron unless they are in negative iron balance or are receiving r-HuEPO. Infants with chronic blood loss will also require iron supplements.

3 Preterm infants should receive folic acid supplements as should infants with hemolysis. Iron supplementation should be avoided in the latter group unless iron deficient because hemolysis increases gastrointestinal iron uptake and in this setting supplemental iron increases the risk of iron overload.

4 r-HuEPO is used for the treatment of anemia of prematurity as discussed previously. In addition, it may have a useful role in other areas such as the management of anemic babies born to Jehovah's Witnesses. R-HuEPO utilizes iron and reduces iron stores. High-dose iron supplementation should be given.

Transfusion

The decision to transfuse red cells to a neonate should not be taken lightly. There is increasing recognition of the potential hazards of transfusion, which are discussed in Chapter 33. The aim of transfusion is to ensure adequate tissue oxygenation and prevent clinically significant symptomatic anemia, but measuring these variables in neonates is difficult. Tissue oxygenation depends not only on the hemoglobin level but also on hemoglobin's ability to give up oxygen and on cardiopulmonary function. Therefore a transfusion trigger must take into account not just the hemoglobin level but the infant's clinical and physiologic state. A number of reviews and guidelines have attempted to identify transfusion thresholds but there is little evidence on which to base practice.^{92,93} Table 7.8 lists possible transfusion thresholds based on consensus guidelines.⁹²

Transfusion may hamper the diagnosis of certain inherited anemias, e.g., sickle cell disease, which would otherwise be identified by neonatal screening programs,⁹⁴ and diagnostic tests to identify the cause of the infant's anemia should be carried out before transfusion if at all possible.

Table 7.8 Suggested transfusion thresholds for anemic neonates.

Anemia in the first 24 hours of life	Hb 12 g/dL
Cumulative blood loss in 1 week in infant requiring intensive care	10% blood volume
Neonate receiving intensive care	Hb 12 g/dL
Acute blood loss	10% blood volume
Chronic oxygen dependency	Hb 11 g/dL
Late anemia, stable patient	Hb 7 g/dL

Immune hemolytic anemias

Bertil Glader

Introduction

Immune hemolytic anemias are a result of abnormal interactions between erythrocytes and the immune system. These occur after antibodies and/or complement components bind to red blood cell (RBC) surface antigens and thereby initiate RBC destruction via the mononuclear phagocytic system (extravascular hemolysis) or within the circulation (intravascular hemolysis).

Autoimmune hemolytic anemia (AIHA) is characterized by the production of antibodies directed against self RBC. AIHA is considered primary when hemolysis is present without other clinical problems; it is considered secondary when associated with immunologic abnormalities, infection, malignancy or administration of drugs.

Alloimmune hemolytic anemia follows exposure to RBC having nonself antigens. The resulting alloantibodies react with RBCs of the same antigenicity, but not with self RBCs. Allogeneic RBC exposure to fetal blood during pregnancy leads to hemolytic disease of the newborn. Similarly, allogeneic exposure during a blood transfusion can lead to acute or delayed hemolytic transfusion reactions.

Yet another type of immune-mediated hemolysis can occur as a result of an acquired intrinsic RBC defect that makes red cells susceptible to destruction by the normal immune system. Paroxysmal nocturnal hemoglobinuria (PNH) is an example of this type of hemolytic disorder.

This chapter reviews the mechanisms of immune hemolysis, the varied etiologies of AIHA in children, the causes and mechanisms of drug-induced immune hemolysis, the pathophysiology and clinical features of neonatal alloimmune hemolysis, and the biologic and clinical features of PNH.

Mechanisms of immune hemolysis

Factors known to determine the nature and severity of

immunologically mediated RBC destruction include the following: specificity of red cell antigens; type and characteristics of anti-RBC antibodies; activation of serum complement proteins; and interaction with the mononuclear phagocytic (macrophage) system.¹

Red blood cell antigens

The erythrocyte membrane contains structural and contractile proteins in conjunction with numerous enzymes and surface antigens. Glycophorin, an "intrinsic" membrane protein, carries the A-, B-, M- and N-specific blood group antigens, as well as receptors for viruses and other surface-reactive substances. The chemical composition of red blood antigens varies: ABO antigens are carbohydrate oligosaccharides, Rh antigens are proteins, MNS antigens are glycoproteins, and the P surface antigens are glycosphingolipids. Approximately 600 antigenic specificities have been recognized on RBCs, comprising almost 20 different blood group systems. The ABO and Rh antigens are the most important with regard to alloimmune hemolytic anemia.

ABO blood group

The ABO blood group is composed of two antigens, A and B. Two independent loci, ABO and H, are involved in determining the expression of ABO. The H gene locus, on chromosome 19, encodes a transferase that adds fucose to the terminal galactose of membrane oligosaccharides, and this structure is referred to as H substance. Group O individuals have the H antigenic determinant that is not detectable on A and B cell types. The genes for the ABO system, located on chromosome 9, encode transferases that add specific sugars to H substance, creating both A and B antigens. The ABH antigens occur frequently in other species, including bacterial flora of the gut; and this widespread occurrence probably accounts for the ubiquitous anti-A and anti-B reactivity of human sera (IgM isohemagglutinins), even in individuals never previously

exposed to human blood groups through transfusion or pregnancy.

Rhesus system

The Rhesus (Rh) system is second only to the ABO blood group system in terms of clinical significance. Its importance lies in its antigenicity and the ease with which an Rh-negative person will form anti-Rh antibodies following transfusion with incompatible Rh-positive blood. In contrast to ABO antigens there are no naturally occurring antibodies to Rh antigens. Approximately 55% of incompatible blood transfusions that involve the D antigen result in the formation of anti-D, followed in frequency by Kell (approximately 20%). Whereas antibodies to ABO are predominantly of the IgM class, anti-Rh antibodies are IgG. Such antibodies can cross the placenta and thus cause significant morbidity and mortality, as in erythroblastosis fetalis (see below).

Unlike the ABO-H system, Rh blood types are restricted to the erythrocyte. This blood group is a complex system of several Rh antigens that are detected by specific antibodies. It is known that Rh blood group antigens are determined by at least two homologous but distinct membrane-associated proteins. Two of these membrane proteins have separate isoforms (C and c; E and e), which are detected by specific antibodies (anti-C and anti-c; anti-E and anti-e). The most important of the membrane Rh proteins is the D antigen. Rh-positive RBCs are those that possess this antigen. The symbol “d” (used to denote the absence of D, or Rh-negative) is not related to a specific antigen in that no anti-d serum has been identified. Rh proteins are encoded by two separate genes located on chromosome 1; they are designated Rh CcEe and Rh D.² The Rh CcEe gene encodes for both the C/c and E/e proteins. The Rh D gene encodes for the Rh D proteins. The Rh-negative phenotype results from deletion of the Rh D gene on both chromosomes. In most cases, the Rh-negative phenotype is also associated with Rh c and Rh e (i.e., Rh cde). The frequency of Rh negativity varies in different racial groups, ranging from a high of 30% in the Basque population to approximately 15% in Caucasians, lower in Africans (5%), and very low (<1%) in Asians. The Rh-positive phenotype may result from homozygosity (DD) or heterozygosity (Dd) for the D antigen; in Rh-positive Caucasians, approximately 44% are homozygous (DD) while 56% are heterozygous (Dd).

Immunoglobulins

All immunoglobulins have a common core structure consisting of two identical light chains (approximately 24 kDa) as well as two identical heavy chains (approximately 55 or 70 kDa). The antibody is constructed such that one light chain is attached to each heavy chain and the two heavy chains are attached to each other. The immunoglobulin heavy chains are of several types and their designation denotes the class

of antibody: IgA, IgD, IgE, IgG and IgM. There are four IgG subclasses numbered according to decreasing serum concentration: IgG1 (9 mg/mL), IgG2 (3 mg/mL), IgG3 (1 mg/mL), IgG4 (0.5 mg/mL).

The ability of immunoglobulin to combine with antigen is dependent on a few amino acid residues at the end of each heavy chain, the Fab fragment, and each IgG molecule possesses two antigen-binding sites. The remainder of the antibody structure, called the Fc region because it can be crystallized, is responsible for other functions such as complement fixation and binding to Fc receptors on macrophages. The most common IgG encountered in AIHA reacts primarily at 37°C, although it may also have some reactivity at lower temperatures. A characteristic of IgG-mediated RBC destruction is the opsonization or clearance of autoantibodies via the macrophage Fc receptor located in the spleen.³

IgM has a pentameric structure with 10 antigen-binding sites and a molecular mass of approximately 900 kDa. IgM clearance of RBCs is characterized by efficient C1 fixation, complement binding and sequestration by the liver. Intravascular hemolysis may occur along with agglutination of RBCs secondary to the multiple binding sites on the IgM molecule. In AIHA, IgM molecules are usually temperature restricted, with optimum activity in the range 4–22°C. Thus, these molecules are termed cold reactive or cold agglutinins. The comparative features of IgG and IgM are listed in Table 8.1.

For an RBC antibody to cause agglutination, it must either overcome the net repulsive force (zeta potential) between RBCs or be structurally large enough to avoid this repellent force. IgM antibodies, because of their size, are capable of bridging this gap and causing agglutination. This is more of a problem for IgG antibodies but, depending on the density of RBC antigenic sites, this distance restriction may be overcome. For example, IgG anti-Rh antibodies do not agglutinate Rh-positive cells because there are at most 30 000 D sites per RBC. In contrast, IgG anti-A is effective at causing agglutination since there may be up to 1 000 000 A sites per RBC.

Table 8.1 General characteristics of antibodies.

	IgG	IgM
Geometric configuration	Monomer	Pentamer
Heavy chain isotype	γ	μ
Molecular mass (kDa)	150	900
Antigen-binding sites	2	10
Serum concentration (mg/dL)	1000–1500	85–205
Subclasses	IgG1, IgG2, IgG3, IgG4	None
Complement fixation	Occasionally	Yes
Fc-receptor binding	Yes	No
Agglutinates red blood cells	Rare	Yes
Crosses placenta	Yes	No

Complement system

The complement system comprises a series of plasma proteins that exist naturally in an inactive form. However, on stimulation by antigen–antibody complexes or bacterial polysaccharides they become activated, generating fragments capable of initiating and propagating immune effector functions. Two groups of proteins, the classical and alternate pathways, can trigger this proteolytic cascade.

The *classical pathway* is initiated by fixation of C1 to the Fc portion of the bound antibody (IgM or IgG) combined to a cell-surface antigen. This reaction requires two Fc complement receptor sites on an antibody molecule to be close together. Thus, the IgM molecule is efficient at C1-complement fixation when bound to the RBC membrane compared with the smaller, monomeric IgG antibody, which is a relatively poor activator of the classical complement pathway. The C1–antigen–antibody complex then initiates the activation of C4 and C2, respectively. The resultant C4b2b complex is known as C3 convertase because it catalyzes the cleavage of C3, resulting in fragments of C3a and C3b. The *alternate pathway*, which is of less significance in AIHA, leads to the same activation and cleavage of C3 but without an antigen–antibody binding requirement. Once C3b is generated, it possesses proteolytic activity that promotes cleavage of C5 into C5a and C5b. A common final effector sequence utilizing C5b though C9 leads to the generation of the membrane attack complex (MAC, C5b–9). This complex mediates cell lysis by creating pores in the antibody-coated cell membrane, increasing ionic permeability and thus causing osmotic lysis of the cell. C5 fixation is a relatively inefficient system in humans, and this inefficiency is partly explained by the existence of regulatory proteins that inactivate C3b before it can trigger C5 cleavage. These regulatory proteins have a central role in the pathophysiology of PNH-related hemolysis (see below).

Mononuclear phagocytic system

ABO-incompatible blood transfusion reactions are a consequence of circulating IgM antibodies that activate complement and thereby cause red cell lysis. This process is called intravascular hemolysis because immune-mediated destruction occurs within the circulation. In most immune hemolytic disorders, however, red cell destruction is primarily extravascular and RBCs are destroyed via phagocytosis by macrophages, particularly in the spleen and liver. This process involves binding of Fc receptors on macrophages to the Fc portion of IgG molecules attached to RBCs. Once bound, RBCs are phagocytosed and removed by macrophages. If not completely phagocytosed, partial removal of antibody–RBC membrane fragments results in a decrease in membrane surface area, and thereby spherocyte formation. These spherocytes have decreased deformability, become trapped in the

reticuloendothelial system, and are subsequently removed by mononuclear phagocytes.

Immune reactions that result in C3b binding to RBCs also cause hemolysis by sequestration in the mononuclear phagocytic system. This occurs because reticuloendothelial macrophages have receptors for C3b as well as IgG. If complement components are present on RBCs, this can potentiate IgG-mediated extravascular hemolysis.

While the spleen is crucial in the clearance of IgG-sensitized cells, the Kupffer cells in the liver are capable of rapid sequestration and clearance of C3b-expressing cells sensitized by complement-binding IgM anti-RBC antibodies. Studies have shown that a greater number of IgG molecules per RBC are required for phagocytosis by the liver in a splenectomized animal.⁴

Antiglobulin test (Coombs test)

In 1945, Coombs⁵ described a method to detect free (unbound) antibodies in serum, and this discovery later led to the demonstration and detection of RBCs coated *in vivo* with antibody and/or components of complement. This was a very important milestone in hematology. Prior to this there was no way to recognize antibody-coated RBCs, aside from those cases where there was visible agglutination (now known to be due to cold IgM antibodies). It was not possible to readily distinguish a common hereditary hemolytic disorder (hereditary spherocytosis) from an acquired hemolytic anaemia (AIHA) since both featured spherocytes in the peripheral blood smear. The ability to detect and characterize antibodies on RBCs has had a major impact on blood banking and on our ability to diagnose immune-mediated RBC destruction.

The antiglobulin test is used to generate visible agglutination of sensitized RBCs. The Coombs reagent for the antiglobulin test is produced by the injection of human globulin into a heterologous species, e.g., rabbit. The resultant serum antiglobulin is capable of overcoming the zeta potential to allow bridging of antibody-coated RBCs and thereby allows agglutination to occur. The direct antiglobulin test (DAT) entails mixing a subject's RBCs with polyspecific anti-human globulin that has both anti-IgG and anti-C3 activities (Fig. 8.1). If agglutination is seen with polyspecific reagents, the sample is next tested separately with specific reagents for anti-IgG or anti-C3. A positive DAT due to IgG is seen with warm autoantibodies that cause AIHA, hemolytic transfusion reactions, hemolytic disease of the newborn, some drug-induced antibodies, and following administration of various therapeutics including intravenous immunoglobulin and Rh immune globulin. A C3-positive DAT occurs with a cold IgG or IgM-mediated process, or it may occur with drug-related disorders. There is much overlap in antibody and C3 reactivity in the DAT, and sometimes both may be present. IgM autoantibodies generally detach from the RBC surface *in vivo*, so they are usually not detected in the DAT and are not present in an eluate made from a subject's RBCs.

Fig. 8.1 The direct antiglobulin test entails mixing a subject’s red blood cells (RBCs) with polyspecific anti-human globulin that has both anti-IgG and anti-C3 activities. The resultant serum antiglobulin is capable of overcoming the zeta potential to allow bridging of antibody-coated RBCs, and thereby allows macroscopically visible agglutination. If agglutination is seen with polyspecific reagents, the sample is next tested separately with specific reagents for anti-IgG or anti-C3.

The indirect Coombs or antiglobulin test is a two-step process that identifies unbound (free) antibodies in the serum or in an eluate from RBCs that manifest positive DAT anti-IgG reactivity. This test is useful in blood-group compatibility testing and for cross-matching for transfusion. Patient serum is incubated with a panel of normal RBCs of known antigenicity. A similar approach can be used to study an eluate from RBCs known to be coated with an IgG antibody. Antiglobulin antibody is then added to the washed RBCs, and any agglutination that occurs indicates a reaction between antibody in the patient’s serum or eluate and an

antigen present on the RBC. By testing against a variety of RBCs with known antigenicity, the specificity of the involved antibody can be ascertained. Together with the DAT, results from serum and RBC eluate antibody studies help distinguish the different forms of AIHA.

Autoimmune hemolytic anemia: general considerations

AIHA is a result of antibodies produced against self RBC antigens. A working classification of AIHA relates to the thermal properties of the offending antibodies: warm AIHA vs. cold AIHA (Table 8.2). Cold AIHA can be further categorized into cold agglutinin disease and paroxysmal cold hemoglobinuria. Warm-reacting antibodies (usually IgG, usually polyclonal) react optimally at 37°C, whereas cold-reacting antibodies (IgG or IgM) react maximally at temperatures below 37°C. Each of the above types of AIHA exist as a primary disorder, with hemolysis being the only manifestation of disease. However, these different types of AIHA also can be associated with other underlying processes, with hemolysis being only one manifestation of the clinical condition.

The etiology of most RBC autoantibodies is not completely understood. One possibility is that autoimmune disease arises from the response to a foreign antigen when the foreign substance shows sufficient homology to a self antigen. In view of the association between AIHA and lymphoid neoplasms, as well as the concurrence with immunodeficiency syndromes and other autoimmune disorders, another possibility is that autoantibodies are a result of generalized immune system dysfunction. The immune system has several control mechanisms that regulate the balance between the need to tolerate self antigens and the need to respond appropriately to

	Warm AIHA	Cold agglutinin disease	Paroxysmal cold hemoglobinuria
Immunoglobulin	IgG	IgM	IgG
Thermal reactivity	37°C	4°C	4°C
Fixes complement	Variable	Yes	Yes
Direct antiglobulin test			
4°C	–	–	IgG
37°C	IgG ± C3	C3	C3
Antigenic specificity	Rh	I/i	P
Site of red cell destruction	Extravascular	Extravascular Intravascular	Intravascular Extravascular
Therapy	Corticosteroids Anti-CD20 Splenectomy	Avoidance of cold Warm blood for transfusion	Avoidance of cold Warm blood for transfusion Corticosteroids

Table 8.2 Characteristics of red cell antibodies in autoimmune hemolytic anemia (AIHA).

foreign antigens. Immune self-tolerance occurs centrally (in the thymus) via clonal deletion of developing lymphocyte precursors and peripherally with the elimination of leaky clones not eradicated by central tolerance. It is now known that peripheral tolerance is sustained by regulatory T cells via downregulation of both Th1 help for cell-mediated immunity and Th2 help for antibody production.⁶ Regulatory T cells constitute 5–10% of CD4⁺ T cells that are not Th1 or Th2; they express a unique transmembrane protein (CD25) on their surface. The antigens recognized by the T-cell receptor of these cells tend to be self peptides, and it is thought that these cells have a role in protecting against autoimmune disease. A mouse model of AIHA has been demonstrated to occur after repeated intraperitoneal injections of rat RBCs leading to the development of autoantibodies that also react with mouse RBCs. The end result is a hemolytic process similar to AIHA seen in humans.⁷ Utilizing this mouse model, which produces AIHA in 30% of mice immunized to rat RBCs, it has been shown that anti-CD25 antibodies increase the development of AIHA to 90%, thus suggesting that CD25 may have a role in inducing this autoimmunity.⁸

This section focuses on the clinical and laboratory features of AIHA in children. Some of the clinical features of AIHA in children and adults are similar, but there are also significant differences. Several excellent overall reviews of AIHA are available.^{9,10} Drug-induced immune hemolytic anemia is another category of hemolysis similar to AIHA and is considered separately in a later section.

Warm autoimmune hemolytic anemia

Children with AIHA are commonly seen in large pediatric medical centers. The incidence is somewhat less than that for immune thrombocytopenic purpura (ITP) but greater than that for aplastic anemia.¹¹ Warm autoantibodies are responsible for most cases of AIHA.^{12,13} The peak incidence in children is in the first 4 years of life, often associated with viral illnesses, and is most commonly a primary disorder unrelated to any other disease process. In some children (as well as adults) warm AIHA can be associated with autoimmune conditions (systemic lupus erythematosus, rheumatoid arthritis) and immunodeficiency disorders (AIDS, hypogammaglobulinemia). Unique pediatric immune disorders associated with AIHA include Wiskott–Aldrich syndrome and autoimmune lymphoproliferative syndrome (ALPS).^{14–16} In adults, but much less commonly in children, warm AIHA is secondary to lymphoid malignancies (chronic lymphocytic leukemia, lymphomas). In adults there is a female predilection for AIHA, presumably a reflection of the increased propensity for autoimmune disease in women. In children, however, no consistent difference of AIHA in boys and girls has been noted.^{17–19} It is of interest that transient neonatal hemolysis due to passively acquired autoantibody can occur in infants born to mothers with AIHA.^{20,21}

Clinical features

The clinical presentation and course of warm AIHA may be either mild, with symptoms attributable to a minor degree of anemia, or more complicated and severe. Children with AIHA frequently present with weakness, malaise, and fever. The symptoms may be of acute or insidious onset. Jaundice, pallor, edema, dark urine (hemoglobinuria), splenomegaly, and hepatomegaly often occur with severe hemolytic anemia. The child's presentation depends on not only the severity of the anemia but also the rapidity of onset of the hemolytic process. Additional physical findings may be present when the hemolytic process is secondary to an underlying disorder such as lupus or immunodeficiency. In cases of secondary disease, the symptoms of AIHA may precede recognition of the underlying illness by months to years but, ultimately, the signs and symptoms of the underlying disorder become manifest.

Laboratory features

Most children with AIHA are anemic at diagnosis, although the hemoglobin concentration varies considerably. It can be markedly decreased in patients with fulminant hemolysis or it may be normal in those with indolent disease. The mean corpuscular volume is usually elevated, reflecting reticulocytosis. Of note, however, reticulocytopenia can exist early in the disorder, presumably because anti-RBC antibodies also recognize an antigen present on RBC precursors, thereby resulting in intramedullary red cell destruction and "ineffective erythropoiesis".^{22–24} Buchanan *et al.*¹⁸ found that most children with moderate-to-severe anemia had inappropriately low reticulocyte counts, with 50% of patients having values of 5% or less. Bone marrow aspiration is seldom needed for diagnosis in children, but if done usually reveals normoblastic erythroid hyperplasia, even in those patients who are reticulocytopenic.¹⁸ The peripheral blood smear manifests variable degrees of polychromatophilia, nucleated RBCs, erythrophagocytosis, and microspherocytes.

White blood cell counts may be low, normal, or elevated. Occasionally, the peripheral blood smear shows early white cell precursors (metamyelocytes, myelocytes, promyelocytes). Platelet counts are highly variable, varying from normal to elevated. Occasionally, patients may present with both immune thrombocytopenia and immune-mediated RBC hemolysis, as in Evans syndrome (see below).

Other laboratory findings include indirect hyperbilirubinemia and increased serum lactate dehydrogenase (LDH) activity as markers of increased RBC destruction. When intravascular hemolysis is severe, the released hemoglobin quickly depletes haptoglobin and produces hemoglobinemia. Because haptoglobin is an acute-phase reactant, its level may be normal or even increased if hemolysis is mild and there is adequate hepatic function. Significant

hemoglobinemia that exceeds the renal reabsorptive capacity of hemoglobin leads to hemoglobinuria and the appearance of urinary hemosiderin.

A positive DAT establishes the diagnosis of AIHA. The factors that influence the risk of hemolysis are the presence of bound IgG1 and IgG3 antibodies,^{25,26} the quantity of bound RBC autoantibodies and the resulting strength of the DAT.^{27–29} The DAT is positive in over 95% of cases of warm AIHA, and it can be positive for IgG alone or IgG and C3.^{12,13,30} Of note, the serologic pattern of the DAT at diagnosis does not help predict the clinical course in patients with warm AIHA. The vast majority of IgG autoantibodies are in the IgG1 subclass; the IgG3 subclass is the next most common, usually in combination with IgG1.^{3,31} There is a small fraction of patients with a clinical picture that strongly suggests AIHA although the DAT is negative. It is thought that these DAT-negative cases may occur in patients with levels of IgG autoantibodies below the detectable threshold for the DAT or that there is an IgA autoantibody.^{32–36} Warm autoantibodies are usually panagglutinins, which react with all cells on the diagnostic antibody panel and which presumably are directed at the Rh locus.³⁷ Other targeted antigens include membrane protein band 4.1, protein band 3, and glyophorin A.^{38–41}

Treatment

Some children with warm antibody AIHA require no therapeutic intervention because of the mildness of the hemolytic process. Others, perhaps most, present emergently with severe hemolysis necessitating immediate medical management. In general, the goal of therapy is to reduce the hemolytic process to a clinically asymptomatic state with minimal medical side-effects. Close attention should always be paid to supportive care issues such as folic acid supplementation, hydration status, urine output, and cardiac status. Those cases associated with another related medical problem require that the underlying condition be managed in the hope of reducing autoantibody production. The mainstays of therapy for hemolytic anemia include steroids, RBC transfusions, and splenectomy. Other old and new pharmacologic approaches are also available. The therapies described in this section apply to warm AIHA. The similarities and differences in therapy for cold antibody AIHA are discussed in subsequent sections.

Steroids

Once anemia develops, glucocorticoids are the first line of therapy. More than three-quarters of all children with IgG autoantibodies show an initial response to high-dose steroids (prednisone 2–6 mg/kg daily). Glucocorticoids have two well-established mechanisms of action in the treatment of immune hemolysis. A rapid clinical response is attributed to the suppression of macrophage Fc and C3b receptors, with

a resultant decrease in the rate of RBC phagocytosis. A reduction in hemolysis and a rise in hemoglobin level may be noticed within a few days. The second mechanism involves the suppression of antibody production and a fall in the level of circulating autoantibody. This effect will produce a delayed increase in the hemoglobin level over a period of several weeks. As hemolysis decreases (as monitored by both the hemoglobin and reticulocyte counts), doses of steroids should be tapered. If a relapse occurs, escalation to the initial therapeutic dose may be required. Risks and benefits of long-term steroid use must be weighed against changing to an alternative treatment modality. When administered in high doses or for prolonged periods, steroids have a number of well-known toxicities that include electrolyte imbalance, exacerbation of diabetes, increased appetite and weight gain, increased risk of infection, and adverse effects on growth.

Transfusions

RBC transfusions should be limited to cases of life-threatening anemia because the benefits are often transient as a result of antibody-mediated destruction of transfused cells. Donor RBCs are usually destroyed at the same rate as autologous RBCs.⁴² Since warm autoantibodies in AIHA are usually panagglutinins, this invariably presents a problem when the transfusion service does the serologic work-up. An autoantibody reactive to all RBCs tested can mask an existing alloantibody by making all donor units appear cross-match incompatible, regardless of whether an alloantibody is present. The blood bank can attempt to find the least incompatible unit but the value of this in most cases is uncertain. In no case should a red cell transfusion be withheld in the presence of life-threatening anemia. Transfusions should be given slowly (5 mL/kg over 3–4 hours), especially in the setting of severe anemia. Also of concern is the risk of transfusion reaction due to the usual *in vitro* incompatibility of patient serum and donor RBCs, but in most cases this is more of a concern than a real problem.

Anti-CD20 (rituximab)

Rituximab is a chimeric human/mouse monoclonal antibody approved for the treatment of relapsed and refractory non-Hodgkin lymphoma. Since rituximab targets a pan-B-cell marker (CD20), any lymphoproliferative or immunologic disease where B cells play a pathogenic role may be amenable to treatment with this agent. Clinical studies now indicate that rituximab is effective in some patients, including children, with chronic ITP and chronic AIHA. Several reports indicate that children with refractory AIHA have durable remissions following a course of rituximab.^{43–46} In one study of 15 children with refractory AIHA, 13 went into remission after two, three or four weekly doses of rituximab (375 mg/m² per dose).⁴⁵ Most importantly, 12 of these 13 children entering remission had not undergone splenectomy. Also, there were three relapses after several months remission, but all three of

these children again remitted following a second course of rituximab.⁴⁵ These studies need further assessment but the data currently available suggest that rituximab should be added to the therapeutic armamentarium, and probably tried before splenectomy.

Splenectomy

For many years splenectomy has been the second line of treatment in patients who fail glucocorticoid therapy. However, this modality should now be considered a tertiary option, after a trial of anti-CD20 therapy (see above). Removal of the spleen theoretically has a twofold effect. First, it removes the primary site of extravascular hemolysis. Secondly, but probably less important, the spleen is also a site of antibody production. Studies indicate that splenectomy has a response rate of approximately 60–75%, but many of these patients require maintenance with lower doses of steroids, and some patients relapse months to years later. The procedure has a low morbidity and mortality rate. Due to the infection risk from encapsulated bacteria, patients should be vaccinated for pneumococcus and meningococcus, preferably before splenectomy is performed. Whenever possible, children should be over 5 years of age before splenectomy and the disease should be present for at least 6–12 months with no significant response to therapy. The decision to recommend splenectomy in patients with an underlying immunologic problem must be individualized for each affected patient, depending on the nature of the underlying disorder.

Other therapies

Some reports suggest that intravenous gammaglobulin is beneficial, while others show no benefit.^{47–50} Most clinicians do not consider this a useful agent. Other therapies for AIHA run the gamut of those used in chronic ITP: danazol, vinca alkaloids, azathioprine, cyclophosphamide and others. In view of the greater rarity of AIHA as compared to ITP, insufficient evidence exists to be conclusive about the use of any of these. If azathioprine is used, it is necessary to continue the drug for 4–6 months before assessing that it is ineffective in decreasing autoantibody production. Plasmapheresis has shown a limited response in warm AIHA. A recent report also demonstrated effectiveness of hematopoietic stem cell transplantation for refractory autoimmune cytopenias including AIHA.⁵¹ Obviously this therapeutic modality should not be attempted until other interventions have failed.

Clinical course and prognosis

Many studies over the past several years allow for some generalizations about the clinical course in warm AIHA patients.^{17–19,52,53} There appear to be two major groups of children with AIHA, a majority (50–70%) who have an acute course and a significant minority (30–50%) who have a more chronic course. The acute course is characterized by a sudden

onset, often preceded by a viral infection, is seldom associated with underlying disorders, occurs in younger children (<4 years old), usually responds to steroids, and shows complete resolution within 3–4 months. In contrast, the chronic AIHA course is characterized by a more indolent onset, no prodromal infections, refractoriness to standard therapy, an ongoing need for other therapies such as splenectomy or other chemotherapy, frequent association with underlying medical conditions, and occurs in all ages but commonly in older children. Heisel and Ortega¹⁹ observed an increased association of chronic AIHA with children over 12 years of age and, interestingly, also in children less than 2 years. This age distribution may reflect the early onset of congenital immune disorders in young children and the onset of autoimmune disorders in teenagers. It is intriguing that these patterns in acute and chronic AIHA are very similar to the acute and chronic pattern of ITP in children, and also parallel the major differences in childhood and adult ITP. In one study of 767 patients, 42.5% of the children had a transient acute clinical pattern of AIHA compared with only 4.5% of the adults. Also, adult AIHA is not associated with an infectious prodromal state, but there is a correlation with concurrent chronic illness. The adult mortality rate in one study was significantly higher (28.7%) than the corresponding pediatric rate (11%).¹⁷ When mortality occurs in children with AIHA it almost always is seen in those with a chronic presentation. The cause of death is rarely from the anemia; more commonly it is a complication of therapy or the underlying medical condition. Some of the causes of death include postsplenectomy sepsis, infection in children with immunodeficiency disorders, renal failure in patients with systemic lupus erythematosus, bleeding in patients with associated thrombocytopenia (Wiscott–Aldrich syndrome, Evans syndrome), and complications from iron overload in massively transfused patients.

Evans syndrome

This disorder, first recognized over 50 years ago, is characterized by AIHA accompanied by immune thrombocytopenia. It results from the development of multiple autoantibodies targeting at least RBCs and platelets. In approximately 50% of cases, neutropenia also is present.⁵⁴ These autoantibodies are directed against specific antigens on erythrocytes and platelets and appear not to cross-react.^{55,56} A variety of defects in cellular immunity have also been proposed, including decreased serum immunoglobulins, decreased T-helper (CD4) function and increased T-suppressor (CD8) cell function. Evans syndrome is a heterogeneous disorder and has been associated with many autoimmune conditions, collagen vascular disorders and malignancies.

An important recent observation is the association of Evans syndrome with ALPS.⁵⁷ The latter is a disorder of lymphocyte homeostasis, characterized by lymphoproliferation,

autoimmune manifestations (AIHA, ITP), increased circulating double-negative T cells ($CD3^+CD4^-CD8^-$), and impaired Fas-mediated apoptosis when studied *in vitro*.^{14–16} In a study of 12 children with Evans syndrome, 7 (58%) were found to meet the diagnostic criteria for ALPS.⁵⁷ The significance of this finding is not entirely clear. It may turn out that many of the autoimmune cytopenias are variants of ALPS, and it seems reasonable to screen for double-negative T cells in children who have chronic single cytopenias such as AIHA or ITP.

If a patient has ITP and a positive DAT, even in the absence of hemolysis, Evans syndrome can be recognized at the time of identification of ITP. However, the converse is not true. The current lack of a diagnostic platelet antibody test does not allow distinction of “routine” AIHA from AIHA associated with Evans syndrome if the platelet count is normal.

The two major therapeutic regimens for autoimmune cytopenias, steroids and splenectomy, are generally not curative for Evans syndrome, and this has been a problem in long-term management of these patients. However, the drug rituximab, discussed previously for other cases of warm AIHA, has also induced sustained remissions in several patients with Evans syndrome.^{45,58} This clinical observation needs to be followed, but the possibilities for successful therapy are encouraging. Also of interest, mycophenolate mofetil, a potent immunosuppressive drug used in organ transplantation, has reportedly helped the cytopenias in 12 of 13 patients with ALPS.⁵⁹ Obviously these therapeutic successes are of interest for all patients with chronic AIHA.

Cold agglutinin disease

Primary, or idiopathic, cold agglutinin disease is a chronic disease of adults over 50 years of age, associated with a monoclonal autoantibody, and characterized by chronic hemolysis and acrocyanosis when exposed to cold. This syndrome does not occur in children. However, secondary cold agglutinin disease is seen in both children and young adults, usually in association with acute infection. Cold agglutinins are IgM autoantibodies that cause clumping of erythrocytes at temperatures below 37°C, with maximal agglutination below 4°C. Clinical hemolysis in postinfectious cases is related to the normal immune response to infection. Symptoms appear 2–3 weeks after the infection starts (corresponding to the rising cold agglutinin titer) and resolve spontaneously 2–3 weeks later.

Cold agglutinins commonly are found in healthy children and adults (at titers of less than 1 : 32), but these low titers are of no clinical consequence.^{60,61} In contrast, the autoantibodies in cold agglutinin hemolytic anemia are present in much higher titers (usually greater than 1 : 1000) and they also have a higher thermal amplitude, meaning that the *in vitro* temperature range at which agglutination occurs is increased. The normally occurring clinically insignificant cold agglutinins do not cause *in vitro* agglutination above 28°C, whereas

Fig. 8.2 Cold IgM autoantibodies are maximally reactive below 4°C while complement is maximally activated at 37°C. The area of overlap between these curves is the range of hemolysis. Modified with permission from Schuboth H. The cold hemagglutinin disease. *Semin Hematol* 1966; 3: 27–47.

pathologic cold antibodies frequently continue to cause agglutination up to 37°C. Any hemagglutination seen at 37°C indicates a clinically significant cold autoantibody.

The pathophysiology of cold agglutinin disease is very temperature-dependent (Fig. 8.2). *In vivo*, pathologic cold IgM agglutinins bind erythrocytes in cooler peripheral areas of the microvasculature, such as the fingers, toes, ears, and nose. Upon return to warmer central areas of the circulation, bound IgM leads to activation of the complement pathway. In most cases C3b is deposited on the red cell membrane, but occasionally the entire complement cascade is activated to the membrane attack complex. At the same time, the higher temperatures cause dissociation of the IgM cold agglutinins, which thereby allows antibodies to bind to other RBCs in the colder peripheral circulation where the temperature may be 28–30°C. Since the complement cascade usually ends with C3b fixation, extravascular hemolysis by tissue macrophages is a major route of RBC destruction. However, when the complement cascade is completely activated, the end result is sometimes cell lysis with intravascular hemolysis.

Laboratory studies

In 1903, Landsteiner⁶² noted that blood sometimes undergoes autoagglutination when chilled. It is now recognized that the presence of a cold agglutinin is often first suspected while performing a complete blood count in the clinical laboratory. RBC clumping artifactually increases the mean corpuscular volume and mean corpuscular hemoglobin concentration to very high levels, but these return to normal values after the blood is warmed.

The hemoglobin concentration in children with cold agglutinin disease is normal to mildly decreased. Reticulocyte count may be elevated. White blood cell and platelet counts

are usually normal. The peripheral blood smear may show agglutination and polychromatophilia. Other laboratory findings reflecting red cell destruction include mildly elevated indirect serum bilirubin and LDH levels. Severe exacerbations can produce decreased haptoglobin, hemoglobinemia, and hemoglobinuria as markers of intravascular hemolysis.

Since cold agglutinins involve IgM autoantibodies and complement, the DAT is positive with polyspecific and anti-C3 reagents, but is negative with anti-IgG. Because the IgM autoantibodies dissociate from RBCs after C3 binding, they are not detected in the indirect antiglobulin test.

The IgM cold agglutinin is most frequently directed against the I/i erythrocyte membrane antigen group. The RBC surface densities of I/i are inversely proportional to one another. Neonatal RBCs almost exclusively express i antigen on their surface but, during infancy, antigen switching occurs and by 18 months of age I antigen is predominant. Antibody panels with adult RBCs will detect anti-I agglutinins while cord RBCs are needed to detect anti-i agglutinins. Secondary postinfectious cold agglutinins include anti-I associated with *Mycoplasma pneumoniae*, anti-i with Epstein–Barr virus (EBV), and both anti-I and anti-i with cytomegalovirus.^{60,61} The majority of patients infected with *M. pneumoniae* transiently produce anti-I agglutinins, and in most cases these are not clinically significant. Similarly, the majority of anti-i cold antibodies secondary to infectious mononucleosis are benign, since up to 70% of affected patients have anti-i but less than 3% manifest any hemolysis.^{63,64}

Treatment

Treatment of hemolysis associated with infection-related cold agglutinin disease is often not necessary. RBC transfusions are reserved for patients with significant hemolysis who are symptomatic. It should be noted that the presence of cold agglutinins often cause serologic difficulties during the blood bank work-up, and the blood bank may have to release least-incompatible RBC units that have a higher risk of containing an undetected alloantibody. The risk of further transfusion-related hemolysis can be reduced by using an in-line blood warmer at 37°C and by keeping the patient warm.⁶⁵

Paroxysmal cold hemoglobinuria

In 1904, while describing an *in vitro* test to diagnose paroxysmal cold hemoglobinuria (PCH), Donath and Landsteiner first demonstrated the antibody which now carries their name.⁶⁶ The Donath–Landsteiner (DL) antibody is a biphasic, usually IgG, hemolysin that binds to erythrocytes at cooler temperatures, activates complement, and thereby causes hemolysis at warmer temperatures.⁶² There are two clinical categories of PCH: a chronic form, which has been associated with late or congenital syphilis, and an acute transient form, found primarily in children. Chronic PCH is characterized

by intermittent episodes of hemolysis and hemoglobinuria occurring after cold exposure. Since the advent of antibiotic therapy, chronic PCH is now quite rare. Today, the vast majority of cases of Donath–Landsteiner hemolytic anemia occur transiently, and are found primarily in children recovering from upper respiratory infections.^{67,68} The causative agent is often not identified. However several infectious agents have been implicated, including measles, mumps, EBV, cytomegalovirus, varicella zoster virus, adenovirus, influenza A, *M. pneumoniae*, *Haemophilus influenzae*, and *Escherichia coli*.

DL antibody-mediated AIHA was previously considered a rare event, but several reports investigating AIHA in children have found a relatively high incidence.^{67,69,70} In a series of 42 children with AIHA, Sokol⁶⁹ found the DL antibody to have mediated 40% of cases. In another series of 68 children with AIHA, Gottsche *et al.*⁷⁰ found nearly one-third to be mediated by the DL antibody. In contrast, of 531 adults with AIHA, the DL antibody mediated none. All DL-mediated cases presented within 3 weeks of the onset of an apparent viral illness, most commonly an upper respiratory infection or enteritis. The vast majority of children diagnosed with DL-mediated AIHA have been aged 5 years or younger with no racial or gender predilection. Hemoglobinuria is the most common clinical finding, followed by jaundice and pallor. In the series reported by Sokol, hepatosplenomegaly was found in about 25% of cases.⁶⁹

Laboratory features

Common laboratory findings include anemia with low hemoglobin levels (4–8 g/dL), and there is often reticulocytopenia early in the acute course, but this is followed by reticulocytosis. Leukopenia may also be seen early in the course but this is frequently followed by a marked leukocytosis (10–80 × 10⁹/L). There are no changes in the platelet count. The peripheral blood smear may reveal normal RBC morphology, although polychromatophilia, spherocytosis, and nucleated red cells are commonly seen.^{67,68} Erythrophagocytosis has also been noted, occurring much more frequently than in other cases of AIHA.^{67,71} There is laboratory evidence for both intravascular and extravascular hemolysis as manifested by increased LDH, indirect bilirubinemia, decreased haptoglobin, hemoglobinemia, and hemoglobinuria.

In the acute transient form of PCH, the DL antibody is usually detectable only in the first several days after presentation.^{70,71} The DL antibody binds to the erythrocyte at cold temperatures, and the binding site for this antibody is the P antigen of the erythrocyte membrane.⁷¹ Once the DL antibody binds to the RBC, early complement components are fixed. The DL antibody has a weak binding affinity and releases at warmer temperatures; however, the early complement components remain fixed and, with warming, frequently activate the terminal complement sequence (through C8 and C9), thereby leading to intravascular hemolysis. Just

as with cold agglutinin disease, cells with C3b complement coating alone are phagocytosed by the reticuloendothelial system. A small amount of weak-binding DL antibody may mediate severe RBC destruction by releasing from complement-bound cells and rebinding to new erythrocytes with the change in temperature between the peripheral and central circulation. Thus DL antibodies are very potent, and low titers can lead to severe hemolysis. However, since the period of antibody production is relatively brief, the disease usually resolves within a few weeks.^{67,70}

As with cold agglutinin disease, the DAT is positive with polyspecific reagents and with anti-C3 reagents. However, with IgG-specific reagents, and at the standard temperature of 37°C, the DAT is usually negative. The indirect antiglobulin test is also negative. However, with cooling to 4°C, the DL antibody binds to the erythrocyte membrane, and the IgG DAT may become positive. Sometimes, it can be difficult to distinguish the DL antibody from a strong cold agglutinin that causes intravascular hemolysis.

The specific diagnosis of DL-mediated AIHA is confirmed by the DL antibody test. The direct DL test utilizes fresh blood from the patient to demonstrate hemolysis in autologous cells after incubation at 4°C followed by warming to 37°C. The indirect test utilizes the patient's serum in combination with washed group O erythrocytes, and fresh normal serum as a source of complement.⁶⁷ The cell suspensions are then incubated under three different conditions. One group of samples is incubated only at 0–4°C, a second group is incubated only at 37°C, while a third group is incubated first at 0–4°C for 30 min and then at 37°C for 60 min. The diagnosis of PCH is indicated when hemolysis is only observed in samples with patient's serum that have been incubated first at 0–4°C for 30 min and then at 37°C for 60 min.

Treatment

Since most cases of PCH are self-limited, treatment is usually symptomatic. As the DL antibody, like the cold agglutinin, binds at lower temperatures, keeping the patient warm is a mainstay of therapy. Similarly, warming of RBCs in a blood warmer prior to transfusion is important.⁶⁸ Transfusion with rare P-negative blood may be theoretically beneficial but this is not a realistic approach because of the rarity of this type of blood. High-dose intravenous immune globulin has not been shown to provide clear clinical benefit in DL antibody-mediated AIHA. Corticosteroids may depress antibody production and decrease complement receptor-mediated phagocytosis in the liver and spleen. However, since clinically detectable production of the DL antibody is limited to a few days to weeks and, more importantly, because hemolysis is largely intravascular and mediated by terminal complement components, corticosteroids do not provide much clinical benefit. In cases of life-threatening PCH, plasmapheresis has proven to be helpful.⁷²

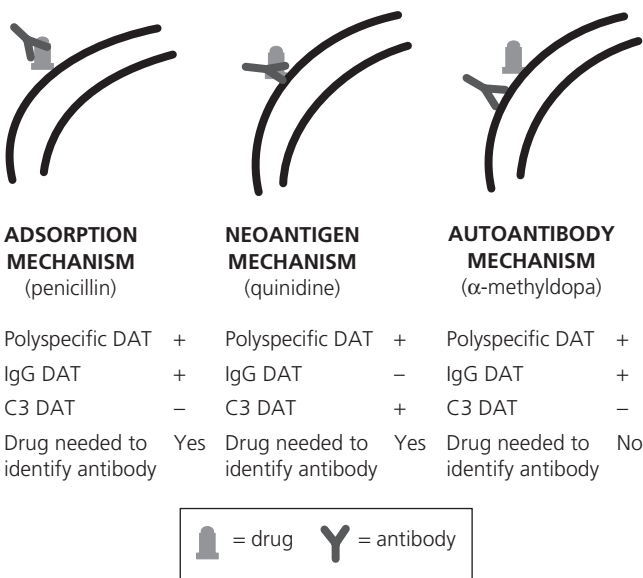

Fig. 8.3 Mechanisms of drug-induced immune hemolytic anemia, showing representative drugs and typical serologic studies. Note that drugs in the patient's serum or drug-treated red blood cells are needed to detect antibodies due to drug adsorption or neoantigen formation. DAT, direct antiglobulin test.

Drug-induced immune hemolytic anemia

For many years it has been known that drugs can cause immune hemolytic anemia. The majority of recognized cases were due to α-methyldopa and high-dose penicillin. Nowadays, the most common cause of drug-induced immune hemolytic anemia (DIIHA) is related to cephalosporins (see below).^{1,73} DIIHA can result from three different types of interactions between drugs, antibodies, and RBC membrane components (Fig. 8.3).

1 Drug adsorption mechanism. This is seen with certain drugs, such as penicillin, that normally bind covalently to the RBC membrane. In itself, this causes no problems. However, at high doses of penicillin, antibody formation can occur, and the antibody combines with drug bound to the RBC membrane, and this can lead to red cell destruction. The IgG DAT test is positive if sufficient drug is present in the RBC membrane. In the absence of drug, the DAT is negative although antibody to drug may persist. Hemolysis occurs only when the drug is present in the blood.

2 Neoantigen mechanism (previously referred to as the immune complex mechanism). This occurs when the immune system perceives a drug–membrane interaction as foreign and produces antibody that binds to both the drug and components of the cell membrane. This mechanism is thought to explain quinidine-related immune hemolysis. The presence of drug or drug metabolites are necessary for antibody binding and RBC destruction. However, in contrast to the drug adsorption mechanism, the drug in the neoantigen

mechanism is loosely bound and complement is also activated leading to C3 deposition. In contrast to the penicillin model, which requires high doses of drug to cause hemolysis, the neoantigen mechanism causes hemolysis with small doses of drug, and the degree of hemolysis can be quite severe. The DAT is positive for C3, but usually not IgG since the antibody is not bound to the cell.

3 Autoantibody mechanism. Antibody forms in response to drug, although the antibody also cross-reacts with the RBC membrane leading to DAT positivity. This type of drug-induced immune hemolysis is serologically indistinguishable from warm AIHA, and the diagnosis can only be confirmed if the patient responds to withdrawal of the drug. The DAT is positive in the absence of drug in the patient's blood sample. This type of hemolysis is seen with α -methyl dopa. The DAT becomes positive in a significant fraction of patients taking α -methyl dopa, but significant hemolysis occurs in only a few. These three mechanisms of DIIHA are not mutually exclusive. For example, cephalosporins are generally associated with immune hemolysis due to a drug adsorption mechanism or a neoantigen process, but they can also induce autoantibody formation.^{74,75}

Over 100 different drugs have been implicated in DIIHA, although most cases are rare (Table 8.3). With the decreased use of intravenous penicillin and α -methyl dopa, the incidence of drug-induced hemolysis associated with these agents has disappeared. Today, the majority of cases of DIIHA are due to second- and third-generation cephalosporins, especially cefotetan and ceftriaxone.^{73,74,76,77} A report from the American Red Cross Blood Services in Los Angeles has indicated that of 119 cases of DIIHA studied over the past 26 years, 74 (83%) were due to cefotetan and 12 (10%) to ceftriaxone. Garraty⁷³ has summarized the published literature related to the clinical and laboratory features of DIIHA due to cefotetan and ceftriaxone.

- Cefotetan DIIHA most commonly occurs after a single dose of drug administered in conjunction with surgery. Previous exposure to drug is uncommon. Hemolysis occurs 1–13 days after receiving drug. Usually there is intravascular hemolysis with hemoglobinemia and hemoglobinuria. Hemoglobin levels are very low (mean 4.8 g/dL). Fatal hemolytic anemia and renal failure have occurred in 19% of patients. The DAT is always positive (anti-IgG 100%, anti-C3 86%) and almost all sera react with normal untreated RBCs in the presence of cefotetan.

- Ceftriaxone DIIHA is more acute and severe in children compared with adults. It occurs within a few minutes up to a mean of 6 days (children) or 9 days (adults). Fatal hemolytic anemia occurred in 6 of 9 children and 3 of 10 adults. There is usually a history of prior ceftriaxone exposure. The DAT is always positive (anti-IgG 75%, anti-C3 100%). Antibodies in sera are detected only in the presence of ceftriaxone (patient serum + drug + normal RBCs).

A positive DAT without clinical hemolysis is not an indica-

tion for discontinuing any needed drug. In the presence of significant hemolysis, however, the suspected drug should be discontinued, particularly when other appropriate drugs are available. DIIHA usually resolves within a few days of stopping the drug. In severe cases, RBC transfusions may be given although the transfused red cells also may hemolyze at a similar rate.

Neonatal alloimmune hemolysis

Hemolysis due to alloimmune antibodies is seen with acute and delayed RBC transfusion reactions, following stem cell transplantation where there is an antigenic blood type difference between the donor and stem cell recipient, and during the neonatal period as a result of differences in maternal and fetal RBC antigens.⁷⁸ This section focuses on neonatal alloimmune hemolysis, the most common cause of hemolysis in newborn infants.

Neonatal alloimmune hemolysis is a consequence of maternal sensitization to fetal RBC antigens inherited from the father. Hemolysis occurs only in the fetus. The spectrum of clinical problems ranges from minimal hyperbilirubinemia to severe anemia with hydrops fetalis and/or kernicterus. Before effective prevention of Rh sensitization was available, hemolytic disease of the newborn was responsible for more than 10 000 deaths annually in the USA.⁷⁹ The incidence of alloimmune hemolysis nowadays is much less, but the majority of cases of serious alloimmune hemolysis are still due to Rh (D) incompatibility, although ABO maternal–fetal incompatibility is much more common. A much smaller fraction of neonatal hemolytic disease is due to sensitization to Kell, Duffy, Kidd, and other Rh antigens.

Rh hemolytic disease of the newborn

The role of Rh (D) antibody in classic erythroblastosis fetalis was first elucidated by Levine and Katzin in 1941.⁸⁰ The classification of Rh antibodies has been discussed above (see RBC antigens). The pathophysiology of alloimmune hemolysis resulting from Rh incompatibility includes the following: a Rh-negative mother, a Rh-positive fetus, leakage of fetal RBCs into the maternal circulation, and maternal sensitization to D antigen on fetal RBCs. The D antigen is the most immunogenic of the Rh antigens and there are no naturally occurring antibodies to Rh antigens. Immunization occurs almost exclusively during pregnancy. Small volumes of fetal RBCs enter the maternal circulation throughout gestation, although the major fetomaternal bleeding responsible for sensitization occurs during delivery.⁸¹

Rh hemolytic disease rarely ever occurs during the first pregnancy. However, once sensitization occurs, reexposure to Rh (D) RBCs in subsequent pregnancies leads to an anamnestic response, with an increase in the maternal anti-D titer and an increased incidence of affected infants. In North America and Europe, significant hemolysis occurring in the first pregnancy is nowadays due to maternal exposure to Rh-positive RBCs from an earlier transfusion, fetal bleeding associated with a previous spontaneous or therapeutic abortion, ectopic pregnancy, or fetal bleeding associated with amniocentesis.

Prevention of Rh immunization in the mother

The major factor responsible for the reduced death rate has been development of Rh immune globulin to prevent maternal sensitization. Important early observations were that fetomaternal RBC transfer (and thereby sensitization) primarily occurred during delivery and that the frequency of Rh immune hemolytic disease was much lower in ABO-incompatible pregnancies (maternal RBC type O, fetal RBC type A or B). The apparent beneficial effect of ABO incompatibility was due to the fact that maternal anti-A and anti-B antibodies recognize the corresponding A and B fetal RBCs, leading to their destruction before sensitization could occur. As a result of these early observations, it became standard practice for unsensitized Rh-negative mothers to receive a single intramuscular dose of Rh immune globulin (300 µg) within 72 hours of delivering of a Rh-positive infant.⁷⁹ The anti-D immune globulin attaches to fetal Rh-positive RBCs in the maternal circulation, thereby leading to their rapid removal and preventing sensitization. The results of this therapy were remarkable, with the virtual elimination of Rh (D) sensitization as a major cause of hemolytic disease in newborns. However, because Rh immunoprophylaxis is not universally available, maternal sensitization still occurs in some developing countries due to failure to receive initial anti-D prophylaxis.

The current standard of practice is to administer a full dose of Rh immune globulin to all unsensitized Rh-negative women at 28 weeks' gestation, with an additional dose given at birth if the infant is Rh positive. Moreover, the dose of Rh immune globulin should be increased proportionately when there is evidence of larger than normal fetomaternal bleeding at delivery. All newborns should be screened using the rosette test to screen for fetal RBCs.⁸² Positive results should be followed by a quantitative test such as the Kleihauer–Betke stain.⁸³ In suspicious cases (e.g., placental abruption, neonatal anemia), the volume of fetal hemorrhage can be quantified using the Kleihauer–Betke procedure. Rh immune globulin also should be administered to unsensitized Rh-negative women after any event known to be associated with increased risk of fetomaternal hemorrhage (e.g., spontaneous or therapeutic abortion, amniocentesis, chorionic villus biopsy). The risk of anti-Rh sensitization ranges from 0.6 to 5.4% when nonsensitized Rh-negative women undergo amniocentesis.⁸⁴

Prenatal management of the Rh-sensitized pregnancy

In utero, varying degrees of fetal hemolysis can occur, thereby leading to anemia, hepatosplenomegaly, and increased bilirubin formation. Bilirubin in the fetus is removed by the placenta into the maternal circulation, and thus hyperbilirubinemia is not a problem until after delivery. The major threat to the fetus is hydrops fetalis, and this can occur as early as 20–22 weeks' gestation. Hydrops fetalis is partly due to

high-output cardiac failure secondary to severe anemia. Low colloid osmotic pressure resulting from hypoalbuminemia, a consequence of hepatic dysfunction, and a capillary leak syndrome secondary to tissue hypoxia also contribute to the edema of hydrops. The major focus of maternal and fetal prenatal management is to prevent severe anemia, hydrops and intrauterine death.

Maternal IgG anti-D titers should be determined at 12–16 weeks' gestation (first prenatal visit) and then at 28–32 weeks and 36 weeks in the completely asymptomatic case with no evident risk other than being Rh negative. Significant hemolytic disease may be indicated by the presence of measurable titers at the beginning of the pregnancy, a rapid rise in the titer, or a titer $\geq 1 : 64$. A history of a previously affected infant suggests a very high likelihood for similar or greater morbidity in association with subsequent Rh-positive pregnancies unless the fetus can be shown to be Rh negative.

Fetal assessment may be obtained through ultrasound, amniocentesis, and percutaneous umbilical blood sampling (PUBS). The development of high-resolution ultrasound has been a major advance that facilitates detection of early hydrops. Evaluation of skin and scalp edema, cardiac and pleural effusions as well as hepatosplenomegaly, ascites and placental thickening are used to assess the severity of the immune destructive process. Amniocentesis provides a means of evaluating hemolysis through spectrophotometric analysis of bilirubin content in amniotic fluid (ΔOD_{450}). Indications for amniocentesis include a maternal IgG anti-D titer of $\geq 1 : 16$ or ultrasonographic evidence of hydrops. Amniocentesis may be performed as early as 14–16 weeks' gestation. If testing or history indicate a high likelihood of fetal anemia with risk of death, ultrasound-guided PUBS can be performed to determine the fetal hemoglobin. Fetal hydrops does not occur until the hemoglobin concentration of the fetus decreases below 4 g/dL (or hematocrit below approximately 15%).

In the past, at-risk fetuses older than 32 weeks' gestation with evidence of mature lung function were delivered early. However, for those fetuses of less than 32 weeks' gestation with immature lung function, early delivery was not possible and fetal RBC transfusions were given. Initially, intrauterine RBC transfusions were administered through the peritoneal cavity, and this procedure ameliorated the anemia sufficiently to save many otherwise doomed fetuses.⁸⁵ However, the success rate with intrauterine RBC transfusions was much lower in some cases where hydrops was already present. This lack of response in some hydropic fetuses occurred because RBC absorption from the peritoneal cavity (complicated by ascites) was too slow to reverse the effects of severe anemia and hypoxia. Subsequently, the advent of ultrasound and PUBS has facilitated direct intravascular RBC transfusion to correct life-threatening anemia, with the reversal of established hydrops in most cases.^{86,87} Both simple transfusions and exchange transfusions have been performed in

a number of fetuses.⁸⁸ Most perinatologists prefer simple RBC transfusion because of its shorter duration, aiming for a posttransfusion hematocrit no greater than 45% to avert circulatory overload.⁸⁹

Diagnosis and management of Rh hemolytic disease in the neonate

Immediately following delivery of all infants born to a Rh-negative mother, blood should be evaluated for a direct Coombs test, ABO and Rh antigen screens, as well as hemoglobin concentration and reticulocyte count. If the Coombs test is positive, further evaluation is indicated to determine specific antibody identity and to prevent any delay in obtaining compatible blood should exchange or straight transfusion be necessary.

Mild hemolytic disease is most common, manifested by a positive DAT with minimal hemolysis, little or no anemia (cord blood hemoglobin > 14 g/dL), and minimal hyperbilirubinemia (cord blood bilirubin < 4 mg/dL). Aside from early phototherapy, these newborns generally require no therapy unless the postnatal rate of rise in bilirubin is greater than expected. Infants who do not become sufficiently jaundiced to require exchange transfusion are at risk of development of severe late anemia associated with a low reticulocyte count, usually at 3–6 weeks of age; thus, it is important to closely monitor hemoglobin levels after hospital discharge.

Moderate hemolytic disease is found in a smaller fraction of affected infants. This is characterized by hemolysis, moderate anemia (cord blood hemoglobin < 14 g/dL), and increased cord blood bilirubin levels (> 4 mg/dL). The peripheral blood may reveal numerous nucleated RBCs, decreased numbers of platelets, and occasionally a leukemoid reaction with large numbers of immature granulocytes. The cause of thrombocytopenia is not understood, but it is unlikely to be an immune reaction because platelets lack Rh antigens. Similarly, the cause of the leukemoid reaction is not defined, although rarely it may be confused with congenital leukemia. Infants with Rh disease may also exhibit marked hepatosplenomegaly, a consequence of extramedullary hematopoiesis and sequestration of antibody-coated RBCs. The risk of development of bilirubin encephalopathy is high if these neonates do not receive treatment. Thus, early exchange transfusion with type-O Rh-negative fresh RBCs is usually necessary, in conjunction with intensive phototherapy. This approach has been responsible for the favorable outcome of most infants with moderate alloimmune hemolysis. It is common for newborns who receive an exchange transfusion to demonstrate a lower than normal hemoglobin concentration at the nadir of their "physiologic" anemia. In part this may be due to persistence of some anti-D antibody and destruction of the patient's own Rh (D)-positive RBCs. Therefore, follow-up of hemoglobin determinations for at least 2 months is important.

Blood type		
Mother	Rh (–)	O
Infant	Rh (+)	A or B
Anemia	Marked	Minimal
Direct Coombs test	Positive	Frequently negative
Indirect Coombs test	Positive	Usually positive
Hyperbilirubinemia	Marked	Variable
Red cell morphology	Nucleated cells	Spherocytes

ABO incompatibility

Hemolysis associated with ABO incompatibility is similar to Rh hemolytic disease in that maternal anti-A or anti-B antibodies enter the fetal circulation and react with A or B antigens on the erythrocyte surface (Table 8.4). In type A and B individuals, naturally occurring anti-B and anti-A isoantibodies are largely IgM molecules that do not cross the placenta. In contrast, the alloantibodies present in type O individuals are predominantly IgG molecules.⁹⁰ For this reason, ABO incompatibility is largely limited to type O mothers with type A or B fetuses. The presence of IgG anti-A or anti-B antibodies in type O mothers also explains why hemolysis caused by ABO incompatibility frequently occurs during the first pregnancy without prior “sensitization”. ABO incompatibility is present in approximately 12% of pregnancies, although evidence of fetal RBC sensitization (i.e., positive DAT) is found in only 3% of births, and less than 1% of live births are associated with hemolysis.⁸¹ The relative mildness of neonatal ABO hemolytic disease contrasts sharply with the findings in Rh incompatibility. In large part, this is because the A and B antigens are present in many tissues besides RBCs. Consequently, of the anti-A or anti-B antibodies that cross the placenta, only a small fraction actually bind to erythrocytes, the remainder being absorbed by other tissues.

Although hemolytic disease resulting from ABO incompatibility is milder than that resulting from Rh disease, severe hemolysis occasionally occurs, and hydrops fetalis has been reported. In these more severe cases it is essential to exclude other antibodies, as well as nonimmune causes of hemolysis such as glucose 6-phosphate dehydrogenase deficiency

or hereditary spherocytosis (HS). In most cases, pallor and jaundice are minimal. Hepatosplenomegaly is uncommon. Laboratory features include minimal to moderate hyperbilirubinemia and, occasionally, some degree of anemia. The DAT is frequently negative, although the indirect antiglobulin test (neonatal serum plus adult A or B RBCs) is more commonly positive. This paradox is related to the fact that fetal RBCs, compared with adult erythrocytes, have less type-specific antigen on their surface.⁹¹

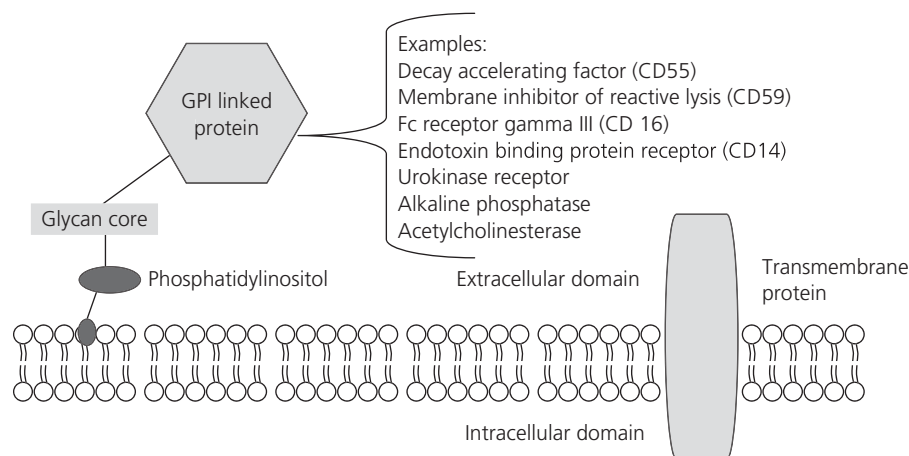

The peripheral blood smear in ABO incompatibility is characterized by marked spherocytosis, and sometimes this can present a problem in distinguishing ABO incompatibility from HS. This is particularly true in those cases of ABO incompatibility with a negative DAT. The osmotic fragility is abnormal in both and will not distinguish the two causes of spherocytosis. However, this is not an important clinical issue since the most important therapy for neonatal hemolysis should focus on controlling hyperbilirubinemia, and this is true for both HS and ABO incompatibility. Specific differentiation of ABO incompatibility from HS can wait a few weeks to months; the former will disappear, while HS will persist.

Hemolysis in ABO incompatibility is usually mild, presenting with some degree of hyperbilirubinemia. Of major concern is that some infants with ABO incompatibility may be discharged home from medical establishments before significant clinical jaundice is evident. It is critical that infants with ABO incompatibility be monitored closely for evolving jaundice and hyperbilirubinemia in the first few days of life. In most cases hyperbilirubinemia is readily controlled by phototherapy.⁹² When hyperbilirubinemia is more severe, exchange transfusion is necessary using group O Rh-compatible RBCs. Additional follow-up at 2–3 weeks of age to check for anemia in these infants is essential.

Minor blood group incompatibility

With the sharp decline of hemolytic disease due to Rh incompatibility, the proportion of cases caused by Rh c, Rh E, Kell, Duff, and Kidd incompatibility has increased from the previous estimate of 1–3% to as high as 20% (for Kell sensitization). The pathophysiology of these disorders is similar to that of Rh and ABO incompatibility. The infrequency of minor group incompatibility is primarily a reflection of the lower antigenicity of these RBC antigens. Diagnosis of minor group incompatibility is suggested by hemolytic anemia with a positive DAT in the absence of ABO or Rh incompatibility and with a negative maternal DAT. Definitive diagnosis requires identification of the specific antibody in neonatal serum or an eluate from neonatal RBCs. This is readily accomplished by testing maternal serum against a variety of known RBC antigens. With some antibodies such as Kell, antibody titer and amniocentesis findings may underestimate the severity of fetal hemolysis. Therefore, frequent ultrasound monitoring

Fig. 8.4 The glycosylphosphatidylinositol (GPI) anchor for attachment of proteins to the cell membrane. The anchor is composed of a glycan core and phosphatidylinositol in the outer face of the lipid bilayer. This GPI structure covalently binds and anchors many proteins to the cell surface. In contrast to surface proteins that use the GPI anchor, transmembrane proteins span the entire bilayer and have extracellular, transmembrane, and intracellular domains. Some examples of GPI-linked proteins are shown.

may be necessary, with fetal blood sampling being done in worrisome cases. Fetal blood sampling is also useful in determining whether the fetus of a heterozygous father has inherited the offending RBC antigen. This identifies those fetuses that need further serial evaluations.

Paroxysmal nocturnal hemoglobinuria

PNH is a disorder characterized by intermittent episodes of intravascular hemolysis and hemoglobinuria. It is due to an acquired stem cell defect that renders RBCs susceptible to complement-mediated lysis.^{93–96} In addition to hemolysis, venous thrombosis and bone marrow failure are features of this condition. PNH occurs primarily in adults, although occasionally it is recognized in children and adolescents.

In 1937, Thomas Hale Ham made the observation that red cells from patients with PNH were susceptible to lysis in an acidic environment, and this became the basis for the first laboratory test (Ham's test) to diagnose this disorder.^{97,98} The reason for this complement sensitivity is that PNH red cells lack two membrane proteins that normally inhibit complement activation and thereby defend against the C5b–C9 MAC and resultant pore formation. One of these proteins is CD55 (decay-accelerating factor or DAF), which binds C3b and thereby prevents C5 cleavage and formation of the MAC. The other is CD59 (membrane inhibitor of reactive lysis or MIRL), which inhibits the insertion of C9 into the membrane.^{99–101} Both of these proteins normally attach to the cell membrane via glycosylphosphatidylinositol (GPI), a cell membrane complex of a glycan core and phosphatidylinositol in the outer face of the lipid bilayer (Fig. 8.4). This GPI structure covalently binds and anchors many proteins to the cell surface.¹⁰²

It is now known that PNH is due to an acquired mutation of the phosphatidylinositol glycan class A gene (*PIG-A*) in pluripotent hemopoietic stem cells. *PIG-A* encodes for a glycosyltransferase required for the synthesis of GPI.^{103,104} The

mutant stem cell has the capacity to form a hematopoietic clone of cells that are deficient in those proteins normally attached to the cell via the GPI anchor.^{103,104} All marrow-derived cells (erythrocytes, granulocytes, platelets, and monocytes) are GPI deficient to varying degrees, thus supporting the concept that PNH is a clonal stem cell disorder. Study of glucose 6-phosphate dehydrogenase isozymes further supports the clonal basis of this condition.¹⁰⁵ Almost 200 different mutations in the *PIG-A* gene have been identified, some leading to complete inactivation of protein, other to partial inactivation. The abnormal PNH clone may be relatively small, affecting only a few percent of circulating erythrocytes and granulocytes or it may become dominant where almost all circulating cells are GPI deficient. Mature blood cells derived from this mutant hematopoietic clone can have a complete deficiency (type III) or partial deficiency (type II) of GPI proteins. In addition, patients with PNH have some cells with normal expression of GPI proteins (previously referred to as type I PNH cells).¹⁰⁶

Clinical features

The classical hemolytic presentation of this disorder was first described more than 100 years ago, depicted as a paroxysmal hemolytic process that was often more frequent at night, associated with hemoglobinuria and abdominal and back pain. The reason why hemoglobinuria occurs in the morning is not known for sure. One consideration is that the pH is slightly lower during sleep, thereby facilitating complement activation and hemolysis. In practice, many patients have dark urine throughout the day whereas others never develop this symptom. In most cases hemolytic episodes occur every few weeks, although some patients have chronic unrelenting hemolysis with severe anemia. Occasionally, infection may trigger hemolysis, although often there is no identifiable reason. A common problem resulting from chronic intravascular hemolysis is iron deficiency, which occurs secondary to hemoglobinuria.

Another severe clinical complication of PNH is venous thrombosis; these thrombi occur in unusual locations, such as the hepatic, portal and mesenteric veins. The complications of venous thrombosis are often fatal, because the hypercoagulability observed in PNH is very difficult to treat even with aggressive anticoagulation. The cause of the hypercoagulable state in PNH is not well established. PNH platelets lack the GPI-linked complement regulatory proteins CD55 and CD59 and complement activation leads to platelet membrane vesiculation and the release of microparticles with procoagulant properties.¹⁰⁷ The levels of natural plasma anticoagulants (protein C, protein S, antithrombin III) are normal in PNH patients.¹⁰⁸

Defective hematopoiesis is seen in many patients with PNH, either at presentation or during the course of the disease. The cause of this impaired hematopoiesis is not well understood, and it is not known whether GPI-linked surface proteins have a role in normal hematopoiesis. PNH can evolve into myelodysplasia or, less commonly, acute non-lymphoblastic leukemia.¹⁰⁹ However, a particularly interesting association exists between PNH and aplastic anemia in that one often evolves into the other.¹¹⁰ The basis for this relationship between aplasia and PNH is not entirely clear. A commonly held view is that aplastic anemia is the result of an immunologic attack on hematopoietic stem cells.¹¹¹ Moreover, many patients with severe aplastic anemia have PNH cells at diagnosis, and the number of these cells often increases during the course of disease.^{111,112} An interesting hypothesis that relates PNH and aplastic anemia is that the immunologic assault on stem cells may be mediated via GPI-anchored proteins. As a consequence, the PNH clone might be protected from immunologic destruction, thus giving them an apparent growth advantage over normal hematopoietic stem cells.^{111,113}

Although primarily a disease of adults, PNH definitely occurs in children and adolescents, and the diagnosis should be considered for any child with unexplained cytopenia or thrombosis. In a report of 26 young patients with PNH, Ware *et al.*¹¹⁴ noted the differences in clinical features compared with PNH in adults. Very few children had dark urine as a presenting symptom, and clinically obvious hemoglobinuria occurred in only 65% of children. Thrombosis occurred in approximately one-third of patients, and some died of this dreaded complication. All patients had laboratory evidence of defective or ineffective hematopoiesis, either at diagnosis or over the course of their disease. In a recent study of childhood PNH in the Netherlands, the vast majority presented with aplastic anemia or myelodysplasia.¹¹⁵ No child presented with nocturnal hemoglobinuria.

Diagnosis

The original laboratory tests used to diagnose PNH were designed to show increased sensitivity of RBCs to comple-

ment lysis. However, both the acid hemolysis (Ham test) and the sugar-water test are now of historical interest only, having been replaced by flow cytometry detection of GPI-linked proteins. Peripheral blood erythrocytes and granulocytes can be analyzed by flow cytometry for surface expression of GPI-linked proteins such as CD16, CD48, CD55, or CD59.^{116,117}

Treatment

Goals of therapy include pharmacologic methods of limiting hemolysis, red cell transfusions, treating and preventing iron deficiency or overload; the treatment and prevention of venous thrombosis; and attempts to replace abnormal stem cells through stem cell transplantation.

RBC transfusions are given to symptomatic anemic patients. Iron losses usually cannot be replenished simply from dietary sources and supplemental iron therapy is often necessary. There is a theoretical concern that iron supplementation in the iron-deficient patient can result in a burst of erythropoiesis and an increase in the number of PNH cells in the circulation, with subsequent exacerbation of hemolysis of the newly formed cells. This possible complication should be appreciated, but it should not prevent the patient from receiving iron therapy.

Therapy with oral corticosteroids (prednisone 1–2 mg/kg daily) can ameliorate hemolysis and is often recommended for 24–72 hours around the time of a hemolytic episode. A recent report suggested good results with eculizumab, a humanized monoclonal antibody that binds to C5, inhibiting its cleavage into C5a and C5b, thereby preventing the formation of the C5b–9 complex. When given to transfusion-dependent PNH patients, hemolysis was decreased as manifested by a reduced serum LDH concentration, decreased transfusion requirements (with some patients becoming free of any transfusion need), and reduced hemoglobinuria in almost all patients.¹¹⁸

An ideal treatment for a disorder due to a stem cell mutation is the replacement of such progenitor cells with donor unaffected stem cells. Because stem cell transplantation can be curative therapy for PNH, it should be considered for selected patients if an HLA-matched donor is available.^{119–121} Both related and unrelated matched donors have been used.

Disorders of erythrocyte metabolism including porphyria

Disorders of erythrocyte metabolism

Lawrence Wolfe and Peter E. Manley

Red cell metabolism

Human erythrocytes are devoid of nuclei and cytoplasmic organelles in order to facilitate their deformability when passing through microcapillaries. Because they have no organelles, they are incapable of synthesizing proteins and lipids and have no capacity for oxidative phosphorylation, and have therefore developed a highly adapted metabolism.¹ Red cells rely completely on the catabolism of glucose (glycolysis) as an energy source to generate adenosine triphosphate (ATP). Red cell metabolic function includes generating compounds with the ability to protect red cell membranes and hemoglobin from oxidative damage, which maintains cell integrity and function. There are two major pathways involved in these important functions (Figs 9.1 and 9.2).

The Embden–Meyerhof pathway (Fig. 9.1) utilizes approximately 90% of available glucose and generates the ATP required for energy. The rate-limiting step is the conversion of glucose to glucose 6-phosphate (G6P) by hexokinase (HK). This pathway is also important in generating 2,3-diphosphoglycerate (2,3-DPG), which alters oxygen affinity, and nicotinamide adenine dinucleotide (NADH), which is used to restore methemoglobin to its functional state. Defects in the enzymes of this pathway are usually associated with chronic or congenital nonspherocytic hemolytic anemias.

The hexose monophosphate (HMP) shunt or pentose phosphate shunt (Fig. 9.2) utilizes approximately 10% of red cell glucose. The rate-limiting step in this pathway is the conversion of G6P to 6-phosphogluconate (6PG), which is catalyzed by glucose 6-phosphate dehydrogenase (G6PD). This pathway is the only way a red cell can produce nicotinamide

adenine dinucleotide phosphate (NADPH). This then regenerates the pool of reduced glutathione (GSH). Reduced glutathione protects the red cell from oxidative damage from superoxide anions, methemoglobin, and hydrogen peroxide, which are formed during the reactions of hemoglobin with oxygen. These oxidants can also be formed when red cells are exposed to exogenous agents such as drugs or to oxygen products formed by granulocytes fighting infection. Therefore patients with defects in the HMP pathway tend to have acute hemolytic crises whenever an oxidant stress is applied.

In addition to these pathways the red cell has an additional mechanism to protect itself. Because the red cell relies mainly on ATP, it is critically important that the cell preserves its purine nucleotides. However pyrimidine nucleotides are toxic to red cells and must therefore be removed. The preservation and formation of the pool of nucleotides begins at the reticulocyte stage when ribosomal RNA is broken down. To successfully retain the purines needed and to remove the toxic pyrimidines the red cell has specific nucleotidases. The enzyme pyrimidine 5'-nucleotidase (P5'N) selectively dephosphorylates the pyrimidines CMP and UMP to cytidine and uridine, and this allows these molecules to passively diffuse from the red cell. Patients with defects in this enzyme have congenital nonspherocytic hemolytic anemias and basophilic stippling due to the excessive pyrimidines within the cell.

In the first half of the twentieth century, the initial attempts at classification were based on the autohemolysis test, in which saline-washed erythrocytes were incubated at 37°C and hemolysis was analyzed after 48 hours.² Autohemolysis was greater in all patients with congenital nonspherocytic hemolytic anemias. They were able to group the erythrocytes they tested into two types: type I, where hemolysis was

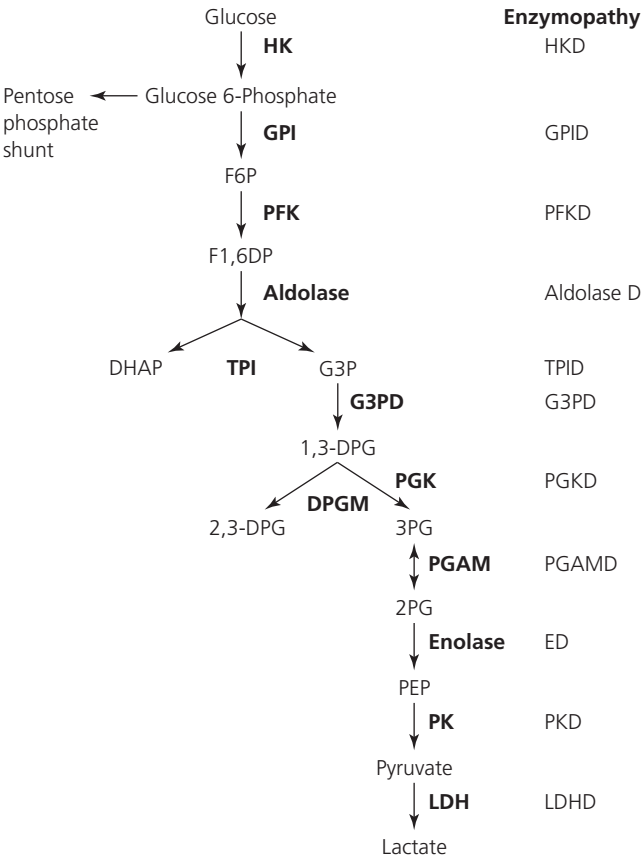

Fig. 9.1 Embden–Meyerhof pathway and known enzymopathies. Enzymes are bold; substrates are faint. ‘D’ added to the enzyme abbreviation in enzymopathy column indicates deficiency of that enzyme. HK, hexokinase; GPI, glucosephosphate isomerase; F6P, fructose 6-phosphate; PFK, phosphofructokinase; F1,6DP, fructose 1,6-diphosphate; DHAP, dihydroxyacetone phosphate; TPI, triosephosphate isomerase; G3P, glucose 3-phosphate; G3PD, glucose 3-phosphate dehydrogenase; 1,3-DPG, 1,3-diphosphoglycerate; DPGM, diphosphoglycerate mutase; 2,3-DPG, 2,3-diphosphoglycerate; PGK, phosphoglycerate kinase; 3PG, 3-phosphoglycerate; PGAM, phosphoglycerate mutase; 2PG, 2-phosphoglycerate; PEP, phosphoenolpyruvate; PK, pyruvate kinase; LDH, lactate dehydrogenase.

reduced if additional glucose was added; and type II, where hemolysis was unchanged or increased with the addition of glucose. It was noted that patients with type II erythrocytes contained low levels of ATP and high levels of 2,3-DPG.³ It was felt that patients with these types of erythrocytes had an underlying defect in the glycolytic pathway and this was why glucose did not affect autohemolysis. This was confirmed when Valentine *et al.*⁴ described the first cases of pyruvate kinase (PK) deficiency.

G6PD deficiency was first described when African-American soldiers developed an acute hemolytic crisis with hemoglobinuria after taking the antimalarial drug primaquine.⁵

Epidemiology

With the exception of PK and G6PD deficiency, the erythroenzymopathies are very uncommon (see Table 9.1 for prevalence).

Investigations when considering a diagnosis of red cell enzymopathy

Clinical findings

The most prominent clinical finding in a patient with a red cell enzymopathy is hemolysis. However, the hemolysis is not the same in all enzymopathies. The Embden–Meyerhof pathway is how the red cell generates the ATP needed for everyday survival and therefore patients with defects in this pathway will usually have constant chronic hemolysis. Patients with defects in the HMP shunt will usually have acute bouts of hemolysis when an oxidative stress is applied, and thus their disease appears episodic. In addition to hemolysis, these conditions can present with various syndromes, including splenomegaly, neurologic symptoms such as spasticity and hypotonia, and musculoskeletal symptoms such as

Fig. 9.2 Hexose monophosphate shunt. G6P (glucose 6-phosphate) is converted to 6PG (6-phosphogluconate) by G6PD (glucose 6-phosphate dehydrogenase) generating NADPH (nicotinamide adenine dinucleotide phosphate reduced), which regenerates GSH (glutathione) through interaction with GR (glutathione reductase) and GSSG (glutathione disulfide). Glutathione is then available for reducing active oxygen compounds or oxidized proteins especially hemoglobin.

Table 9.1 Prevalence of enzymopathies.

Type	Prevalence
<i>Embden–Meyerhof pathway</i>	
Hexokinase deficiency	22 cases described ^{6,7}
Glucosephosphate isomerase deficiency	60 cases described ⁸
Phosphofructokinase deficiency	35 cases described ⁹
Aldolase deficiency	5 cases described ¹⁰
Triosephosphate isomerase deficiency	34 cases described ¹¹
Phosphoglycerate kinase deficiency	20 cases described ¹²
Diphosphoglycerate mutase deficiency	20 cases described ¹³
Phosphoglycerate mutase deficiency	5 cases described ¹⁴
Enolase deficiency	3 cases described ¹⁵
Pyruvate kinase deficiency	>400 cases described ¹⁶
Lactose dehydrogenase deficiency	4 families described ¹⁷
<i>Hexose monophosphate shunt</i>	
Glucose 6-phosphate dehydrogenase deficiency	400 million cases ¹⁸
Glutathione synthetase	20 cases described ¹⁹
Glutamylcysteine synthetase	3 cases described ²⁰
Glutathione reductase	3 cases described ²¹
<i>Erythrocyte nucleotide metabolism</i>	
Pyrimidine-5'-nucleotidase deficiency	40 cases described ²²
Adenosine deaminase overexpression	14 cases ^{23–25}

easy fatigability and severe muscle cramps. These patterns of presentation can help discriminate among the conditions. Although these symptoms are rare, the simultaneous appearance of muscle cramps with or without effort, myoglobinuria or rhabdomyolysis, and hemolytic anemia requires examination of red cell enzymes. Table 9.2 summarizes the symptoms of the red cell enzymopathies.

Erythrocyte morphology

In any hemolytic anemia, one of the first steps in the diagnostic process is examination of the peripheral blood smear. A large percentage of patients with hemolytic anemia can be detected by simple perusal of the smear. In addition, primary examination of the smear helps design the subsequent work-up. In patients with defects of the Embden–Meyerhof pathway, most exhibit less active smears and little spherocytosis, often being termed “congenital nonspherocytic hemolytic anemia” or so-called “smear-negative” hemolysis (where there is no predominant morphology). This should lead the hematologist to specifically consider a small group of disorders including red cell metabolic defects and Wilson disease. The HMP shunt defects, when oxidative stress is present, may show “bite” and “blister” cell morphologies, but more characteristically the hematologist is asked to examine a smear after a bout of hemolysis or between attacks, and at these times it would appear normal. Patients with P5N deficiency will have significant basophilic stippling of

their smears, reflecting the inability to clear pyrimidine nucleotides from the cytoplasm.

Patients with PK deficiency can have a high reticulocyte count, crenated burr cells, echinocytes, and dehydrated effete red cells, reflecting severe ATP depletion. Spherocytes are not elevated in patients with PK deficiency.

Laboratory information

Basic laboratory data

Patients who have any type of hemolytic anemia should have certain standard laboratory studies performed. These include (i) blood type and cross-match for red cell antibodies and to prepare the patient for transfusion if necessary, (ii) a complete blood count, (iii) blood smear and reticulocyte count, (iv) urinalysis to assess if hemolysis is intravascular, (v) serum lactate dehydrogenase (LDH), (vi) fractionated bilirubin and (vii) haptoglobin. Most patients with red cell enzymopathies will have a grossly normal osmotic fragility test.

Analysis of intermediate metabolites

When there is inhibition of a step in the glycolytic pathway, it can be helpful to examine the measurable intermediates proximal or distal to the deficient enzyme, such as 2,3-DPG and glutathione in HMP shunt defects. Red cell ATP can also be measured (Table 9.3). Analysis of these intermediates must be interpreted with caution because patients with anemia have increased levels of 2,3-DPG in order to improve oxygen delivery.²⁶ Another subtlety of evaluation involves the fact that hemolytic anemia leading to reticulocytosis will increase the population of young red cells, and their higher levels of ATP mask an overall depletion of ATP.

Triosephosphate isomerase (TPI) catalyzes the interconversion of dihydroxyacetone phosphate (DHAP) and glyceraldehyde 3-phosphate. If DHAP is not converted to glyceraldehyde 3-phosphate, it will spontaneously degrade to methylglyoxal.²⁷ These excessive intermediates can be measured when TPI deficiency is suspected. With the development of direct measurement for all enzymes of the glycolytic pathway, the analysis of intermediate metabolites is not obligatory but may be able to assist the investigator to target a specific enzyme. Patients with low levels of glutathione suggest deficiencies in either γ -glutamylcysteine or glutathione synthetase.^{28,29}

Enzyme screening tests

Since these diseases are very rare, screening tests have been developed only for the more common disorders, such as G6PD deficiency. The fluorescent spot test is the oldest and most reliable screening test for G6PD.^{30,31} It is based on the fluorescence of NADPH after G6P and NAD are added to a

Table 9.2 Clinical features associated with enzymopathies.

Enzyme	Inheritance	Hemolysis	Neurologic	Myopathy	Other
<i>Embden–Meyerhof pathway</i>					
Hexokinase deficiency	AR	+*			
Glucosephosphate isomerase deficiency	AR	+ [†]	+ (rare)	+ (rare)	Fetal hydrops, splenomegaly, recurrent infection
Phosphofructokinase deficiency	AR	± [‡]		+	Myoglobinuria, myopathy, hyperuricemia
Aldolase deficiency	AR	+*	±	±	3 of 6 patients with rhabdomyolysis
Triosephosphate isomerase deficiency	AR	+*	+	+	Recurrent infection, sudden cardiac death, neonatal jaundice
Phosphoglycerate kinase deficiency	XL	+*	±	±	Myoglobinuria
Diphosphoglycerate mutase deficiency	AR	±			Erythrocytosis
Phosphoglycerate mutase deficiency	AR			+	Myoglobinuria
Enolase deficiency	AD	(+) ^{‡§}			Spherocytosis
Pyruvate kinase deficiency	AR	+ [§]			Iron overload
Lactose dehydrogenase deficiency	AR	+		+	
<i>Hexose monophosphate shunt</i>					
Glucose-6-phosphate dehydrogenase deficiency	XL	+ [†]			Acidosis, 5-oxoprolinuria
Glutathione synthetase	AR	+*	+		Recurrent infection
γ-Glutamylcysteine synthetase	AR	+*	+		Favism, cataracts
Glutathione reductase	AR	+*			
<i>Erythrocyte nucleotide metabolism</i>					
Pyrimidine 5'-nucleotidase deficiency	AR	+ [‡]			Basophilic stippling
Adenosine deaminase overexpression	AD	+*			
Adenylate kinase deficiency	AR	(+)			

* Nondiagnostic smear.

† Oxidant hemolysis morphology may appear.

‡ Stippling may be seen.

§ Active smear.

Parentheses indicate that link to enzyme deficiency is unproven.

AR, autosomal recessive; AD, autosomal dominant; XL, X-linked.

Table 9.3 Metabolic intermediates in red cell enzymopathies.

Defect	2,3-DPG levels	ATP levels	Comments
Proximal glycolysis: HK, GPI or PFK	Normal to low	Normal to low	Multiple variability within each defect
Distal glycolysis: PK or PGK	Elevated	Normal to low	Low ATP and 2,3-DPG more useful in PK deficiency PK deficiency also has high levels of 3-PG
Overproduction of ADA	Normal	Low	Due to rapid breakdown of adenosine

ADA, adenosine deaminase; 2,3-DPG, 2,3-diphosphoglycerate; GPI, glucosephosphate isomerase; HK, hexokinase; PFK, phosphofructokinase; 3-PG, 3-phosphoglycerate; PGK, phosphoglycerate kinase deficiency; PK, pyruvate kinase.

hemolysate of test cells. Recently, a new diagnostic kit has been described that detects patients with < 50% G6PD activity.^{32,33} This test uses a formazan, WST-8, which is converted to an orange color detectable in the presence of G6PD and this is visible to the naked eye. New rapid microarray-based assays have also been developed to detect G6PD deficiency in specific populations.³⁴

For PK, several screening tests have been developed but these may not detect some of the PK variants,³⁵ and they have not been extensively used.

The red cells of patients with P5'N deficiency exhibit a different spectral analysis and this can be used as a screening test for this disorder. Normal red blood cells have an absorption peak at 257 nm owing to the high percentage of

adenosine compounds; patients with P5'N deficiency have a higher percentage of pyrimidine compounds, changing the absorption peak to 268 nm.³⁶

Direct enzyme measurement and DNA measurement

Definitive diagnostic measurements are discussed with each specific disorder. All enzymes can be directly measured. Now that many mutations of the various enzymopathies have been discovered, DNA analysis can be performed to make the diagnosis. When direct enzyme measurement is employed there are a few pitfalls of which the investigator needs to be aware. In patients who have an episode of acute hemolysis, the most severely deficient red cells have usually been removed, especially in defects of the HMP shunt. When there is a reticulocytosis immediately following acute hemolysis or in patients who have recently been transfused, the enzyme levels can be read as abnormally high. Therefore correction for increased activity of enzymes and reticulocytes must be made. Some assays require leukocytes to be removed as they have higher levels of the enzyme.³⁷ The age of the patient being examined must also be taken into account when evaluating enzyme levels.³⁸

Disorders of the Embden–Meyerhof pathway

Hexokinase deficiency

HK is the first enzyme of the pathway and plays an important role. HK phosphorylates glucose, forming G6P, using magnesium as a cofactor and ATP as a phosphate source. It provides the substrate for both the HMP shunt and anaerobic glycolysis necessary for red cell survival. HK deficiency is an autosomal recessive disease.

The enzyme

There are four major isozymes of mammalian HK.³⁹ The most prevalent isozyme involved in erythrocytes is HK-1. Recent studies have identified a specific erythroid isoform, HK-R.⁴⁰ The human HK-1 gene is located on chromosome 10q22,⁴¹ which contains an erythroid cell-specific promoter.⁴² HK activity initially declines rapidly. Specifically, HK-R activity, which is mainly expressed in reticulocytes, falls off quickly due to its short half-life (10 days). HK-1 becomes the predominant isoform as the erythrocyte ages because its half-life is much longer (66 days).⁴⁰ HK-1 is inhibited by its product G6P, which competitively inhibits ATP binding.⁴³ Mutations of the HK-1 gene have been reported and appear to decrease the enzyme's ability to undergo needed conformational changes during substrate binding.⁴⁴

Clinical presentation

All patients with HK deficiency have hemolytic anemia.⁴⁵ The severity of the hemolysis is generally moderate. Severely affected individuals may have hyperbilirubinemia as a neonate. Patients may appear jaundiced or have splenomegaly. Development of gallstones may occur at an earlier age. Several affected patients have had congenital malformations or psychomotor retardation,⁴⁶ but it is not clear if these manifestations are directly caused by HK deficiency. Patients may also have severe tissue hypoxia because they are unable to decrease oxygen affinity and increase delivery to tissue by increasing the production of 2,3-DPG.

Diagnosis

Patients with HK deficiency may have a reduced level of 2,3-DPG, while ATP levels can be normal or reduced.^{47,48} A moderate anemia with unremarkable red cell morphology is seen. The diagnosis of HK deficiency can be made by showing the enzyme to have aberrant kinetics, reduced stability, or altered electrophoretic mobility.⁴⁵ It is important to note that HK deficiency is an age-dependent enzyme with higher activity in reticulocytes than old erythrocytes. When interpreting the data it should include a comparison with other age-dependent enzymes such as PK or G6PD as an internal control and with HK levels in normal subjects with high reticulocyte counts. Otherwise the values can be interpreted as normal. Prenatal diagnosis of HK deficiency has been performed and described in a fetus with intrauterine growth retardation.⁴⁹

Treatment

The treatment of patients with this disorder is to alleviate symptoms. It consists of transfusions and supplementation with folic acid; in severe cases (transfusion-dependent) splenectomy has abolished the need for transfusions.

Glucosephosphate isomerase deficiency

Glucosephosphate isomerase (GPI) catalyzes the isomerization of G6P to fructose 6-phosphate (F6P). Deficiency of this enzyme was first described in 1968,⁵⁰ and is the third most common cause of nonspherocytic hemolytic anemia after G6PD and PK deficiency. It is an autosomal recessive disease.

The enzyme

GPI is a dimeric enzyme with a molecular mass of 134 kDa. The gene encoding GPI is found on chromosome 19q13.1.⁵¹ There are no isozymes for GPI, and thus in affected patients all tissues and cells are deficient in the enzyme. The majority

of the gene defects (24 of the 29 found in this disorder) are point mutations.⁵² More than 50% of patients affected with this disorder are compound heterozygotes. These mutations are very heterogeneous, with only 7 of the 29 mutations found in more than one family. GPI deficiency leads to a build-up of G6P, which is a potent inhibitor of HK. Deficiency of GPI affects not only anaerobic glycolysis but also the HMP shunt, leaving the patient susceptible to oxidative stress. The correlation between genotype and severity of disease has not been fully elucidated.

Sequencing of a protein called neuroleukin (NLK), which has neurotrophic and lymphokine properties, has shown that it is identical to GPI.^{53,54} Deficiencies in NLK have been associated with motor neuron disease.⁵⁵

Clinical presentation

Patients with GPI deficiency present with anemia, which varies from mild to severe. Patients also have variable degrees of jaundice, splenomegaly, and an increased risk of gallstones. As there are no isozymes of GPI, an affected patient has GPI deficiency in all tissues; thus GPI deficiency has also been associated with hydrops fetalis, neonatal death, and priapism.^{56–58} The latter unusual symptom is theorized to be due to poor red cell deformability. Patients with GPI deficiency have had associated neurologic and white blood cell impairment. The homology with NLK has implicated GPI as the cause of these defects.^{59,60} Hemolytic crises associated with GPI deficiency due to infection or exposure to oxidant drugs may occur. This may be due to the inability to recycle F6P through the HMP shunt.⁵⁰

Diagnosis

A complete blood count shows a normochromic anemia with an increased reticulocyte count. Patients have decreased levels of ATP, 2,3-DPG, and GSH, due to decrease in HK secondary to high levels of G6P. GPI deficiency is mainly identified by the thermolability of the mutant *in vitro*. Enzyme activity can also be measured directly and is typically 10–40% of normal, with an increase in the G6P/F6P ratio.

Treatment

There is no specific therapy for GPI deficiency. Patients may require transfusions in acute situations or to maintain an adequate level of hemoglobin. In an acute hemolytic crisis, patients should be treated for any infection and have any offending oxidant agent removed, giving blood and fluid management to maintain adequate urine output. In patients who required chronic transfusion, splenectomy usually alleviated the need for continuation of transfusion therapy.⁵²

Phosphofructokinase deficiency

Phosphofructokinase (PFK) catalyzes the principal rate-limiting step in glycolysis: the phosphorylation of F6P to fructose 1,6-diphosphate (FDP). Deficiency of this enzyme was first noted by Tauri *et al.*⁶¹ It occurs as an autosomal recessive disease. It is also called glycogen storage disease VII or Tauri disease.

The enzyme

The heterogeneity of clinical syndromes associated with deficiency of PFK mirrors the complexity of its genetic control. PFK is a homotetrameric or heterotetrameric enzyme with three types of subunits: muscle (M), liver (L), and platelet (P) subunits are encoded by separate structural genes. The M subunit is isolated to chromosome 12q13,⁶² the L subunit to chromosome 21q22,⁶³ and P subunit to chromosome 10p15.⁶⁴ Muscle PFK is composed entirely of M subunits, and liver PFK is made up entirely of L subunits. In red cells, both M and L subunits combine to form different tetramers, the relative proportions of which vary during development. This may explain the lower activity of PFK in neonatal red cells, the composition of which includes the relatively unstable L₄ isozyme that is not found in normal adult red cells. To date there have been 39 reports of unrelated families with PFK deficiency,⁹ with multiple different mutations described in the PFK-M gene.^{9,65} PFK-M deficiency appears to be more prevalent in people who are of Ashkenazi descent and have two typical mutations: one that alters a splice site or one which leads to nucleotide deletion in the PFK-M gene.^{66,67}

Clinical findings

PFK deficiency can present with a variety of symptoms. It is characterized by myopathy or hemolysis. The majority of presenting symptoms relate to myopathy, including fatigue, muscle cramps, and exercise intolerance. The classic presentation has these symptoms exacerbated after a high-carbohydrate meal.⁶⁸ Patients can exhibit myoglobinuria secondary to rhabdomyolysis after exercise. Muscle weakness characteristically worsens during exercise because of the reliance of muscle cells on anaerobic glycolysis for energy generation. As red cell PFK is composed of both L and M subunits, red cells that have homotetrameric enzyme can be spared the full metabolic effects of M-subunit deficiency in classic PFK deficiency. Cases of PFK deficiency with isolated hemolysis and normal muscle enzyme activity have also been recognized.^{69,70} When present, anemia is usually mild or moderate. In its most severe form, PFK deficiency may present at birth, cases having been described in infants deficient in all three isoforms. These patients suffer not only myopathy but also central nervous system dysfunction and cardiomyopathy, and can follow an inexorable course with death from

respiratory failure in infancy.^{71,72} Usually, the onset of symptoms is delayed until later childhood or even adult life. Increased purine generation in muscle and red cells may lead to hyperuricemia and arthropathy, which can be present even if no myopathy is present.⁷³

Diagnosis

Patients may have a mild erythrocytosis due to reduced 2,3-DPG concentration, which occurs because the block is upstream from the formation of 2,3-DPG. Even in this situation the red cell lifespan is shortened. With the exception of prominent basophilic stippling seen in a few cases, red cell morphology is not helpful diagnostically. Patients can also have elevated serum creatine kinase and hyperuricemia. Reduced muscle PFK activity may be inferred from a failure of lactate production after anaerobic (ischemic) forearm exercise or by magnetic resonance spectroscopy.⁷⁴ The diagnosis of PFK deficiency can be confirmed by assay of red cell enzyme activity and intermediates. Typically, red cell PFK activity is about 50% of normal. Direct confirmation may be obtained by assay of enzyme activity on biopsied muscle tissue. Since muscle contains exclusively M₄ tetramers, the reduction in enzyme activity is correspondingly greater than in red cells.⁷⁵ In patients of Ashkenazi descent, genetic testing can be performed as 95% of these patients will have one of the two most common mutations.⁷⁶

Treatment

Treatment is mainly through prevention. Avoidance of strenuous exercise can prevent episodes of muscle cramping, fatigue, and rhabdomyolysis. Anemia can be treated by red cell transfusions. There is one reported case in a patient with infantile PFK deficiency who showed some improvement in symptoms with a ketogenic diet; however this patient subsequently died.⁷⁷

Aldolase deficiency

Aldolase is responsible for conversion of FDP to glyceraldehyde 3-phosphate and DHAP. The main enzyme that causes defects in erythrocyte glucose metabolism is aldolase A. Aldolase deficiency is an autosomal recessive disease.

The enzyme

Three tissue-specific isozymes, A, B and C, exist. Aldolase C is found in brain. Aldolase B is expressed mainly in the liver, kidney, and intestine, where its main role is in exogenous fructose utilization, mutations in this enzyme causing fructose intolerance. Aldolase A is more ubiquitous and is the enzyme that drives the red cell glycolytic pathway.⁷⁸ Aldolase A is encoded on chromosome 16q22–24 and the

protein is a homotetramer.⁷⁹ Note that only six cases of hemolytic anemia due to inherited aldolase deficiency have been described.^{80,81}

Clinical signs and symptoms

All patients with aldolase A deficiency have exhibited anemia, ranging from mild to severe; three of six patients had myopathy and one patient had mental retardation. In one case, myopathy characterized by exercise intolerance and rhabdomyolysis was a prominent manifestation.⁸² Episodes of rhabdomyolysis were precipitated by fever. This was attributed to marked thermal instability of the mutant enzyme.

Diagnosis

All patients have a nonspherocytic hemolytic anemia. They can have hemoglobinuria and myoglobinuria. Patients with associated myopathy have elevated creatine kinase. Aldolase A enzyme activity can be measured and is low in patients with this disorder.

Treatment

In patients with severe anemia the treatment is red blood cell transfusion. One patient had resolution of transfusion requirements after splenectomy.⁸¹ As with other shared enzymopathies with muscle involvement, strenuous exercise needs to be avoided.

Triosephosphate isomerase deficiency

TPI catalyzes with high efficiency the interconversion of the triosephosphates DHAP and glyceraldehyde 3-phosphate, the equilibrium favoring DHAP formation by a factor of 22 : 1. The clinical phenotype was first described by Schneider *et al.*⁸³ TPI deficiency is an autosomal recessive disease.

The enzyme

TPI is a homodimeric enzyme expressed in all cell types. It is encoded by a single gene on chromosome 12p13.^{84,85} It is not only involved in glycolysis but is also an important enzyme in gluconeogenesis and triglyceride synthesis. To date, 14 mutations in the TPI gene have been identified.^{11,86} The most common mutation found is a point mutation in codon 104 resulting in a substitution of Glu for Asp,⁸⁷ which creates a thermolabile unstable protein. The fact that TPI is a ubiquitous enzyme found in all cells is reflected in the multisystem nature of the clinical deficiency state. Patients with TPI deficiency have elevated levels of methylglyoxal, a degradation product of DHAP. This leads to increased glycation and nitrosation of proteins and may contribute to the pathogenesis of neurodegeneration.²⁷

Clinical signs and symptoms

Patients who have TPI deficiency are either homozygotes or compound heterozygotes. Pure heterozygotes are clinically normal. TPI deficiency is the most severe disorder of the Embden–Meyerhof pathway. Patients with TPI deficiency usually present in the first year of life with nonspherocytic hemolytic anemia, which can result in neonatal jaundice. The degree of anemia in TPI deficiency is variable. Although severe anemia may be encountered, most patients require only occasional transfusions after the neonatal period. Patients also have an increased susceptibility to bacterial infections. This is most likely due to the deficiency of the leukocyte enzyme. The anemia may also worsen during periods of infection. Between 6 months and 2 years of age neuromuscular dysfunction becomes evident. The constellation of neurologic abnormalities observed in TPI deficiency includes motor delay or regression, spasticity, hypotonia, dystonic movements, opisthotonos, nystagmus, and optic atrophy.^{87–89} These findings suggest that specific structures in the basal ganglia, brainstem, and spinal cord (anterior horn cells) are damaged in TPI deficiency.⁸⁹ Neuromuscular impairment is usually progressive, and most affected children fail to survive beyond 5 years of age. Rarely, the neurologic deficits may stabilize during childhood and there have been isolated cases in which there is no overt neurologic dysfunction.^{90,91} Cognitive function is normal and correlates with the fact that there is little cortical damage in TPI deficiency. Patients have developmental delay more likely related to motor dysfunction than cognitive dysfunction. The cause of death in these patients is usually sudden and not well understood but cardiac arrhythmia has been invoked as a likely cause.

The mechanisms underlying the neuropathic effects of TPI deficiency are poorly delineated. Neuroimaging studies have failed to reveal extensive structural changes in the brain. Electrophysiologic studies show evidence of denervation myopathy in some cases. DHAP is an essential precursor in biosynthesis of ether glycerolipids (plasmalogens). Plasmalogen biosynthesis is impaired in peroxisomal disorders such as Zellweger syndrome and neonatal adrenoleukodystrophy, in which neurologic manifestations are prominent.⁹² A kindred has been described in which only one of two affected siblings manifests neurologic dysfunction.⁹¹ This was a family in which two Hungarian brothers were found, one with neurologic deficits and one without. As previously mentioned, patients with TPI deficiency have elevated levels of methylglyoxal, a degradation product of DHAP, which may lead to neurodegeneration. Interestingly, the one Hungarian brother with no neurologic deficits had lower levels of methylglyoxal than his brother with deficits.

Diagnosis

Morphologically, occasional spherocytocytes may be visible

on the blood film but there are no distinguishing features. TPI deficiency is diagnosed by assay of red cell enzyme activity in conjunction with metabolic intermediates. The biochemical hallmark of homozygous TPI deficiency is intracellular accumulation of DHAP. This is most marked (20–100 fold) in red cells which, unlike other tissues, lack the capacity to metabolize DHAP in the glycerol phosphate shuttle via α -glycerophosphate dehydrogenase. Recently, a sural nerve biopsy was performed in a patient with TPI deficiency confirming the peripheral neuropathy. However, because there is a dominant genetic defect among the many mutants described, DNA analysis of the many mutants described may be attempted on infants and family members suspected of TPI deficiency. As the disease can be devastating, DNA studies have been done prenatally as well.⁸⁶

Treatment

Unfortunately there are no definitive treatments for TPI deficiency. Transfusion for anemia should be performed as needed clinically. Rapid treatment of infections should be initiated as patients can have worsening anemia and increased neurologic complications with infection. There have been recent studies looking at enzyme replacement as a treatment for TPI deficiency.^{93,94}

Phosphoglycerate kinase deficiency

Phosphoglycerate kinase (PGK) is a key enzyme in the glycolytic pathway. It catalyzes the conversion of 1,3-diphosphoglycerate (1,3-DPG) to 3-phosphoglycerate (3-PG) with the concomitant generation of ATP. The deficiency is an X-linked inherited disease but, ironically, PGK deficiency was first recognized in a female with hemolytic anemia.⁹⁵

The enzyme

PGK has two isozymes, PGK-1 and PGK-2. PGK-1 is the more abundant of the two and is expressed in all somatic cells. It is encoded by a single gene on the X chromosome (Xq13).⁹⁶ PGK-2 is encoded on chromosome 19 and is only expressed in late stages of spermatogenesis.⁹⁷ The PGK reaction can be bypassed by the Rapoport–Luebering shunt catalyzed by 2,3-diphosphoglyceromutase, forming 2,3-DPG. Only mutations in the PGK-1 gene have been found to cause the clinical symptoms seen in this enzyme deficiency. To date 16 mutants have been identified, including both missense and nonsense mutations.^{9,98}

In hemizygous males, red cell PGK activity is usually less than 20% of normal. Enzyme levels in female heterozygotes vary not only because of lyonization, as in other X-linked disorders, but also because of the preferential survival of PGK-replete red cells that have the normal allele on their active X chromosome.

Clinical signs and symptoms

PGK deficiency is associated with nonspherocytic hemolytic anemia. Hemizygous males tend to have a more severe anemia than heterozygous females. The anemia may be exacerbated by an intercurrent infection. These patients may also suffer from neurologic dysfunction, including seizures, movement disorders, hemiplegia, aphasia, mental retardation, and behavioral disturbance including emotional lability. These are usually associated with severe enzyme deficiency in hemizygous males. Patients may also suffer from myopathy, including exercise intolerance, muscle cramps, rhabdomyolysis and myoglobinuria. Patients with myopathy do not usually have hemolytic anemia.⁹⁹

While onset in the neonatal period with jaundice and seizures is reported, there may be latency in the appearance of neurologic manifestations with normal development in infancy.¹⁰⁰ The basis for the differing patterns of clinical expression in PGK deficiency is not understood since the same isozyme is expressed in all somatic cells.¹⁰¹ Heterozygote females may manifest mild hemolysis but have normal neurologic function.

Diagnosis

The profile of red cell intermediates in affected males is consistent with a block in glycolysis at the PGK step. There will be a nonspherocytic hemolytic anemia on the blood smear if anemia is present. Reduction in the concentration of ATP is characteristic, as this step generates one molecule of ATP. Patients with defects in PGK will bypass this step via the Rapoport–Luebering shunt, thereby increasing levels of 2,3-DPG. Patients with myopathy can have an increase in myoglobinuria and creatine kinase. These patients may require a muscle biopsy to exclude glycogen storage diseases, which can present in a similar fashion (McArdle disease and Tauri disease). Enzyme levels of PGK-1 can be measured directly.

Treatment

Patients with severe hemolytic anemia require transfusions. In these patients, splenectomy has alleviated transfusions.⁹ Patients with myopathy need to avoid strenuous exercise.

Phosphoglycerate mutase deficiency

Phosphoglycerate mutase catalyzes the reaction of 3-PG to 2-phosphoglycerate. This is a very rare disorder with only five cases reported.¹⁴ There are two isozymes, a muscle isozyme, mapped to chromosome 7p13,¹⁰² and a brain isozyme, mapped to chromosome 10q25.¹⁰³ It is an autosomal recessive disease and is caused by mutations in the muscle isozymes. Patients with this defect do not have hemolytic anemia. As the defect is in the muscle isoform, these patients exhibit

exercise intolerance, muscle cramping, and rhabdomyolysis. These symptoms usually begin in childhood or adolescence. Diagnosis is by enzyme measurement, muscle biopsy, and elevated creatine kinase levels. There is no effective therapy for phosphoglycerate mutase deficiency. Patients with this disease need to avoid strenuous exercise.

Diphosphoglycerate mutase deficiency

Diphosphoglycerate mutase (DPGM) acts in the Rapoport–Luebering shunt to regulate the metabolism of 2,3-DPG. Its main catalytic function is the conversion of 1,3-DPG to 2,3-DPG. In addition, DPGM possesses phosphatase activity that is responsible for the conversion of 2,3-DPG to 3-PG and functions, albeit at low efficiency, as a monophosphoglycerate mutase. Human DPGM activity is confined to red cells. 2,3-DPG is the most abundant glycolytic intermediate and serves to lower the affinity of hemoglobin for oxygen, thereby shifting the oxygen dissociation curve to the right.

DPGM deficiency is an autosomal recessive illness, with only 20 cases described.¹³ The phenotype of DPGM deficiency has been documented in most detail in a single kindred in which both homozygotes and heterozygotes exhibited erythrocytosis but no signs of hemolysis.^{13,104}

Enolase deficiency

Enolase catalyzes the conversion of 2-phosphoglycerate to phosphoenolpyruvate (PEP). This enzyme is encoded by a gene located on chromosome 1q36.¹⁰⁵ This is also a very uncommon phenotype. Unlike the other deficiencies, enolase deficiency is an autosomal dominant disease. Patients with enolase deficiency do have spherocytic hemolytic anemia. Patients with this disorder may also be at increased risk for hemolysis after exposure to oxidant drugs. The pathogenesis for this deficiency is unknown and no mutations have been discovered. There is no therapy for this disorder but avoidance of oxidant drugs is suggested.

Pyruvate kinase deficiency

PK catalyzes the conversion of PEP to pyruvate and generates one ATP molecule. PK deficiency is the most frequent enzyme abnormality found in the Embden–Meyerhof pathway. It was first described in 1961 by Valentine *et al.*⁴ PK deficiency is an autosomal recessive disease.

The enzyme

PK catalyzes the last reaction in the glycolytic pathway. It requires both magnesium and potassium for activity. The conversion of PEP to pyruvate is irreversible under physiologic conditions. Activity of the enzyme is increased in the presence of FDP.

The enzyme is a tetramer composed of four identical subunits. There are several isozymes present in mammalian tissue. The red cell (R) and liver (L) subunits are encoded by the PK-L/R gene found on chromosome 1q21.¹⁰⁶ These isoforms vary because of tissue-specific promoters, and because of this the R form is 31 amino acids longer than the L form.¹⁰⁷ The L form is also expressed in renal cortex and small intestine. The M isozyme is divided into two subsets, M1 and M2. Both are encoded on chromosome 15q22 by alternative mRNA splicing.^{108,109} The M1 form is expressed in skeletal muscle, heart and brain. The M2 type is dominant during fetal life and is replaced in skeletal muscle, heart and brain by the M1 type. However, the M2 isoform remains the dominant form in leukocytes and platelets. In red blood cells, the M2 isoform is dominant in the progenitors but is eventually replaced by the R form.¹¹⁰ This occurs in the normoblast and reticulocyte phase and is made up of L' tetramers (L₄') called PK-R1. Proteolysis converts the L' tetramer to a heterotetramer (L₂'L₂') called PK-R2, which is the main form in mature red cells.^{111,112} In some cases of severe deficiency of the R subunit, reversion to synthesis of the M2 form may partially rescue the deficient phenotype.¹¹³ This has been likened to the persistence of fetal hemoglobin in β -thalassemia. Persistence of the M2 isozyme in red cells may also account for the rare "high ATP" syndrome in which supraphysiologic PK activity leads to metabolic depletion of 2,3-DPG, with increased hemoglobin oxygen affinity and erythrocytosis.^{114,115}

Patients with PK deficiency have mutations only in the PK-L/R gene. To date, 142 mutations have been described in PK deficiency.^{116,117} The majority of them are missense, splicing, and stop codon mutations. Mutations of the enzyme are felt to potentially alter the affinity for PEP, alter the affinity for FDP, increase inhibition to ATP, or alter enzyme stability.¹¹⁸ These mutations are spread throughout the coding region with no preference for the coding region.¹¹⁹ Only two mutations have been found in the promoter region.¹²⁰ Most mutations have only been described once, but there are three mutations that are prevalent in different populations: 1468 C→T, 1529 G→A, and 1456 C→T. The 1456 C→T mutation is most common in southern Europe,¹²¹ the 1468 C→T mutation is most common in Asia,¹²² and the 1529 G→A mutation is most common in northern Europe and the USA.^{123,124} This has prompted speculation as to whether deficiency of the liver enzyme may contribute to jaundice. Evidence of abnormal liver function in some cases of PK deficiency supports this possibility.

Pathophysiology of hemolytic anemia

The mechanism for hemolysis in PK deficiency is not well understood. It is felt that red blood cells become deficient in ATP, which leads to a cascade of events that begins with loss of cation homeostasis, with efflux of potassium and water leading to cellular dehydration and culminating in contraction

and rigidity of erythrocytes, forming the characteristic crenated cells. These cells will then be removed in the reticuloendothelial system, particularly the spleen. This is not a full explanation as some patients with PK deficiency do not have low levels of ATP¹²⁵ and other disorders with ATP deficiency are not associated with hemolysis.¹²⁶ 2,3-DPG has been implicated in the hemolytic process. 2,3-DPG is an inhibitor of G6PD and may impair the HMP shunt. This may contribute to increased hemolysis in times of stress such as pregnancy or infection.¹²⁷ 2,3-DPG also inhibits the enzyme 5-phosphoribosyl-1-pyrophosphate. This mechanism is also not completely explanatory as patients with PK deficiency do not have severe hemolysis after exposure to oxidative agents as seen in G6PD deficiency and do not manifest the red cell changes on smear seen with classical oxidative hemolysis. 5-Phosphoribosyl-1-pyrophosphate is a critical enzyme in the purine salvage pathway that provides the red cell with adenine and thus this defect could diminish synthesis of NAD and NADPH, also leading to decreased red cell oxidant protection.¹²⁸ A high number of erythroid progenitors and reticulocytes are found in the spleen of PK-deficient patients, suggesting that there is ineffective erythropoiesis.¹²⁹ This is further substantiated by the paradoxical increase in the reticulocyte count in PK-deficient patients who undergo splenectomy.

Clinical presentation

Over 80% of cases present during childhood. The spectrum of clinical severity is wide.¹³⁰ However, it is important to note that the only gene affected in PK is the PK-L/R gene and the hepatic enzyme deficiency does not result in liver dysfunction. Therefore, the only clinical manifestations are limited to red blood cells. The clinical spectrum concerns chronic hemolytic anemia, which ranges from mild fully compensated anemia that remains undetected into later life to life-threatening anemia in the newborn period.¹¹⁶ Anemia may also manifest *in utero*, causing nonimmune hydrops fetalis.^{131,132} Neonatal jaundice is a common manifestation of PK deficiency and, if pronounced, may herald a severe course. Kernicterus, although rare, has been described. In severely affected cases, patients require chronic transfusion therapy. A particularly severe form of PK deficiency has been described in the Dutch Amish population in Pennsylvania.¹³³ As a result of the chronic hemolysis, other common clinical complications can result (Table 9.4).

An interesting aspect of PK deficiency is the ability of many of these patients to tolerate day-to-day life with hemoglobin levels as low as 6–7 g/dL. This is due to the fact that the PK defect is downstream from the production of 2,3-DPG. Patients can have high erythrocyte 2,3-DPG levels, which shifts the hemoglobin oxygen dissociation curve to the right, favoring oxygen delivery to the tissues.¹³⁴ Nonetheless, patients with severe anemia can have increased myocardial

hypertrophy due to increased cardiac output secondary to the anemia.

Iron overload is also common in patients with PK deficiency and has been reported in more than half of nontransfusion-dependent patients.¹³⁵ The degree of iron overload can be exacerbated in patients who have undergone splenectomy or have defects in the *HFE* gene.

In severely affected children there may be growth delay and skeletal changes due to expanded erythropoiesis. Spinal cord compression due to extramedullary hematopoiesis has been described.¹³⁶ Exacerbation of hemolysis in PK deficiency may occur during intercurrent infection and, less consistently, in pregnancy¹³⁷ and during oral contraceptive use.¹³⁸ Quite often pregnancy is uncomplicated, with no adverse effects on maternal or fetal well-being.

Diagnosis

The presence of characteristic changes in red cell morphology, unusual among glycolytic disorders, may assist in the diagnosis of PK deficiency.¹³⁹ Typically, there is slight macrocytosis and poikilocytosis with ovalocytes and elliptocytes accompanied by polychromasia and occasional contracted crenated red cells (spherocytocytes). The latter are accentuated after splenectomy. Patients with chronic hemolysis can have elevated LDH levels, low haptoglobin, and hyperbilirubinemia. Biochemically, PK deficiency is heterogeneous. Homozygotes typically exhibit < 25% and heterozygotes 40–60% residual enzyme activity. There is, however, considerable overlap and some PK-deficient variants are associated with normal or minimally reduced activity *in vitro*. Quantitative assays should be performed at high and low substrate concentrations in the presence or absence of the allosteric effector FDP in order to detect PK variants with abnormal kinetic properties. Accumulation of glycolytic intermediates preceding the PK step in glycolysis, particularly PEP, 2-phosphoglycerate, 3-PG, and 2,3-DPG,¹⁴⁰ but sometimes extending proximally due to feedback inhibition of other glycolytic enzymes by 2,3-DPG provides evidence of defective function *in vivo*. ATP formation is reduced but in the presence of marked reticulocytosis absolute levels may be normal. An increase in the ratio of 2,3-DPG to ATP has been found to be a more reliable predictor of PK deficiency.¹⁴¹ The

majority of PK variants exhibit reduced stability and/or altered kinetic properties *in vitro*. The interpretation of kinetic studies in PK deficiency is complicated in compound heterozygotes by the varying proportion of tetramers formed by the two mutant subunits. As there are common mutations in patients with PK deficiency, DNA analysis can be performed for the diagnosis both prenatally and postnatally.^{124,142}

Treatment

Therapy for PK deficiency is supportive. In fetal anemia with hydrops, intrauterine transfusions may need to be performed. In neonates with hyperbilirubinemia, exchange transfusion may be needed and then followed by chronic transfusions. As PK-deficient patients have high levels of 2,3-DPG, transfusions should be based on clinical symptoms and not the level of hemoglobin.

In severely affected patients who require prolonged transfusions, splenectomy can be performed. Delay until after the age of 5, if possible, is advisable. Splenectomy does not stop the hemolysis but removal of the spleen is accompanied by a rise in hemoglobin, which typically stabilizes at 1–3 g/dL higher than the level before splenectomy. There is a paradoxical rise in reticulocyte count that accompanies splenectomy, sometimes reaching 40–60%. It is important to note that there have been case reports of thrombosis in PK-deficient patients after splenectomy.^{143,144}

Folic acid can be given to patients with PK deficiency as there is rapid cell turnover and there are no contraindications to do so. However, iron should be avoided in these patients as iron overload is a common problem in PK-deficient patients. It is important to monitor all patients with PK deficiency for signs and chemical levels suggestive of iron overload, especially if they have had a splenectomy or have a mutation of the *HFE* gene.

Bone marrow transplantation has been performed with success in one severely affected patient.¹⁴⁵ Gene transfer studies have been successful in animal models,^{146,147} but a great deal of work remains before clinical trials are available.

Disorders of the hexose monophosphate shunt

Glucose 6-dehydrogenase deficiency

G6PD catalyzes the initial step in the HMP shunt. Though ubiquitously expressed by all cells, the pathophysiologic consequences of G6PD deficiency are confined almost exclusively to red blood cells, which lack the capacity to synthesize the enzyme and are inherently vulnerable to endogenous oxidative damage because of their role in oxygen transport. Through oxidation, G6PD converts G6P to 6PG and reduces NADP to NADPH in the process. This is the erythrocyte's

only means of regenerating its supply of NADPH, which is crucial for maintaining glutathione levels and preventing oxidative damage to the red blood cell. G6PD deficiency is the most common human enzyme deficiency, with an estimated 400 million people affected. It was first described in the 1950s after a group of patients had a hemolytic crisis after taking the antimalarial drug primaquine.⁵ It was quickly determined that patients with this deficiency do not have a chronic hemolytic process and are usually asymptomatic. As the metabolic role of G6PD has little to do with providing energy to the red blood cell, hemolysis only occurs when the red cell is under oxidative stress. G6PD deficiency is an X-linked disorder.

The enzyme

The gene for G6PD has been localized to the X chromosome (Xq28)¹⁴⁸ and has been cloned.^{149,150} It comprises 13 exons encoding 515 amino acids and a GC-rich promoter. The active form of G6PD is a dimer that contains two binding sites for NADP and G6P.¹⁵¹ The enzyme activity is the same in both males and females as one of the X chromosomes remains inactive. Hemizygous males carrying a defective variant gene express the deficiency, whereas most heterozygote women are clinically normal with a normal G6PD level in approximately 50% of their red cells. Those deficient cells in females are still susceptible to oxidative hemolysis.

Since the discovery of G6PD deficiency, over 300 variants of the gene have been reported.¹⁵² The variants are almost all missense point mutations causing single amino acid substitutions.¹⁵³ There have been a few mutations described caused by small deletions.¹⁵⁴ Large deletions or frameshift mutations have not been identified and are thought to be incompatible with life.¹⁵² Of the mutations, those that cause milder forms are not found in the C-terminal portion of the enzyme. There is a cluster of mutations that causes severe G6PD deficiency within exon 10, which encodes the amino acid sequence involved in the formation of the active dimer of the enzyme.¹⁵³

G6PD variants have been classified by the World Health Organization according to the level of residual enzyme activity and associated clinical manifestations (Table 9.5). The variants can also be divided into two forms, sporadic mutations and polymorphic mutations. Sporadic mutations are

usually associated with more severe types of G6PD deficiency (class I). Polymorphic mutations of G6PD have prevailed as they transfer a protective effect against malaria. These mutations tend to be less severe (class II or III) and do not outweigh the advantage of malaria protection; they have thus been transmitted throughout populations.^{146,147,148}

Common G6PD variants include the following:

- *G6PD B*. This is considered the wild-type G6PD. It is found in most Caucasians, Asians and Blacks. In Black Africans there is another variant, *G6PD A*, which is found in 20–30% of this population. The A variant has an activity of approximately 90% of the wild type and people have normal phenotypes. The mutation in this variant is at nucleotide 376, which results in an Asn→Asp substitution.¹⁵⁵
- *G6PD A⁻*. This is the most common variant, associated with mild to moderate hemolysis. It is found in 10–15% of African Blacks and African-Americans and has an enzyme activity of 10–15%. This variant has two mutations within the gene. The first mutation is the same one that results in the A variant. The second mutation occurs 95% of the time at nucleotide 202, resulting in a Val→Met substitution. There are less frequent mutations at nucleotide 680 or 968.¹⁵⁶
- *G6PD Mediterranean variant*. This is the most common abnormal variant found in Caucasians. It is a single-base substitution at nucleotide 563 that causes a Ser→Phe substitution.¹⁵⁵ This causes a decrease in protein synthesis and therefore the enzyme’s catalytic activity is much reduced, resulting in severe hemolysis (class II).¹⁵⁷

Protection against malaria

There is a geographical correlation in the distribution of polymorphic variants of G6PD deficiency with areas known to be endemic for *Plasmodium falciparum* malaria. The mechanism for malaria resistance in G6PD deficiency is not known but there are multiple theories. One possibility is that after a deficient cell is infected with the parasite, there is an increase in oxidative stress in the cell and because of the deficient enzyme an increase in toxic oxidized species that impair the growth of the parasite.¹⁵⁶ Another possibility is that due to oxidative stress there is an increase in methemoglobin and Heinz body formation, causing membrane damage. In addition to the production of methemoglobin, ferriheme may be

Class	Enzyme activity (% of normal)	Examples	Clinical effects
I	Variable and rare (<10)	San Diego	CNSHA
II	<10	Mediterranean, Canton	AHA, NNJ
III	10–60	A ⁻	AHA, NNJ
IV	100	A, B*	None
V	>100	Verona	None

* Wild type.

Table 9.5 Classification of glucose 6-phosphate dehydrogenase variants.

released, which is also cytolytic. Both Heinz body formation and ferriheme can promote phagocytosis of the infected red cell by the reticuloendothelial system.^{158,159}

Pathophysiology of hemolysis

Red cells deficient in G6PD cannot replete their glutathione reserves, which leaves them at risk from oxidative damage by other sulfhydryl-containing proteins as the glutathione diminishes. Oxidation of the sulfhydryl groups on hemoglobin leads to the formation of methemoglobin or sulfhemoglobin, which forms the insoluble Heinz bodies that attach to and damage the red cell membrane. There is also oxidation of membrane proteins, which causes the red cell to be less deformable and thus susceptible to phagocytosis in the spleen. Red blood cells can hemolyze intravascularly, especially in patients with very low levels of G6PD activity.

Clinical signs and symptoms

Acute hemolytic anemia

Under conditions of oxidative stress, acute hemolysis may occur abruptly in a child with G6PD deficiency who at other times is clinically well. Not all individuals, even those with the same G6PD variant, are equally susceptible. The most common trigger is infection followed by drugs or other exogenous oxidants. Table 9.6 lists common drugs associated with hemolysis. The release of peroxides generated during phagocytosis of bacteria may be important in triggering hemolysis during bacterial infection. Pneumonia, β -hemolytic streptococcal infection, viral hepatitis, *Escherichia coli* infection, and typhoid are particularly likely to precipitate hemolysis in children with G6PD deficiency.¹⁶⁰ More tenuously, diabetic ketoacidosis and hypoglycemia have been linked to acute hemolysis in G6PD-deficient subjects.¹⁶¹

The course and severity of acute hemolysis in G6PD deficiency is highly variable. Males are more frequently affected than females. The onset usually follows within 2–3 days of oxidative challenge. Constitutional symptoms, including irritability and lethargy, may herald overt hemolysis. Typically, these are followed by the development of fever sometimes accompanied by gastrointestinal symptoms. Hemoglobinuria ensues, the cardinal sign of intravascular hemolysis, with dark-red or brown urine often colloquially described as the color of Coca-Cola. This precedes or coincides with the onset of jaundice and is accompanied by signs of anemia with pallor, tachycardia and, if the hemolysis is severe, hypovolemic shock. The degree of anemia is variable but may be extremely severe. Other causes of intravascular hemolysis, such as *P. falciparum* malaria (“blackwater fever”), hemolytic transfusion reaction, autoimmune hemolysis, microangiopathy, paroxysmal cold hemoglobinuria, paroxysmal nocturnal hemoglobinuria, *Clostridium welchii* septicemia and

Neonatal jaundice

Neonates born with G6PD deficiency are at increased risk for hyperbilirubinemia. The consequences can be serious and, if untreated, may have irreversible neurologic sequelae. In Africa and Southeast Asia, G6PD deficiency is a common cause of kernicterus.¹⁶² Although early reports highlighted the prevalence of neonatal jaundice in Mediterranean and Southeast Asian infants, this complication affects all indigenous and immigrant populations in which G6PD deficiency occurs. Jaundice develops later than in Rhesus alloimmunization, typically on the second or third day of life, but can occur within the first day of life.¹⁶³ A hemolytic component may predominate when neonatal exposure occurs to oxidants,¹⁶⁴ for example drugs or naphthalene in the form of mothballs or in clothing. In the majority of cases, hyperbilirubinemia occurs in the absence of increased red cell breakdown or external exposure to oxidants. It is felt that the underlying mechanism of hyperbilirubinemia is primarily hepatic in origin.^{165,166} Supporting this finding is that neonates with G6PD Mediterranean have a partial defect in bilirubin glucuronide conjugation similar to that seen in Gilbert disease.^{167,168}

Favism

Hemolysis following ingestion of broad beans (*Vicia faba*), or favism, usually occurs within 1 day of ingestion of the beans. The highest incidence occurs in young boys. People who have hemolysis after ingestion of fava beans are always deficient in G6PD but not all variants are susceptible to this. The variant that is classically associated with favism is G6PD Mediterranean,¹⁵² although it can occur in other variants including G6PD A⁻.¹⁶⁹ Variability in sensitivity to fava beans among individuals with G6PD deficiency and even in the same individual at different times suggests other factors, including perhaps absorption and metabolism of the toxic constituents. Maternal ingestion of fava beans¹⁷⁰ has been reported to cause hydrops fetalis *in utero* and to lead to hemolysis in breast-fed infants with G6PD deficiency.¹⁷¹ Favism has even been attributed to inhalation of bean pollen.¹⁷² The pyrimidine aglycones divicine and isouramil have been implicated as the toxic component of fava beans.^{173,174} These chemicals deplete the red cell's glutathione stores and reduce the activity of catalase, both of which are important in reducing reactive oxidant species in the red cell.

Chronic nonspherocytic hemolytic anemia

In contrast to the episodic pattern of hemolysis associated with polymorphic G6PD variants, patients with class I G6PD deficiency have such low enzyme activity that they will have lifelong chronic hemolytic anemia. This will occur in the absence of oxidant stressors such as drug exposure and, to date, 90 variants have been classified as class I causing chronic nonspherocytic hemolytic anemia.¹⁷⁵ Such cases are usually sporadic and show no geographic or ethnic predilection. All reported cases have been male. Neonatal jaundice, sometimes severe, is often the first manifestation. After infancy the clinical expression varies, from patients showing compensated hemolysis to those who become transfusion dependent. Most will have hemoglobin levels of 8–10 g/dL, with an elevated reticulocyte count. This reflects the heterogeneity of molecular defects among class I G6PD variants. Hemolysis in patients can be exacerbated by oxidative stress, particularly during intercurrent infection, and is occasionally accompanied by frank hemoglobinuria.

Even medications that are safe in patients with class II or III G6PD deficiency can cause hemolysis in class I patients. The spleen, though typically only moderately increased in size, may be sufficiently enlarged to cause hypersplenism. In the steady state, hemolysis is primarily extravascular, as evidenced by the absence of hemoglobinuria.

Diagnosis

The diagnosis of G6PD deficiency is usually recognized after an acute hemolytic crisis due to infection or after drug exposure. It is evidenced by the presence of characteristic poikilocytes, including “hemighosts” and “bite cells” on a

blood smear. There may be marked reticulocytosis. Heinz bodies may be visualized by supravital staining with methyl violet. Since Heinz bodies are removed by the spleen and red cells containing them are rapidly destroyed, their appearance may be transient. Serum haptoglobin is absent. The urine may be described as the color of tea or Coca-Cola. These patients will have a negative Coombs test.

The fluorescent spot test is the oldest and most reliable screening test for G6PD.^{30,31} It is based on the fluorescence of NADPH after G6P and NAD are added to a hemolysate of test cells. A new diagnostic kit to detect patients with < 50% G6PD activity has been described (see p. 174).^{32,33} Other screening tests such as the methemoglobin reduction test measure the transfer of hydrogen ions from NADPH to an acceptor, in this case methemoglobin. The diagnosis of G6PD deficiency can also be confirmed by a quantitative assay of red cell activity, which measures by spectrophotometry the reduction of NADP to NADPH in the presence of G6P.³⁵

A positive screening test should be confirmed by quantitative enzyme assay. Caution must be exercised in interpretation since false-negative results may occur. This rarely occurs in hemizygous Caucasian males but is more of an issue in heterozygous females and African-Americans (G6PD A⁻ enzyme activity is relatively well preserved in young red cells). This is especially true immediately after a hemolytic crisis and during the compensatory reticulocytosis. In practice, these limitations can usually be circumvented by assaying enzyme activity separately in old and young red cells fractionated by centrifugation, relating G6PD activity to that of another age-dependent enzyme (e.g., HK) performing a confirmatory test 2–3 months after the hemolytic crisis or by studying family members.

A specific problem arises in the diagnosis of chronic nonspherocytic hemolytic anemia in a G6PD-deficient child who originates from a population in which the prevalence of G6PD deficiency is high. In this situation, biochemical characterization of the G6PD variant is necessary. If this proves to be a common variant, an alternative explanation for chronic hemolysis must be sought. Genotypic diagnosis, which is feasible by rapid techniques for several polymorphic G6PD variants, is also useful in this context.

The diagnosis of G6PD deficiency in heterozygous females warrants special mention. Unbalanced mosaicism in favor of cells in which the active chromosome carries the wild-type G6PD allele may render the enzyme activity of a red cell lysate normal. In this situation (and after red cell transfusion), cytochemical staining with tetrazolium, which is capable of detecting minor populations of Gd⁻ red cells, may be helpful.¹⁷⁶ Somatic selection in favor of Gd⁺ red cells may also mask the heterozygous phenotype, particularly in the case of severely deficient variants.¹⁷⁷ If a common variant is suspected, genetic studies can be done on the family. New rapid microarray-based assays have also been developed to detect G6PD deficiency in specific populations.³⁴

Treatment and prevention

Prevention plays an important role in reducing the risk of drug-induced hemolysis and favism in G6PD deficiency. In Sardinia, prospective neonatal screening combined with health education has resulted in a decline in the incidence of favism among children with G6PD deficiency.¹⁷⁸ In Singapore, screening has essentially eliminated kernicterus in the newborn.¹⁷⁹ Immunization against hepatitis A has been proposed, as this virus can cause significant hemolysis.¹⁸⁰ Once the diagnosis of G6PD deficiency has been made, parents should be counseled regarding avoidance of oxidants and the risk of hemolysis due to an infection. A list of drugs capable of causing hemolysis should be provided and screening of family members should be initiated. If it is necessary to give an individual with G6PD deficiency a drug that can cause hemolysis, such as primaquine for the treatment of *P. vivax* or *P. malariae* infection, dose reduction may reduce hemolysis to a tolerable level.^{181,182}

Transfusion

Blood transfusion may be required and although no didactic rules apply, useful guidelines have been recommended by Luzzatto.¹⁸³ These advise immediate transfusion if the hemoglobin level is less than 7 g/dL or between 7 and 9 g/dL in the face of hemoglobinuria. At higher hemoglobin levels it may be justified to withhold transfusion, providing the child is kept under close observation and transfusion instigated if the hemoglobin falls below the threshold identified above. As G6PD deficiency is common in the population, blood donors can be G6PD deficient. Therefore, avoidance of transfusion with G6PD-deficient red cells is theoretically desirable, although in practice difficult to achieve. Recovery of hemoglobin to steady-state levels may take 3–6 weeks. This is quicker in the case of G6PD variants (e.g., A⁻) where enzyme activity is relatively well preserved in reticulocytes, making them less susceptible to destruction.

Neonatal jaundice

With respect to management, the degree of hyperbilirubinaemia that triggers the need for phototherapy or exchange transfusion follows conventional criteria, adjusted for birth-weight. A lower threshold may be applied in the face of rapid hemolysis. Prompt correction of hypoxia, acidosis, sepsis and other factors that exacerbate jaundice in the G6PD-deficient neonate is important. It is more important in neonates who require exchange transfusions to use blood from donors not deficient in G6PD.¹⁵²

Chronic nonspherocytic hemolytic anemia

Individuals with type I G6PD deficiency will need more care throughout their lifetime. Patients usually have mild to moderate anemia and transfusion should be used only if the patient is symptomatic. Splenectomy has not had any significant

benefit in these patients.¹⁸⁴ As with other chronic hemolytic anemias, patients may have increased iron absorption and they should be monitored for iron overload. They should also be evaluated for hereditary hemochromatosis as this puts them at even higher risk for iron overload. As a result of chronic hemolysis, they can also develop gallstones, causing cholecystitis, and prophylactic cholecystectomy can be considered. Care should still be taken to counsel these patients with regard to infection and oxidant medications as this can exacerbate hemolysis. Vitamin E can be given to these patients as an antioxidant, but its effect is controversial.^{185,186} Folic acid can be given to these patients due to the rapid cell turnover.

Deficiencies of glutathione reductase, glutathione peroxidase, and glutathione synthesis

Glutathione, a tripeptide composed of glutamic acid, cysteine and glycine, is synthesized via sequential reactions catalyzed by γ -glutamylcysteine synthetase and glutathione synthetase. Glutathione is present in the red cell at millimolar concentrations, and in its reduced form (GSH) provides the main defense against oxidative damage. The conversion of harmful peroxides to water is catalyzed by glutathione peroxidase. Intracellular levels of GSH are maintained by both regeneration from oxidized glutathione, catalyzed by glutathione reductase, and *de novo* synthesis.

Of the two main enzymes of the HMP shunt, only deficiency of glutathione reductase has been reported to cause hemolysis, which has been reported in three siblings born of a consanguineous marriage.²¹ Early cases of glutathione reductase deficiency have subsequently been shown to be due to inadequate synthesis of its cofactor, flavin-adenine dinucleotide, secondary to nutritional riboflavin deficiency.¹⁸⁷

Of the enzymes involved in glutathione synthesis, hemolytic anemia due to γ -glutamylcysteine synthetase deficiency has been described, although it is very rare.²⁰ In one case, an affected patient developed progressive spinocerebellar ataxia.¹⁸⁸ Glutathione synthetase deficiency is the most common metabolic defect to cause GSH deficiency. Over 20 families with the condition have been reported.¹⁹ Two phenotypes are recognized: when the enzyme deficiency is isolated to the red cell, there is mild hemolytic anemia, which may be exacerbated by oxidant stress; if all tissues are deficient in glutathione synthetase, this may result in a multisystem disorder characterized by hemolysis, metabolic acidosis, neurologic abnormalities, neutropenia, and susceptibility to bacterial infection. Acidosis is caused by the accumulation of 5-oxoproline, a metabolic product of γ -glutamylcysteine. Urinary excretion of 5-oxoproline is markedly elevated. Vitamin E has been used with clinical benefit in patients with recurrent infection,¹⁸⁹ but its overall efficacy is still under question.¹⁹⁰ As with G6PD deficiency, exposure to drugs with oxidative potential should be avoided.

Disorders of erythrocyte nucleotide metabolism

Pyrimidine 5'-nucleotidase deficiency

P5'N or uridine monophosphate hydrolase (UMPH) is involved in the removal of pyrimidines from the red blood cell, because ribosomal RNA is no longer needed for protein synthesis and the pyrimidines need to be removed from the cell. P5'N catalyzes the dephosphorylation of pyrimidine nucleoside monophosphates to their corresponding nucleosides. The nucleosides, uridine and cytidine, then diffuse across the red cell membrane. This allows the red cell to preserve phosphates and purines for ATP synthesis. P5'N deficiency is an autosomal recessive trait. It was initially described by Valentine *et al.*^{191–193}

The enzyme

P5'N is a protein that exists as two isozymes, P5'N-1 and P5'N-2,¹⁹⁴ that have different substrate specificities and which are encoded by separate structural loci. P5'N-2 is localized to chromosome 17q23.2,¹⁹⁵ P5'N-1 to chromosome 7p15.¹⁹⁶ The predominant enzyme in the maturing red blood cell is P5'N-1 and is the more active of the two enzymes. It requires magnesium for activity. The associated defects causing hemolytic anemia are the result of a deficiency in P5'N-1 (UMPH-1). To date, 16 mutations have been described in the P5'N-1 gene.^{196–199} They involve missense mutations, nonsense mutations, and large deletions causing decreased function of the enzyme. If the ribosomal RNAs remain and the pyrimidine nucleic acids cannot be removed, intracellular aggregates of RNA will accumulate within the cell. Approximately 40 cases have been reported.²⁰⁰

How intracellular accumulation of pyrimidines causes hemolysis is not known. Selective accumulation of CDP choline and CDP ethanolamine occurs in P5'N-1 deficiency and this may have an effect on structural aspects of the red cell membrane. Inhibition of glycolysis or adenine nucleotide salvage through competition of UTP and CTP with ATP has been postulated, as well as the fact that pyrimidines are strong chelators of magnesium that may inhibit other enzymes.²⁰¹

Clinical signs and symptoms

Deficiency of P5'N is associated with hemolytic anemia of mild to moderate severity that may worsen during infection or pregnancy. The degree of anemia is variable, with hemoglobin levels ranging from 7.5 to 10 g/dL. The age of presentation ranges from infancy to adult life, but the majority of patients present at a younger age. They will have a reticulocytosis and also hyperbilirubinemia. Patients may have

jaundice, pallor, and splenomegaly. A conspicuous feature of P5'N deficiency is basophilic stippling (ribonucleoprotein aggregates) due to impaired degradation of RNA, which may be visible in up to 5% of red cells. P5'N is also expressed in brain, kidney and spleen tissue.²⁰² Of note, mental retardation has been described in some P5'N-deficient individuals.²⁰³

It is also important to note that acquired P5'N deficiency is seen in lead poisoning²⁰⁴ and underlies the mechanism of lead-induced hemolytic anemia.²⁰⁵ P5'N is sensitive to inactivation by low concentrations of lead and exposed individuals show a dose-dependent depression of nucleotidase activity. Patients with severe acute lead toxicity have enzyme levels comparable to those found in homozygous deficiency states.

Diagnosis

A blood smear needs to be observed to look for basophilic stippling. Blood collected in EDTA must be examined fresh, since stippling is no longer discernible after 3 hours. P5'N is increased in young red cells.²⁰⁶ When corrected for reticulocytosis, the enzyme activity in homozygous P5'N deficiency is generally about 5% of that in normal red cells. Normally, adenosine phosphates account for at least 97% of cellular nucleotides, causing ultraviolet absorption at 257 nm during spectral analysis. In P5'N deficiency, there is a much higher concentration of pyrimidine compounds and this shifts the ultraviolet absorption spectrum from the normal peak at 257 nm to 265–270 nm.²⁰⁰ The diagnosis may be confirmed by measuring the enzyme levels directly.

Recently, patients with β -thalassemia and hemoglobin E have been shown to have low levels of P5'N deficiency and this can contribute to a marked increase in instability of these thalassemias.²⁰⁷ Although the underlying mechanism is unknown, this suggests that the milieu of P5'N-deficient red cells may accentuate oxidative damage, a finding of potential importance in understanding the pathophysiology of HbE/ β -thalassemia.

Treatment

Patients with P5'N deficiency are usually not transfusion dependent. However, in the presence of worsening anemia due to infection, especially with parvovirus B19, fever and pregnancy, patients may require intermittent red blood cell transfusion. Although patients with P5'N deficiency have splenomegaly, splenectomy has variable results and might be reserved to help those patients who are more severely affected.²⁰⁸

Adenosine deaminase overexpression

Adenosine deaminase (ADA) deaminates adenosine and 2'-deoxyadenosine to inosine and 2'-deoxyinosine respectively.

The ADA gene is localized to chromosome 20.²⁰⁹ The mutations produce an increased expression, causing depletion of ATP. Clinically, overproduction of ADA is characterized by a well-compensated hemolytic anemia showing dominant inheritance. Red cell ADA levels are increased up to 100-fold, reflecting upregulation of transcription of the ADA gene. This phenomenon appears specific to red cells, since ADA levels in other cells are normal. Linkage studies indicate that the genetic defect responsible lies in *cis* rather than *trans* to the ADA gene,²¹⁰ but its identity remains obscure. Cases are very rare, with only 14 reported in the world's literature.

Porphyria

Lawrence Wolfe and Peter E. Manley

Porphyrias are a group of metabolic disorders caused by genetic or acquired deficiencies in the enzymes of the heme biosynthetic pathway.¹ They were first classified by Gunther in 1911. The causative effect was discovered by Meyer-Betz in 1912 who actually injected himself with hematoporphyrin and developed skin photosensitivity.² Porphyrias can be divided into two distinct groups based on their clinical characteristics: the first group causes neurovisceral crises and is associated with overproduction of δ -aminolevulinic acid (ALA) or porphobilinogen (PBG);³ the second group is associated with skin lesions due to photosensitization by porphyrins. Each type of porphyria has a characteristic pattern of overproduction of heme precursors. The particular precursor or substrate that is elevated allows determination of the specific enzyme deficiency in the biosynthetic pathway. With specific diagnosis, a comprehensive treatment plan can be developed.

Our first goal is to offer an approach to the clinical appreciation of the porphyrias, their work-up and their diagnosis. Each individual disease is then considered further, including a more detailed discussion of therapeutic approaches.

Epidemiology

Porphyrias are uncommon in the pediatric population and patients rarely present with hematologic complications. Those that do present with hemolytic or hypoproliferative anemia (congenital erythropoietic porphyria, hepatoerythropoietic porphyria, and erythropoietic porphyria) also have concomitant photodermatitis, pointing toward porphyria as

the diagnosis. However, because this is a problem with heme synthesis, the pediatric hematologist may be called upon to evaluate a patient with suspected porphyria, even in the absence of hematologic issues, to make the diagnosis by ordering the appropriate tests, interpret the test results, and manage the therapy of these patients. Table 9.7 lists the prevalence of the porphyrias among reported populations.

Classification

Table 9.8 shows the classifications of the porphyrias along with their corresponding clinical symptoms. It can be clearly seen from the age of presentation column in this table that δ -aminolevulinic acid dehydratase (ALAD) deficiency porphyria, congenital erythropoietic porphyria, erythropoietic porphyria, variegate porphyria, and hepatoerythropoietic porphyria may present in the pediatric age range while the more common acute intermittent porphyria and porphyria cutanea tarda usually appear later.

An additional challenge is the diagnosis of latent disease in offspring of affected adults. Prior to the biochemical classification of the porphyrias, they were predominantly identified by which tissues appeared to produce the toxic porphyrin metabolite (hepatic vs. erythroid) or what symptoms were produced (acute and neurovisceral vs. cutaneous). Ironically, major hematologic problems do not appear in the general classification scheme of these diseases. Significant hemolytic anemia occurs rarely and total heme deficiency or attendant hypoproliferative anemia is uncommon as well (Table 9.9). We will use clinical classifications in discussion of diagnosis and move toward biochemical classification in discussing therapy, which requires more understanding of pathophysiology. This is because treatment relates to preventing metabolite build-up, shutting down overproduction, or protecting against the effects of created toxic metabolites.

Clinical signs and symptoms when considering a diagnosis of porphyria

Heme intermediates are all toxic when produced in excessive amounts. These disturbances can present clinically in two ways. The hepatic porphyrias present with neurovisceral complications and the cutaneous porphyrias present predominantly with skin findings due to photosensitization.

Table 9.7 Prevalence of the porphyrias.

Type	Prevalence
Acute intermittent porphyria	1 in 50 000 ¹
δ -Aminolevulinic acid dehydratase deficiency porphyria	5 reported cases ⁴
Congenital erythropoietic porphyria	150 reported cases ⁵
Erythropoietic protoporphyria	1 in 75 000–200 000 ⁶
Hepatoerythropoietic protoporphyria	30 reported cases ^{7–9}
Hereditary coproporphyria	1 in 500 000 ¹⁰
Porphyria cutanea tarda	1 in 10 000 ¹¹
Variegate porphyria	3 in 1000 in South Africa ¹² 1 in 100 000 ^{13,14}

Table 9.8 Characteristics of the porphyrias.

Disorder	Neurovisceral crises	Skin lesion	Age at presentation	Inheritance
<i>Acute porphyrias</i>				
ALAD deficiency porphyria	+	–	Any age	AR
Acute intermittent porphyria	+	–	Second to third decade	AD
Hereditary coproporphyria	+	+*	Fifth decade	AD
Variegate porphyria	+†	+†	Before puberty	AD
<i>Cutaneous porphyrias</i>				
Congenital erythropoietic porphyria	–	+	Before age 1	AR
Erythropoietic protoporphyria	–	+	Childhood before age 4	AD‡
Hepatoerythropoietic protoporphyria	–	+	Early childhood	AR
Porphyria cutanea tarda	–	+	20–80 years	Variable§

* Some patients can experience chronic neuropathy without acute crises.

† Patients may present with skin lesions, neurovisceral attacks, or both.

‡ Related to coinheritance of both a ferrochelatase gene mutation and weak normal allele.¹⁵

§ Dominant in familial porphyria cutanea tarda but disease can also be acquired.

ALAD, δ -aminolevulinic acid dehydratase; AR, autosomal recessive; AD, autosomal dominant.

Table 9.9 Presentation of single and mixed manifestations of porphyria.

Neurovisceral	Photosensitivity	Hematologic
ALAD deficiency porphyria	Porphyria cutanea tarda	Congenital erythropoietic porphyria
Acute intermittent porphyria	Congenital erythropoietic porphyria	Hepatoerythropoietic porphyria
<i>Hereditary coproporphyria</i>	Hepatoerythropoietic porphyria	Erythropoietic protoporphyria
<i>Variegate porphyria</i>	Erythropoietic protoporphyria	
	<i>Hereditary coproporphyria</i>	
	<i>Variegate porphyria</i>	

Porphyrias in *italic* share neurovisceral and photosensitivity symptoms. Porphyrias in **bold** share photosensitivity and hematologic symptoms (usually hemolytic anemia or hypoproliferative anemia). Note that hematologic symptoms may not be prominent and these porphyrias usually present to the physician because of severe photosensitivity.

ALAD, aminolevulinic acid dehydratase.

Tables 9.10 and 9.11 list common signs and symptoms seen in patients with acute hepatic/neurovisceral porphyrias and the cutaneous porphyrias respectively. In the case of cutaneous porphyria, the pathogenesis is well understood and can readily be reproduced experimentally. In contrast, the mechanism of neurologic manifestations remains uncertain.

Neurovisceral manifestations

As with all hepatic porphyrias, the initial sign of an acute attack is abdominal pain, which often radiates to the back, thighs or buttocks. This can be accompanied by diarrhea, anorexia, constipation, vomiting, and abdominal distension. There may be some guarding but no true peritoneal findings. Central nervous system (CNS) symptoms include mental confusion, neuropathy, and seizures. Psychiatric symptoms include anxiety, depression, phobias, and psychosis. These

psychiatric manifestations can appear simultaneously or exclusively and can potentially be the sole feature of the disease.

More intense attacks include seizures, which may be provoked by hyponatremia, caused by inappropriate secretion of vasopressin, or by direct metabolic effects on the CNS.¹⁸ These severe attacks may progress within days to a predominantly motor neuropathy, which may remain peripheral or become generalized with respiratory paralysis. Moderate tachycardia and hypertension are common; patients with fluctuating blood pressure and/or arrhythmias are at particular risk for cardiac arrest.¹⁶

These manifestations flare and then settle as the stimulus to heme production fades or is halted medically. The neuropathy will reverse slowly as axons grow back from the periphery. Long-term complications include physical disability, hypertension, chronic renal failure, and an increased risk of hepatocellular carcinoma.¹⁶

Diagnosis of acute hepatic porphyria

As porphyria is not a common illness, there are many factors that need to be considered when determining if further work-up should commence. Pure neurovisceral porphyrias (acute intermittent porphyria and ALAD porphyria) are difficult to diagnose, as symptoms may fall into the background of mistaken psychiatric or neurologic diagnosis. Moreover, the requirement in neurovisceral or hepatic porphyria for an inciting event to occur that triggers heme synthesis in order for the disease to manifest can be an additional confounding factor. Because of these issues there should be a complete family history, looking at both medical and psychiatric history, as the majority of hepatic porphyrias are autosomal dominant in nature. A detailed description of the attacks, especially considering behaviors or events prior to the attack, is critical. The clinician is basically looking for characteristics that may stimulate the production of ALA (see later). This stimulation can be due to hormonal shifts in either gender, but premenstrual attacks may be the first sign of disease in women. The induction of even a brief starvation state

from stress or planned dieting also begins the process of ALA synthesis. Smoking or medications that induce hepatic cytochrome P450 enzymes can precipitate an attack. In those rare conditions where photosensitivity and neurovisceral disease appear simultaneously (hereditary coproporphyria and variegate porphyria), suspicion of porphyria and the ensuing investigation are much clearer. If after this the suspicion for hepatic porphyria is high, the investigation should proceed.

Pathogenesis of neurovisceral disease

Acute attacks of porphyria are always associated with induction of hepatic ALA synthase (ALAS1) activity and a marked increase in production of ALA over the basal level for that patient. These changes are often provoked by drugs, particularly those that induce cytochrome P450 proteins. Associated histopathologic lesions include axonal degeneration and chromatolysis, particularly of the anterior horn cells of the spinal cord and brainstem nuclei, with some secondary demyelination.

Numerous hypotheses have attempted to relate signs and symptoms to neuronal dysfunction. Attention has focused on several putative mechanisms of this dysfunction that are not mutually exclusive.

- Neurotoxicity is due to the effects of ALA and not PBG. This is supported by the fact that in ALAD deficiency porphyria, PBG levels are normal but similar symptoms are seen. Therefore it is felt that ALA is the main toxic intermediate.
- ALA is a γ -aminobutyric acid (GABA), glutamate, and aspartate analog and can bind to GABA receptors; this is thought to be neurotoxic. In addition, ALA can inhibit GABA binding to synaptic membranes.^{17,18}
- Neuronal heme deficiency.¹⁸
- Decreased plasma melatonin levels,¹⁹ which enhance ALA-mediated lipid peroxidation.^{20,21}

Clearly, there is still mystery and confusion about pathophysiology. For instance, neurovisceral attacks are *always* associated with overproduction of ALA. However, there is no clear dose–response relationship between ALA concentration and neuronal dysfunction. For example, asymptomatic patients often excrete excess ALA.

Various effects of ALA on neuronal function have been demonstrated in animal experiments and *in vitro* preparations but their physiologic relevance is uncertain. Administration of ALA to normal subjects has no discernible effect on plasma concentrations, similar to patients during acute attacks.²² The blood–brain barrier is relatively impermeable to ALA; concentrations in cerebrospinal fluid (usually < 12 nmol/L) are about 10-fold lower than in plasma.²³ Decreased tryptophan deoxygenase activity in the liver leads to increased delivery of tryptophan to the brain and formation of serotonin (or 5-hydroxytryptamine, 5-HT). Plasma 5-HT concentrations are increased in acute porphyria²⁴ and serotonergic effects may

underlie some clinical symptoms, particularly those ascribed to the autonomic nervous system.¹⁸ A recent study looking at patients who were homozygous dominant for acute intermittent porphyria has provided new insight into the neurotoxicity of the acute porphyria.²⁵ The homozygous dominant patients had white matter changes in areas susceptible to excitotoxic agents. These patients did not have mitochondrial dysfunction and if neuronal heme deficiency was important, it would be expected that there would also be changes in the gray matter, where neurons reside. This lends credence to the toxicity of ALA through either a direct effect or increased binding to GABA receptors.

Cutaneous manifestations

After excluding drug-induced causes, direct sun-related rashes (e.g., polymorphous light eruption), and systemic lupus, porphyria should be considered as a potentially important diagnostic consideration.

Diagnosis of cutaneous porphyria

As with the hepatic porphyrias, the cutaneous porphyrias are very uncommon. However, the clinical presentation may make it easier to proceed with a work-up for cutaneous porphyria. Patients with cutaneous porphyria present clinically in one of two ways, dictated primarily by the partitioning of specific porphyrin metabolites into the skin.

In erythropoietic protoporphyria (EPP), because of the ability of the lipophilic protoporphyrins to penetrate into the upper dermal layers, one sees immediate pain on skin exposure to natural and even artificial light and waxy thickening of the skin without skin fragility. When photosensitivity appears with evidence of hemolytic anemia and/or liver disease, EPP must be considered. EPP should be suspected when there is a history of a child complaining of skin pain when immediately exposed to the sun. When this is coupled with anemia or signs of liver disease, investigations for EPP should be initiated.

All other cutaneous porphyrias may lead to skin fragility and subepidermal bullae, often associated with hypertrichosis and patchy pigmentation due to the accumulation of water-soluble uroporphyrinogens and coproporphyrins. The most common type of cutaneous porphyria is porphyria cutanea tarda (PCT). PCT is most often acquired and if a patient presents with skin findings that suggest cutaneous porphyria, PCT should be considered early on and a search for an underlying cause should be initiated. Because these illnesses often depend on adult behaviors (Table 9.12), PCT is rarely encountered in childhood. Cases of severe photodermatitis in childhood raise the possibility of the rare illness congenital erythropoietic porphyria (CEP). This is a very uncommon disorder and the patient usually has very distinctive findings such as pink urine (which will stain the diaper),

Pathogenesis of cutaneous manifestations

Despite clinical differences in the expression of photosensitivity, the histopathologic changes in light-exposed skin are qualitatively similar in all porphyrias. The characteristic finding is the presence of amorphous, hyaline, PAS-positive material in and around the walls of small blood vessels in the dermis and, often, also at the dermoepidermal junction.^{27,28} This material is derived from the walls and contents of blood vessels and represents the cumulative reparative response to repeated cycles of endothelial cell injury with local leakage of vascular contents.²⁹ Bullae are formed by a split in the lamina lucida of the basement membrane;³⁰ dermal papillae, stiffened by hyaline deposits, project into the floor and there is no surrounding inflammatory infiltrate.

These changes are provoked by the oxygen-dependent action of light at wavelengths around 400 nm on porphyrins in the dermis. Light at this wavelength penetrates the deeper layers of the dermis and passes through window glass. This energy is strongly absorbed by porphyrins (Soret absorption peak), generating an excited state that either returns rapidly to the ground state with emission of red light (fluorescence) or undergoes intersystem crossing to the longer-lived triplet state. Triplet-state porphyrins react with molecular oxygen by transferring energy to form singlet oxygen species or, less efficiently, by electron transfer to form a superoxide anion. They may also directly initiate other free radical reactions.

Oxygen free radicals are the most important mediators of photodamage to the skin. Since they are short-lived, the site of photodamage is determined largely by the distribution of porphyrins within the cell. Protoporphyrin has particular affinity for membrane lipids, both the endothelial cells and epithelial cells, while more water-soluble porphyrins preferentially accumulate in the lower dermis and cells of the basement membrane zone. These differences in distribution may explain the clinical differences between EPP and the other cutaneous porphyrias (CEP, PCT). Porphyrin-catalyzed

photodynamic reactions damage proteins, lipids and DNA,³¹ and may activate complement, especially in endothelial cells in EPP,³² degranulate mast cells,³³ and enhance degradation of dermal components by metalloproteinases.³⁴

Diagnosing porphyria and attending to family members

When a diagnosis of porphyria is suspected, the appropriate laboratory markers need to be collected and correctly interpreted (Table 9.13). Once the history, physical examination, and screening laboratory tests have revealed which porphyria(s) might be possible (see Table 9.9), scrutiny of Tables 9.13 and 9.14 and the sections on diagnosis above will provide clarification of the porphyria(s) under consideration. This will ensure that stool and urine porphyrins are measured (there is a tendency to forget their importance) as well as blood enzymes and porphyrins when appropriate.

Identification of asymptomatic affected individuals is an essential part of the management of families with acute intermittent porphyria (AIP), hereditary coproporphyria (HCP) or variegate porphyria (VP). Detection of latent porphyria during childhood before there is any real risk of acute porphyria should be the goal of the physician encountering signs or symptoms of porphyria in any member of a family (Table 9.14).

There are issues to consider in the laboratory analysis of the porphyrias. Metabolite measurements are normal before puberty, with the possible exception of the fecal coproporphyrin isomer ratio in some children with latent HCP.³⁵

Assay of PBG deaminase activity in erythrocytes is currently the most widely used method for detection of latent AIP. Enzyme activity decreases markedly as erythrocytes age and is dependent on the age distribution of the circulating cells. Its use should be restricted to hematologically normal individuals over the age of 8 months. Enzyme methods for the detection of latent HCP and VP require nucleated cells and are technically more complex than the PBG deaminase assay (Table 9.13).

New mutations for the porphyrias are being discovered frequently. However, there is no single test for all these DNA variations. Therefore, DNA testing is not suitable for screening for porphyrias, except within families. For these reasons, DNA testing is most meaningful only after standard testing for porphyria has confirmed a diagnosis.

Heme biosynthesis and pathway (Fig. 9.3)

Daily heme synthesis in normal adults is about 7 $\mu\text{mol/kg}$. The majority is produced within the bone marrow and used for hemoglobin formation. The remainder of the synthesis occurs in the liver. Approximately half is incorporated into the heme proteins of the cytochrome P450 enzymes. Heme is also incorporated into heme proteins, the mitochondrial and microsomal cytochromes involved in the electron and oxygen transport chain.³⁸ Heme synthesis starts in the mitochondria. The intermediate steps take place in the cytosol and the products of synthesis then reenter the mitochondria for the final two steps in the process.

Disease	Test	Limitations	Sensitivity	Specificity
AIP	Urinary PBG	Normal before puberty	Low	High
	Erythrocyte PBGD	Not before age of 8 months	Overlap between AIP and normal ranges contains 10–20% of asymptomatic relatives	
HCP	Fecal coproporphyrin (isomer III/I ratio)	Sensitivity in children not established	High*	High*
	CPO	Requires fresh lymphocytes or cell culture; technically complex	ND	ND
VP	Fecal porphyrins; copro isomer ratio	Normal before puberty	36% at age 15 or over	100% [†]
	Fluorescence emission spectroscopy of plasma	Normal before puberty	86% at age 15 or over	
	PPO	Requires fresh lymphocytes or cell culture; technically complex	ND	ND

* For adults.

[†] When erythrocyte free protoporphyrin concentration is normal.

AIP, acute intermittent porphyria; CPO, coproporphyrinogen oxidase; HCP, hereditary coproporphyria; ND, not determined (overlap between activities for affected and unaffected individuals small); PBG, porphobilinogen; PBGD, porphobilinogen deaminase; PPO, protoporphyrinogen oxidase; VP, variegate porphyria.

Regulation of heme is through the first enzyme in the pathway, ALAS. There are two forms of ALAS. ALAS1 is produced in the liver and other tissues; the gene that codes for this enzyme is found on chromosome 3 (3p21.1). The ALAS2 isozyme is specifically found in the erythroid line and is encoded on the X chromosome (Xp11.21).³⁹ This enzyme catalyzes the reaction of glycine and succinyl-CoA to form ALA. Deficiencies in the ALAS1 enzyme have not been described. Defects in ALAS2 do not cause porphyria but are responsible for X-linked sideroblastic anemia.⁴⁰

Regulation of heme synthesis in the liver is through ALAS1. The activity of ALAS is substantially lower than the subsequent enzymes, with the exception of PBG deaminase in nonerythroid cells. In the liver ALAS1 levels are rapidly turned over in response to metabolic needs. ALAS1 is under positive control by porphyrinogenic chemicals and under negative control by heme.⁴¹ Its levels can be increased by drugs that increase hepatic cytochrome P450, a rapidly metabolized heme protein,⁴² or by induction of heme oxygenase, which will degrade heme.⁴³ When there is excess heme in the cellular heme pool, this will inhibit ALAS1 via negative feedback regulation. This can also be accomplished by giving exogenous heme or by inhibiting heme oxygenase, methods relied upon for treatment of severe acute attacks.^{44,45} The regulation of ALAS1 occurs at several levels, by destabilization of ALAS1 mRNA by heme or by decreasing the rate of entry of the enzyme into the mitochondria.⁴²

ALAS2 is not under the direct control of heme production. Rather it is under the control of the iron supply. However, heme does play an important role in providing iron in heme synthesis. In higher concentrations heme inhibits the acquisition of iron

from transferrin and diminishes the availability of iron. Within the mRNA of ALAS2 there is an iron-responsive element (IRE). In the absence of iron, iron regulatory proteins bind to the IRE on mRNA, blocking translation of the enzyme.^{46,47}

Acute hepatic porphyrias

ALAD and ALAD deficiency porphyria

ALAD is the enzyme involved in the second step of heme synthesis; it is also known as porphobilinogen synthase. It catalyzes the formation of PBG from two ALA molecules. Its deficiency is the least common of all the porphyrias. It was initially described by Doss *et al.*⁴⁸ There have been only five reported cases of this disease in the literature.⁴ It is an autosomal recessive disorder.

The enzyme

Human ALAD is encoded by a single 13-kb gene on chromosome 9 (9q34) that contains 13 exons.⁴⁹ The enzyme is an octamer with identical 35-kDa subunits. It contains eight Zn²⁺ atoms, of which four are needed for catalytic activity. The zinc atoms allow the interaction with the octameric enzyme and the first ALA molecule.⁵⁰ ALAD is inhibited by compounds of clinical importance. Heavy metals, especially lead, act as potent inhibitors of the enzyme by displacing zinc, which is essential for catalytic activity;⁵¹ the intermediate succinylacetone, which is formed in hereditary tyrosinemia, is also a potent inhibitor of ALAD.^{52,53}

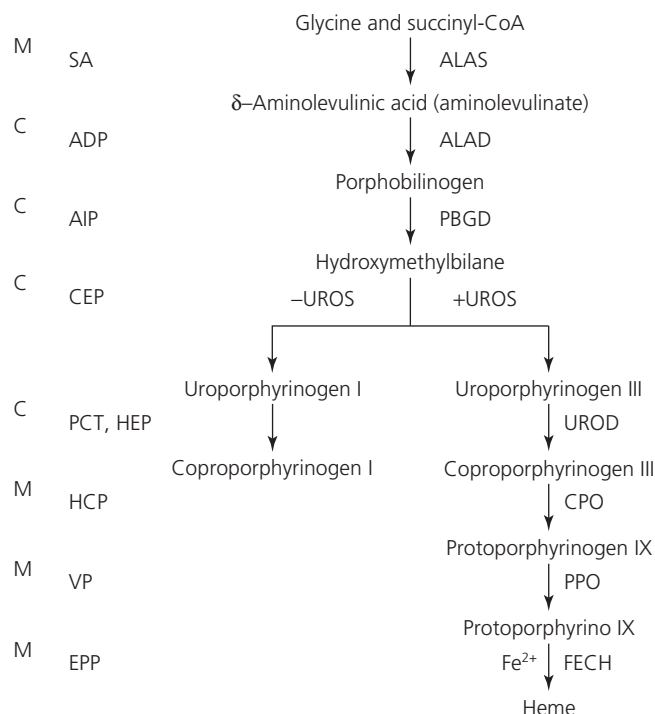

Fig. 9.3 Heme synthesis. M, reactions that occur in mitochondria; C, reactions that occur in cytosol. ALAS, δ-aminolevulinic acid synthetase; ALAD, δ-aminolevulinic acid dehydratase; PBGD, porphobilinogen deaminase; UROS, uroporphyrinogen III synthase; UROD, uroporphyrinogen III decarboxylase; CPO, coproporphyrinogen III oxidase; PPO, protoporphyrinogen oxidase; FECH, ferrochelatase; SA, X-linked sideroblastic anemia; ADP, δ-aminolevulinic acid dehydratase deficiency porphyria; AIP, acute intermittent porphyria; CEP, congenital erythropoietic porphyria; PCT, porphyria cutanea tarda; HEP, hepatoerythropoietic porphyria; HCP, hereditary coproporphyria; VP, variegate porphyria; EPP, erythropoietic protoporphyria.

All the mutations have been identified. With the exception of one patient, all the patients were compound heterozygotes.^{54–57} The patient who only had one mutant allele was asymptomatic and was identified through newborn screening for tyrosinemia.⁵⁸ Three patients were diagnosed with this disease at an early age and all their mutations were early stop codons, mutations in the substrate-binding site, or mutations in the zinc-binding site. One patient, an elderly man, did not develop any symptoms until he developed a myeloproliferative syndrome. He had two mutations: one of these did not affect the folding of the enzyme and thus the enzyme could function properly. When he developed his myeloproliferative syndrome with polycythemia, a preference occurred for one erythroid clone. It was found that this erythrocyte clone carried the nonfunctional ALAD allele.⁴

Clinical presentation

The age at presentation can be variable. Disease has been seen in a newborn, a teenager and the elderly man described

above, who developed the symptoms after he was diagnosed with a myeloproliferative disorder.^{48,59,60} Clinical symptoms have included colicky abdominal pain and polyneuropathy. The affected infant had generalized hypotonia and respiratory insufficiency. His treatment eventually required liver transplantation.⁵⁹ There were no significant hematologic abnormalities in these patients, although myeloproliferative disorders may occur.

Diagnosis

Conditions where ALAD are suppressed need to be excluded, as this type of porphyria is very uncommon. These include lead poisoning, zinc deficiency, chronic renal insufficiency,⁶¹ and diabetes mellitus.⁶² Symptoms similar to ALAD porphyria can present in patients with these medical problems, with elevation of urine ALA. ALA is excreted exclusively in the urine and normal excretion is less than 7 mg in 24 hours. In a patient with ALAD porphyria, ALA excretion will be three to ten times higher. This disease can be distinguished from AIP in that PBG excretion will be normal to only slightly above normal in the latter disease. Total porphyrin levels will also be elevated in a nonspecific fashion in ALAD porphyria. In addition, erythrocytes and lymphocytes can be assayed for ALAD activity, which is less than 5% of normal levels.

PBG deaminase and acute intermittent porphyria

PBG deaminase (PBGD) is the third enzyme in the synthesis of heme. It is responsible for the conversion of PBG into hydroxymethylbilane. AIP is due to a decrease in the production of this enzyme. This porphyria is an autosomal dominant disorder. Patients who inherit this disease will have levels 50% of normal. Approximately 90% of patients will have no clinical symptoms throughout their entire life. AIP is the most common type of acute hepatic porphyria.

The enzyme

PBGD (hydroxymethylbilane synthase) catalyzes the head-to-tail polymerization of four PBG molecules to form the linear tetrapyrrole, hydroxymethylbilane (pre-uroporphyrinogen). The discovery by ¹³C NMR spectroscopy of the extremely unstable product of this reaction initiated a series of investigations that have produced an almost complete picture of the mechanism of this fascinating and unique enzyme.^{63–65} The structure of the enzyme from *Escherichia coli* has been determined by X-ray crystallography at 0.176 nm resolution.⁶³ It contains three domains of similar size with a deep catalytic cleft between domains 1 and 2. The shape of these two domains resembles transferrin and the periplasmic binding proteins, proteins that undergo marked conformational change on interaction with their ligands.

PBGD first binds to two molecules of PBG. This forms a dipyrrolmethane cofactor that allows for the binding sites for subsequent PBG molecules to form a linear tetrapyrrole, hydroxymethylbilane (HMB).⁶⁶ HMB is a very unstable molecule and a short intermediate to the next step. Uroporphyrinogen III cosynthase needs to be present to quickly convert HMB to uroporphyrinogen III that can then continue to form heme. If this enzyme is not present, HMB will spontaneously convert to uroporphyrinogen I, which cannot go on to form heme molecules.

Human PBGD exists in two forms: a 40-kDa erythroid isozyme and a housekeeping (or ubiquitous) isozyme that contains an additional 17 amino acids at its NH₂-terminus and which is expressed in all tissues. Both are encoded by a single 10-kb gene on chromosome 11 (11q24.1–24.2) containing 15 exons.⁶⁷ Tissue-specific expression is determined by separate erythroid and ubiquitous promoters 5' to exons 2 and 1, with translation initiation codons in exons 3 and 1, respectively.⁶⁸ More than 100 mutations that cause AIP have been identified in the PBGD gene.⁶⁹ AIP can be divided into three groups.⁷⁰

- *Type 1 mutations:* PBGD activity is decreased by 50% in all tissues. The mutations are usually single-base substitutions or deletions. This will lead to single amino acid changes or truncated proteins.

- *Type 2 mutations* occur in less than 5% of patients with AIP. These are characterized by decreased PBGD activity in non-erythroid cells (50% of normal) but normal erythroid PBGD activity. The defect in this mutation is due to a single-base substitution in the 5' splice donor site of intron 1. Since erythroid PBGD uses a promoter downstream of the mutation site, its production is not compromised.⁷¹

- *Type 3 mutations:* PBGD activity is 50% of normal in all tissues. These lesions are CRIM positive. Mutations occur

mostly in exons 10 and 12, which are felt to be the regions essential for catalytic activity and substrate binding.⁶⁴

Clinical presentation

Patients with this disease usually present after puberty, although there have been a few cases of symptoms at a younger age.^{72,73} This disease is more common in women than men. As mentioned previously in the discussion of neurovisceral presentations, the initial sign of an acute attack is abdominal pain, which often radiates to the back, thighs or buttocks. Urinary retention, incontinence and dysuria can also occur. Cardiac and autonomic symptoms also appear and patients can succumb to blood pressure extremes or arrhythmias. In addition, hypertension may become sustained between the acute exacerbations of AIP. CNS symptoms include mental confusion and seizures. Seizures can be the result of hyponatremia, a result in some patients of inappropriate secretion of vasopressin, or possibly a result of metabolic effects on the CNS.¹⁸ Peripheral neuropathy is a common feature of AIP. This usually begins in the lower extremities but can also involve the upper extremities. In severe attacks, bulbar involvement can appear, leading to irreversible CNS damage or death. Psychiatric complaints are prevalent in AIP. In addition to formal psychiatric diagnoses, patients can also enter an altered state of consciousness ranging from somnolence to true coma. Psychiatric symptoms may represent the sole feature of the disease.⁷⁴ There is little evidence that acute porphyria causes long-term psychiatric illness, apart from generalized anxiety.⁷⁵ See Table 9.15 for a comprehensive analysis of symptom frequency in this complex illness.

Most patients have only one severe attack; a minority suffer from repeated attacks over several years. Regular premenstrual

attacks may occur in young women and may be initiated by the return of menstruation after pregnancy. The prognosis for most patients is good; few attacks now end fatally, particularly if the diagnosis is made early.^{76,77} The neuropathy reverses slowly as axons grow back from the periphery. Long-term complications in patients with AIP include physical disability, chronic renal failure, and an increased risk of hepatocellular carcinoma.¹⁶ The risk of hepatocellular carcinoma is thought to be due to increased reactive oxygen species that initiate DNA strand breaks.⁷⁸

Precipitating factors

Precipitating factors responsible for attacks in AIP are those events that cause an increase in ALAS1 (see previous discussion). With the upregulation of ALAS1 and the limiting levels of PBGD, an increase in both ALA and PBG occurs, precipitating an attack. In adults, most attacks are provoked by drugs, particularly those that induce cytochrome P450 (Table 9.16), and menstruation.^{16,76,79,80} Exogenous estrogens and progesterones can also precipitate attacks, although the exact mechanism is not known.^{81,82} Other precipitants include alcohol, smoking, calorie restriction, infection and stress. Caloric restriction, most notably lack of carbohydrate, increases heme oxygenase, which also increases ALAS1 due to decrease in hepatic heme concentrations.⁸³ Of note, patients with AIP who developed type II diabetes have been reported to have a *decrease* in their acute attacks. This may be due to increase in glucose levels and higher amounts of carbohydrate.⁸⁴ In the past, general surgery has been hazardous but the dangers seem largely to be related to use of inappropriate drugs and anesthetic agents. Provided the diagnosis of porphyria is known in advance and the patient is managed accordingly, surgery need not be discouraged.¹⁶

Diagnosis

The diagnosis of AIP can be established by finding elevated PBG or ALA in the urine. Total urine porphyrins will be elevated. One method for measuring PBG in urine is ion-exchange chromatography followed by reaction with Ehrlich's aldehyde reagent (*p*-aminodimethylbenzaldehyde in HCl) to produce a red product.^{85,86} There are rapid tests designed to detect PBG in the urine, such as the Watson-Schwartz test and the Hoesch test.⁸⁷ Screening tests, such as the Watson-Schwartz test, are less sensitive and less specific.^{85,86} Newer techniques have improved the detection by measuring PBG in its native form, improving the sensitivity of the diagnosis.⁸⁸ Positive screening tests should always be confirmed by a specific, quantitative method. In AIP, PBG and ALA urine excretion usually remains increased for many weeks after the onset of an acute attack. Erythrocyte PBGD activity may be measured to determine the patient's type of PBGD deficiency. Type II AIP patients should have normal

[†] Porphyria is listed as a contraindication, warning, precaution, or adverse effect in 1994 US labeling for these drugs.

[‡] There is little evidence that estrogens alone are harmful in acute porphyrias. They have been implicated as harmful based mostly on experience with estrogen-progestin combinations and because they can exacerbate porphyria cutanea tarda. Some patients with acute intermittent porphyria, hereditary coproporphyria, variegate porphyria and aminolevulinic acid dehydratase deficiency porphyria may tolerate a low-dose estrogen patch.

[§] Although porphyria is listed as a precaution in US labeling for this drug, it is regarded as safe by other sources.

[¶] There is strong evidence in laboratory studies and some clinical evidence that these agents may be harmful.

The text of this table was prepared by Karl E. Anderson and Douglas E. Goeger of Texas Medical Branch at Galveston.

erythrocyte PBGD levels. Type I and type III patients (representing the vast majority of defects) will have 50% or less of normal PBGD activity. If there is any confusion about the presence of additional hematologic or cutaneous disease in a patient thought to have AIP with normal red cell PBGD activity (type II), fecal porphyrins should be evaluated (see below).

Hereditary coproporphyria and coproporphyrinogen oxidase

HCP occurs when there is a defect in the enzyme coproporphyrinogen oxidase (CPO). CPO is involved in the sixth step of heme synthesis. It converts coproporphyrinogen III to protoporphyrinogen IX. This is an autosomal dominant hepatic porphyria. Patients who inherit this disorder will have enzyme activity 50% of normal. Symptoms of this disease are similar to AIP but a subset of patients will have cutaneous photosensitivity.

The enzyme

CPO is a mitochondrial enzyme and it is at this step in heme synthesis that the process reenters the mitochondria for completion to form heme. CPO is involved in the sequential hydrogenation and decarboxylation of the 2- and 4-propionate side-chains of coproporphyrinogen III to protoporphyrinogen IX, with formation of the tricarboxylic intermediate, harderoporphyrinogen. Coproporphyrinogen I is not metabolized so it is at this stage that the pathway becomes specific for the asymmetric series III isomers. Human CPO is encoded by a single 14-kb gene on chromosome 3 (3q12) that contains seven exons.⁸⁹ Human CPO is a metal-free 74-kDa homodimer situated in the mitochondrial intermembrane space, possibly loosely attached to the outer surface of the inner membrane.^{90,91} It is synthesized as a precursor with a 110 amino acid presequence that directs it to the intermembrane space.⁸⁹ For mammalian CPOs to function, they have an absolute requirement for molecular oxygen; no cofactors have been identified as a requirement for function. In erythroid cells CPO transcripts increase during cell differentiation. Functional analysis of the promoter has demonstrated that the synergistic action of an Sp-1 like element, a GATA site, and a novel regulatory element (CPO promoter regulatory element) that interacts with a leucine zipper-like structure, K1p1, are prerequisites for activity in erythroid cells.⁹² Conversely, in nonerythroid cells the GATA site is not required, indicating that regulation of CPO is tissue-specific.⁹³

Multiple different mutations have been described in the CPO gene.^{94–97} There are two mutations that result in elevated levels of the intermediate porphyrin harderoporphyrinogen. These involve exon 6, which implies that this region is important for the decarboxylation in the conversion of harderoporphyrinogen to protoporphyrinogen.⁹⁸

Patients with this defect are said to have harderoporphyrin. It is also important to note that the clinical severity of HCP does not correlate with inactivation of the CPO mutation.⁹⁸

Clinical presentation

Symptoms in HCP rarely present before puberty. There have been some cases of homozygous HCP that presented before puberty with neurovisceral symptoms, hemolytic anemia and jaundice. The patients who presented with hemolytic anemia had the subset condition harderoporphyrin.^{99,100} As HCP is a hepatic porphyria, it presents in a similar fashion to that of AIP. The common presentation is again with abdominal pain, vomiting, neuropathy, and psychiatric symptoms. However, up to 30% of patients may present with skin lesions. The skin lesions are very similar to those seen in PCT.

HCP is exacerbated by many of the same factors that precipitate attacks in AIP, such as medications, stress, fasting, and alcohol consumption. These patients, as in AIP, are also at increased risk for hepatocellular carcinoma.

Laboratory diagnosis

Patients with HCP will have elevated levels of ALA, PBG, and coproporphyrin (predominantly in the type III form) in the urine. These patients differ from patients with AIP in that ALA and PBG levels drop quickly. In the quiescent state, affected patients will excrete predominantly coproporphyrin III in their feces and the ratio of this to coproporphyrin I will be elevated. The enzyme can be directly measured in mononuclear cells but this should not be used as the sole diagnostic tool for this disease.¹⁰¹ Patients with harderoporphyrin will have harderoporphyrin in their feces as well as coproporphyrin. As HCP can have both cutaneous and neurovisceral findings, it is important that it not be confused with AIP or PCT. Therefore, fecal porphyrin analysis is critical when this diagnosis is considered. Only HCP will have elevated levels of coproporphyrin.

Variegate porphyria and protoporphyrinogen oxidase

VP is an autosomal dominant hepatic porphyria. It occurs when there is a defect in the enzyme protoporphyrinogen oxidase (PPO). Enzyme levels are less than 50% of normal. PPO is the seventh step in the formation of heme. It converts protoporphyrinogen IX to protoporphyrin IX. The term “variegate” was applied because VP can present with neurovisceral symptoms or cutaneous symptoms or both.

The enzyme

Human PPO is encoded by a gene on chromosome 1 (1q21–23) that contains 13 introns spread over 5.5 kb.^{102–104}

PPO is a flavoprotein with an absolute requirement for molecular oxygen.¹⁰⁵ This enzyme catalyzes the removal of six hydrogen atoms from the porphyrinogen nucleus. The enzyme is associated with the inner mitochondrial membrane but no transmembrane-spanning region has been identified.¹⁰⁶ Unlike the other mitochondrial enzymes of heme synthesis, PPO is not synthesized with a presequence to target import into the mitochondria.¹⁰⁴

More than 100 disease-specific mutations of the PPO gene have been identified.¹⁰⁷ However, there is less allelic heterogeneity as an estimated 20 000 descendants of a South African individual have been demonstrated to have inherited the same PPO mutation.¹⁰⁸ There is even less heterogeneity in Finnish and Swedish populations.^{14,109}

Clinical presentation

As with all hepatic porphyrias, neurovisceral attacks are common, leading to abdominal pain, nausea, vomiting, tachycardia, hypertension, neuropathy, back pain, and psychiatric symptoms. However, in comparison with AIP, attacks of VP are generally milder and recurrent attacks less frequent.¹¹⁰

Although VP is classified as a hepatic porphyria, cutaneous photosensitivity is common. Lesions are very similar to those seen in PCT and HCP. These include vesicles, bullae, erosions, hyperpigmentation and hypertrichosis of sun-exposed areas. Skin findings are less prevalent in the northern countries where sun exposure is less intense.

VP is exacerbated by many of the same factors that precipitate attacks in AIP, such as medications, stress, fasting, and alcohol consumption. These patients, as in AIP, are also at increased risk for hepatocellular carcinoma.

Of specific importance to the pediatrician, 12 unrelated patients with homozygous VP have been described.^{111,112} Except for one patient, all have developed skin fragility, subepidermal bullae and hypertrichosis before the age of 2 years. Other clinical manifestations include growth retardation, clinodactyly and flexion deformities of the fingers, mental retardation, convulsions, and nystagmus.

Laboratory diagnosis

Patients experiencing an acute attack of VP will have elevated urinary ALA, PBG and uroporphyrin. Patients will also have increased fecal protoporphyrin and coproporphyrin III. Fecal X-porphyrins are ether/acetic acid-soluble porphyrins extracted from feces. X-porphyrins are significantly elevated in VP. However, the most effective way to diagnose VP is by measurement of plasma porphyrin levels. Plasma porphyrins are especially increased in patients with cutaneous findings. In VP, dicarboxylporphyrin is bound tightly to plasma proteins. In order to distinguish VP from the other porphyrias, plasma emission scanning can be done. Plasma

porphyrins have an emission maximum at 626 nm, unlike any other porphyria.^{113,114}

Treatment of hepatic porphyrias

Acute attack

In a patient with acute hepatic porphyria exacerbation, the cause of the attack needs to be quickly identified. All medications that could potentially cause an increase in cytochrome production and thus increase ALAS synthesis need to be stopped. If the attack was brought on by infection, the infection needs treatment. Carbohydrate loading is the next approach to treatment. The patient should receive high doses of glucose because it is effective at inhibiting ALAS production. An adequate dose is 300–400 g daily. In sick patients this can be administered via nasogastric tube or intravenously through central venous lines. In patients with initial severe neurologic involvement or in those who have not responded to carbohydrate loading over 1–2 days, heme preparations are the next choice. They consistently reduce ALAS formation, but have side-effects that reserve them for severe disease or when patients fail to respond to glucose treatment. Hemin (Panhematin; Abbot) should be given during an acute attack. This is the most effective agent for reducing acute neurovisceral attacks.⁴⁴ The recommended dose for treatment is 3–4 mg/kg once a day for at least 4 days. The side-effects of hemin are phlebitis and coagulopathy. Although acute hemorrhage has not been seen with the use of hemin, concurrent anticoagulant therapy should not be used. To decrease the risk of phlebitis, patients will sometimes require the placement of a central venous catheter. Heme arginate preparations (Normosang; Orphan Europe, Paris) are available outside the USA and significantly reduce the risk of adverse events.

Cimetidine has also been shown to suppress ALAS and can be used as an alternative if standard modalities are not available. Doses of 800 mg/day in adults have had a positive effect during acute attacks.¹¹⁵ Heme oxygenase inhibitors can also be used. However, these drugs (e.g., tin protoporphyrin) have toxic side-effects and zinc mesoporphyrin is not widely available.^{116,117} Patients may also require antiemetics, pain control, antihypertensive agents, and close monitoring of electrolytes. If patients have bulbar dysfunction that leads to respiratory difficulty, mechanical ventilation may be required. Currently, recombinant PBGD is being studied in the treatment of acute attacks of AIP.

Prevention

As this disease has many triggers, the best way to avoid an acute attack is to avoid those factors known to exacerbate hepatic porphyrias. A list of potentially safe and unsafe agents can be found at the American Porphyria Foundation

website (www.porphyrifoundation.com) (see also Table 9.16). For women whose acute exacerbations occur during menstruation, suppression of ovulation with LHRH analogs can reduce the number of attacks.¹¹⁸ Care needs to be taken to treat infections and monitor these patients when they have any surgical procedures. Patients need to avoid episodes of starvation or reduced caloric intake, which can also exacerbate this disease. In patients with frequent recurrent attacks, weekly administration of hemin may help control the disease.^{119,120} Liver transplantation has been successful in two patients, one with AIP and one with VP who failed all other treatments.^{121,122} New research into gene therapy has looked into transferring the enzyme PBGD via viral vectors into hepatocytes. This approach is still in its very early stages.^{123,124}

Photocutaneous porphyrias

Congenital erythropoietic porphyria and uroporphyrinogen III synthase

CEP is an autosomal recessive disease that is due to a deficiency of the enzyme uroporphyrinogen III synthase (UROS). It is also called Gunther disease. UROS is the fourth step in the formation of heme. It converts HMB to uroporphyrinogen III. Enzyme levels of UROS in this disorder are markedly deficient but not absent and are usually less than 1%.

The enzyme

The human UROS gene on chromosome 10 (10q25.2–26.3) covers 45 kb and contains nine exons that encode a 29-kDa protein.¹²⁵ UROS catalyzes both cyclization and reversal of the orientation of ring D of HMB to give the uroporphyrinogen III isomer, which is the common precursor of all tetrapyrrolic pigments. In the absence of UROS, HMB rapidly cyclizes to the symmetrical hexahydroporphyrin, uroporphyrinogen I, and this molecule has no physiologic function. This molecule is then converted to coproporphyrinogen I and cannot be metabolized further. Several mechanisms for this unique reaction have been suggested; current evidence favors the formation of a spiro-intermediate, an unusual molecular configuration that would yield the products seen in the normal patient.¹²⁶ In addition, like ALAS there are two forms of this enzyme, an erythroid-specific and a housekeeping form.¹²⁷

To date, 36 mutations in the UROS gene that cause CEP in homozygotes or compound heterozygotes have been characterized.¹²⁸ The majority of patients with CEP are compound heterozygotes for the UROS mutations. The most common mutation (C73R) represents about 35% of mutant alleles, followed by L4F and T228M mutations representing 7% and 6% respectively. There is a correlation between the genotype and

phenotype of patients with CEP. Those patients homozygous for the C73R mutation have a UROS activity of <2% and have particularly severe disease. Patients who have mutations that express some residual activity have milder forms of the disease. Some of these have been identified in patients with only mild cutaneous symptoms.¹²⁹

Clinical features

The age at onset and clinical severity of CEP are highly variable. It can range from nonimmune hydrops fetalis *in utero* due to severe hemolytic anemia to milder later-onset forms in which patients only develop cutaneous lesions. There are a number of factors that cause this phenotypic variability, including the amount of UROS activity,¹²⁹ the degree of hemolysis and subsequent stimulation of erythropoiesis, and the amount of exposure to ultraviolet (UV) light. Most patients have the severe infantile-onset form.¹³⁰

Cutaneous involvement

Common early signs are blisters and erosions on light-exposed skin, especially on the hands and face. The severe and persistent skin lesions resemble those of other bullous porphyrias: subepidermal bullae, skin fragility with erosions and vesicles, which contain serous fluid and are prone to rupture and infection. The serous fluid will fluoresce due to the high content of porphyrin. Milia, hypertrichosis (particularly of the face), and patchy pigmentation are all common.¹³¹ Repetitive cycles of symptomatic episodes lead to photomutilation, with erosion and resorption of the terminal phalanges, contractures, destruction of the ears, nose and eyelids, and scarring alopecia. Corneal scarring may lead to blindness.

Hematologic involvement

Clinical manifestations are not confined to the skin. Hemolytic anemia and splenomegaly are common. On a peripheral smear, anisocytosis, poikilocytosis, polychromasia, basophilic stippling, reticulocytes, and nucleated red blood cells can be seen. Neonates can have hyperbilirubinemia due to anemia and if CEP is not recognized, treatment using phototherapy can be quite harmful. Splenomegaly will usually develop because of the increased turnover of damaged red blood cells. Hypersplenism causing anemia, thrombocytopenia and leukopenia eventually occurs. This may result in purpura, bruising and hemorrhagic blisters. Hydrops fetalis, extensive bruising and hepatosplenomegaly may be present at birth due to severe hemolytic anemia.

Additional clinical features

Pink or red staining of diapers or pink/red-brown amniotic fluid due to increased urinary porphyrins may be the first sign of disease. Porphyrin from CEP can be deposited in the bones and teeth. This causes the teeth to appear reddish-brown in natural light (erythrodontia). The teeth will also

fluoresce when exposed to long-wavelength UV light. Porphyrin deposition in the bones will cause bone loss due to demineralization.¹³² Bone loss may also occur secondary to erythroid marrow expansion to compensate for ineffective erythropoiesis.¹³³ Other skeletal changes include bone resorption from photomutilation and decreased bone density with pathologic fractures. Vitamin D metabolism may be impaired because of the avoidance of sunlight.

Diagnosis

Investigations for CEP should be initiated in patients with pink- or red-stained diapers and skin photosensitivity. In patients with CEP, urine porphyrins, uroporphyrinogen I and coproporphyrinogen I are significantly elevated. Fecal and plasma coproporphyrinogen I levels are also increased. A Wood's light will demonstrate fluorescence of teeth. Assays for UROS enzyme activity have been developed as well as detection of the gene mutations, which can help with genotype/phenotype correlations.¹³⁴ If a family has already had an infant with CEP, prenatal testing can be performed to detect if the fetus has the disease and then the necessary precautions can be taken to prevent the harmful effects of phototherapy for neonatal hyperbilirubinemia. Prenatal detection can be performed by direct observation of UROS gene mutations or measurement of UROS activity in cultured amniotic cells.^{135,136}

Treatment

Treatment of these patients involves multiple interventions. The first is sun protection or sun avoidance. If a patient needs to go out in the sun, adequate coverage of skin is needed; sunscreens and β -carotene have been beneficial in protecting the skin.¹³⁷ If any of the patient's bullae or vesicles become infected, rapid treatment should be initiated to prevent scarring.

Patients with severe hemolytic anemia will require blood transfusions. Blood transfusions have multiple benefits: they suppress erythropoiesis, decreasing the amount of porphyrins and thus photosensitivity. If a patient develops hypersplenism, splenectomy may alleviate the thrombocytopenia and reduce the number of transfusions.¹³⁷ To achieve the desired benefit from transfusion therapy, the patient's hematocrit should be kept above 32% and deferoxamine should be administered appropriately to avoid iron overload.¹³¹ Other therapies that have been useful include hydroxycarbamide to reduce porphyrin synthesis and oral charcoal to increase the fecal loss of porphyrins.^{138,139} These therapies are more effective in patients with milder forms of the disease.

Hematopoietic stem cell transplant (HSCT) has been used and can be curative in patients with CEP. Ten patients have undergone HSCT, with nine surviving with a significant reduction in symptoms and signs of their disease.¹⁴⁰ Future directions include using gene therapy to introduce UROS

activity into the hematopoietic stem cells of patients with CEP. This approach would avoid the toxicities associated with allogeneic HSCT.

Porphyria cutanea tarda, hepatoerythropoietic porphyria and uroporphyrinogen decarboxylase

PCT is the most common type of porphyria, with onset usually in adulthood. It is due to a defect in the enzyme uroporphyrinogen decarboxylase (UROD). There are three different forms of PCT.

- Type I represents approximately 80% and is known as the sporadic form. In these patients, levels of UROD are decreased only in the liver and not in red blood cells. Levels of UROD are only low during acute attacks and return to more normal levels once treatment is initiated.¹⁴¹ This is most common in male patients and is the result of certain disease associations (see Table 9.12).

- Type II represents approximately 20% of patients. This is the autosomal dominant form of PCT and shows a 50% reduction of UROD activity. Activation of PCT in these patients occurs more readily if they contract any of the disorders listed in Table 9.12 as they already have a 50% reduction in the enzyme.

- Type III resembles type I in that no mutation is detected but disease occurs in more than one family member, suggesting there is an inherited predisposition. Patients with type III disease can have onset of disease at an earlier age than patients with type I or type II.

Patients with hepatoerythropoietic porphyria (HEP) are homozygous or compound heterozygous for UROD deficiency and this porphyria is very uncommon.

The enzyme

The cytosolic enzyme UROD is the fifth step in heme formation. It catalyzes the decarboxylation of uroporphyrinogens I and III to the corresponding coproporphyrinogens.¹⁴² The enzyme decarboxylates all four isomers but the type III isomer is decarboxylated the fastest. Human UROD is an 82-kDa homodimer¹⁴³ encoded by a gene on chromosome 1 (1p34) that contains 10 exons spread over 3 kb.⁷ With uroporphyrinogen III as a substrate and under physiologic conditions, the acetic acid substituents are decarboxylated in a clockwise order around the porphyrinogen macrocycle, starting at ring D, with the formation of 7-, 6- and 5-carboxyl intermediates. The affinity of the enzyme for substrate decreases with the removal of each carboxyl group from the substrate. All URODs are inhibited by sulfhydryl group-containing reagents, including heavy metals. Evidence from study of natural mutants and from site-directed mutagenesis experiments is consistent with the hypothesis that each side-chain is decarboxylated at the same catalytic site,^{142,144} but the mechanism by which the substrate rotates remains obscure.

Patients with the sporadic forms of PCT do not have any evidence of UROD mutations.¹⁴¹ In the familial form of PCT, over 45 different mutations have been reported.¹⁰⁷ Patients with HEP, although they have mutations in both UROD alleles, still have some residual UROD activity. However, most mutations found in HEP are not found in familial PCT. Thus, the mutations in familial PCT appear to be more critical to enzyme activity than those found in HEP.¹⁴⁵

Pathogenesis

To cause the symptoms of PCT, approximately 75% of the enzyme needs to be inhibited.¹⁴¹ Abnormal iron metabolism appears to be a major precipitating factor in PCT. This is most likely due to the production of oxygen free radicals produced by reactive intracellular iron. Patients with PCT typically have higher levels of iron compared with control populations. Not surprisingly, patients with PCT commonly have mutations in the *HFE* gene that is associated with hemochromatosis.^{146–148} Polyhalogenated hydrocarbons such as hexachlorobenzene inhibit UROD and can cause PCT. This is sometimes referred to as toxic porphyria. Estrogen-containing contraceptives can precipitate PCT in women.¹⁴⁹

Clinical features

Patients with PCT can have blisters and erosions on light-exposed skin especially on the hands and face. These sub-epidermal bullae, which contain serous fluid, then denude and become crusted. These heal slowly and are prone to infections. Facial hypertrichosis and hyperpigmentation are common. Cutaneous thickening of the skin with scarring and calcification can be seen and is sometime termed “pseudo-scleroderma”.¹⁵⁰ Milia may also develop within the areas of bullae. Patients may also develop onycholysis. In patients with HEP, the skin findings are similar to those found in CEP.

Patients with PCT almost always have liver dysfunction, even in cases not associated with hepatitis C. Porphyrin levels within the liver and needle-like inclusions have been found in the cytoplasm of hepatocytes. It is thought that these may be composed of uroporphyrin and may cause liver damage in PCT.¹⁰⁷

Diagnosis

When an apparently “acquired” porphyria is discovered, PCT should be considered and an analysis of underlying causes initiated (see Table 9.12). Patients with evidence of PCT will have increased uroporphyrin I. In the feces, isocoproporphyrin (coproporphyrin I) is dominant. However, concentrations of coproporphyrin and X-porphyrin may also be elevated. Uroporphyrin and 7-carboxyporphyrin are elevated in the liver. Plasma porphyrins will fluoresce at 620 nm. Sporadic and familial (type II) PCT can be distinguished by

measuring erythrocyte UROD activity.¹⁵¹ In children, measurement of erythrocyte UROD activity and protoporphyrin concentration is required to distinguish HEP from type II PCT.

Treatment

When patients are diagnosed with PCT, an underlying cause for this disease needs to be evaluated. Infectious diseases should be investigated and treated, precipitating factors should be removed, evaluation for hepatitis C and hepatocellular carcinoma should be initiated, and testing for hemochromatosis accomplished.

The most effective treatments for PCT are low-dose chloroquine and phlebotomy. Phlebotomy was introduced in 1961 and remains the standard of care. It can induce remissions in most patients. There are many different protocols for phlebotomy in patients with PCT.¹⁵² These may be similar to those used in hereditary hemochromatosis, commonly removing 300–450 mL of blood every 1–2 weeks and continuing until the ferritin level is at the lower limit of normal. Urinary porphyrin levels are monitored every 3 months during this time. Care must be taken to keep the hemoglobin above 10 g/dL.

When phlebotomy is contraindicated or when there is not marked iron overload, low-dose chloroquine is the most effective alternative (200–250 mg once to twice a week or hydroxychloroquine 100 mg twice a week). The mechanism of effect is not well understood. It is important for patients when beginning this treatment to know that normal doses of chloroquine (200 mg/day) can cause a hepatitis-like syndrome from the initial release of stored porphyrins in the liver. In this case, urinary porphyrins will significantly increase. In severe cases, both treatment modalities can be used. Urinary porphyrins should be monitored. In preliminary studies thalidomide appears to have some efficacy in treating PCT.¹⁵³

Patients with end-stage renal disease can have severe forms of PCT. Porphyrins in this patient population are not easily dialyzable. In these patients the treatment of choice has become erythropoietin. This can correct anemia, mobilize iron and raise the hemoglobin enough to enable phlebotomy to decrease iron levels.^{154,155}

Erythropoietic protoporphyria and ferrochelatase

EPP is an autosomal dominant disease due to a deficiency in the enzyme ferrochelatase (FECH). FECH is the last step in heme formation. It catalyzes the insertion of iron into protoporphyrin IX.

The enzyme

Human FECH is encoded by a single 45-kb gene on chromosome 18 (18q21.3) that contains 11 exons. The gene contains

two polyadenylation sites, the upstream site producing a 2.2-kb transcript that may be used preferentially in erythroid cells.^{80,156} Newly synthesized FECH contains a sequence that directs transport into the mitochondrion and is then cleaved to form the mature 40-kDa protein. FECH functions *in vitro* as a monomer,¹⁵⁷ but radiation inactivation experiments suggest that it may be present in the mitochondrial membrane as a dimer.¹⁵⁸ Mammalian but not bacterial FECH has a carboxy-terminal extension that contains a [2Fe–2S] cluster.¹⁵⁹ Removal of this extension inactivates the enzyme, an unexpected finding in view of the similarity of the remaining sequence with those of active bacterial enzymes.¹⁶⁰ In addition to protoporphyrin IX and Fe²⁺, other dicarboxylic porphyrins (mesoporphyrin, deuteroporphyrin) and metals (Zn²⁺, Co²⁺) serve as substrates. Mechanistic studies using *N*-alkylporphyrins as inhibitors suggest that the porphyrin ring becomes distorted during the reaction in order to facilitate Fe²⁺ insertion. The residues that bind Fe²⁺ have not been unequivocally identified. More recent site-directed mutagenesis experiments implicate histidine residues, particularly H263 in the human enzyme.¹⁵⁷

Over 70 mutations of the FECH gene have been identified.¹⁶¹ Most patients who inherit a mutant allele are asymptomatic. For protoporphyrin to accumulate to the level that will cause clinical symptoms, enzyme activity must be below 35%.¹⁶² In most patients this is due to inheritance of a wild-type allele that has low expression of FECH in addition to a mutated allele (IVS3-48C allele).^{15,163}

Autosomal recessive EPP, unlike homozygous variants of the other autosomal dominant porphyrias, is not phenotypically distinct. Prevalence in UK patients with EPP is 3% and those patients who have autosomal recessive disease have a higher risk of liver disease.¹⁶¹

Clinical presentation

EPP usually presents in early childhood. It is characterized by skin pain with erythema, itching and edema that develops rapidly on sun exposure. The pain after sun exposure can sometimes last for several days. Some patients initially manifest their illness as solar urticaria. These lesions occur mainly on the face and hands. If sun exposure is not avoided, chronic lesions develop with waxy thickening of the skin and scarring. Photosensitivity is worse during the summer months and may be exacerbated by heat exposure or temperature gradients.¹⁶⁴ In approximately 25% of patients with EPP, anemia can be found. This can be due to disturbed erythropoiesis or hemolysis.¹⁶⁵

Liver disease is the most prevalent additional manifestation observed in this cutaneous porphyria. Protoporphyrin is lipophilic and is excreted in bile and enters the enterohepatic circulation; excess protoporphyrin will be taken up by hepatocytes and can exacerbate hepatotoxicity and biliary cholestasis. Patients can suffer from biliary stones causing

obstruction and elevated liver enzymes, and a minority of patients will develop severe liver disease and failure.

Diagnosis

Patients will have increased free protoporphyrin in the feces and the plasma, with plasma fluorescence at 630 nm. Urinary porphyrin levels should be normal. There are also changes in the pattern of porphyrin levels that can be indicative of liver disease. Patients will have an increase in erythrocyte and plasma protoporphyrin and a decrease in stool protoporphyrin. There is also an increase in coproporphyrin I levels in the urine.¹⁶⁴

Treatment

In patients with EPP, skin protection is very important as sun exposure can be debilitating. Sun avoidance, even through windows, is very important. Protective clothing and sunscreens should be used routinely. Care should be taken in patients with EPP undergoing surgery as prolonged exposure of internal organs to artificial light can severely burn internal organs and exacerbate anemia. β -Carotene has been used since 1970 to successfully diminish photosensitivity.¹⁶⁶ Doses range from 30 to 180 mg/day depending on the size of the patient. Other therapies, such as oral cysteine, phototherapy with narrow-band UVB (TL01 therapy), and cholestyramine to increase protoporphyrin excretion, have been used.²⁶ In patients with fulminant liver failure, liver transplantation is required.¹⁶⁷ Transfusion and exchange transfusion may decrease serum protoporphyrin levels.¹⁶⁸ Although these procedures may be valuable for acute toxicity,¹⁶⁹ they may not significantly reduce chronic liver toxicity or prevent progression to hepatic failure. The only way to induce remission in this disease is through HSCT.^{167,170,171,172} Gene therapy attempting to express the FECH gene in hematopoietic stem cells is under investigation. Some animal models have shown success using this approach.¹⁷⁰

Sickle cell disease

Corrina McMahon

Introduction

The first recorded description of sickle cell crisis was by Africanus Horton who noted the association of bone pains and cold weather.¹ The first medical description of sickle cell disease was published in 1910. It described thin sickle-shaped red cells occurring in a Caribbean student who was hospitalized with back and muscle pain and suggested that the illness might be related to the abnormally shaped cells.² In 1949 Pauling and Itano described sickle cell anemia as the first molecular disease when they found that hemoglobin from a patient with sickle cell anemia (HbS) differed in electrophoretic mobility from normal hemoglobin (HbA) and that hemoglobin from a subject with sickle cell trait was a mixture of HbS and HbA.³ Some years later Ingram described the valine for glutamine substitution of normal hemoglobin that produces HbS.⁴

Sickle cell disease (SCD) is a generic term for a group of disorders that includes homozygous sickle cell anemia (HbSS), sickle cell hemoglobin C disease (HbSC), sickle cell thalassemia disease (S/thal) and other compound heterozygous conditions. They are all characterized by the presence of the mutated β -globin gene, β^S -globin, and all cause clinical disease.⁵ Homozygous HbSS and compound heterozygosity for β^0 -thalassemia have the most severe phenotype. Compound heterozygosity with HbC, and β^+ -thalassemia have a less severe phenotype and an increased life expectancy. Sickle cell trait (HbAS) is the carrier state and is not classified as a sickle cell disease.

Epidemiology

The β^S -globin gene mutation has arisen independently several times and at least five mutations, four in Africa and one in India, have been selected and expanded.⁶ The three major African genotypes are localized exclusively to one major

geographical area: Benin to central west Africa, Senegal to the African west coast and Bantu (Central African Republic) to central Africa. The Arab-Indian mutation probably originated in the Indus valley and extended to Saudi Arabia, Bahrain, Kuwait and Oman.⁷ The African and Arab slave trades have been responsible for genetic dissemination throughout Europe and America and more recently war and economic migration has brought the gene to countries where it was formerly unknown. In many cases there is now a considerable admixture of the African genotypes in America and Europe.

The prevalence of sickle cell trait in western, central and eastern Africa is 5–40% but is less common in northern and southern Africa.⁸ It occurs in 8% of the African-American population and SCD affects about 1 in 600 African-Americans.⁹ In the UK, it is estimated that about 3000 babies (0.47%) are born each year with sickle cell trait and 0.28 per 1000 conceptions are affected by SCD.¹⁰

The median life expectancy for those with homozygous SCD (HbSS) in the USA was reported at 42 years for males and 48 years for females in 1994, whereas those with HbSC had a median life expectancy of 60 and 68 years respectively. The study found that 33% of deaths occurred during an acute crisis; the other major cause of death was acute organ failure.¹¹ Factors that predict adverse outcome are dactylitis, severe anemia (hemoglobin < 7 g/dL), and leukocytosis within the first 2 years of life.¹² A 2004 study clearly demonstrates the influence of aggressive management strategies in childhood. It reports a death rate of 0.4 per 100 patient-years and a sickle-related survival rate of 93.6% by 18 years of age. The mean age of death in this study was 5.6 years and the most common cause of death was infection.¹³ The most common portal of entry for infection is the upper respiratory tract and death commonly occurs within the first 24 hours following an acute presentation.¹⁴ The situation in Africa is quite different. In 1989 the death rate was estimated to be 50% before the age of 1 year in Nigeria,¹⁵ and in Kenya some years later it was noted that 77% of those with SCD were aged less than 15 years, suggesting that most died in their teenage years.¹⁶

Pathophysiology

SCD is caused by a single point mutation at codon 6 of the β -globin gene that results in a valine \rightarrow glutamine substitution. The resultant mutant hemoglobin (HbS) polymerizes when deoxygenated (Table 10.1) because valine can dock with complementary sites on adjacent globin chains. Polymerization depends on intracellular HbS concentration, the degree of cell deoxygenation, pH and the intracellular concentration of fetal hemoglobin (HbF). The polymers form bundles that distort the red cell into the classic sickled or crescent shape and interfere with red cell membrane structure and deformability.⁷ Some coinherited or acquired conditions, e.g., hereditary persistence of HbF and α -thalassemia, can reduce HbS polymerization and reduce sickling (Table 10.2).

Damage to the red cell membrane produces a series of abnormal sodium, potassium and calcium fluxes that lead to red cell dehydration (Table 10.3).^{7,17} Red cell dehydration increases the intracellular HbS concentration and promotes sickling.

Vasooclusion, the key feature of SCD, is the end result of a series of red cell, endothelial, monocyte and platelet interactions (Table 10.3). A proposed unified schema is that the endothelium is activated by cytokines released by infection, inflammation or directly by migrating leukocytes.¹⁸ The red cell adheres to the endothelium through a series of mechanisms, either directly via exposed red cell membrane phosphatidylserine or sulfated glycans, or by using soluble adhesion molecules (e.g., integrins and thrombospondin and/or high-molecular-weight von Willebrand factor) as a bridge.^{18,19,21} Adherent leukocytes and red cells narrow

Table 10.3 Factors contributing to sickle cell crisis.

<i>HbS polymerization</i>
<i>An increase in red cell dehydration</i> ^{7,17}
Increased cation (sodium, potassium, magnesium and calcium) membrane permeability
Calcium ion entry activates the Gardos channels
Activation of the Gardos channels (calcium-sensitive K ⁺ -efflux channels) triggers the loss of potassium and water and leads to red cell dehydration
K/Cl cotransporter mechanism is activated by lower pH and deoxygenation contributing to intracellular dehydration
<i>Disruption of the red cell bilayer and exposure of phosphatidylserine</i> ⁷
<i>Upregulation of endothelial adhesion molecules</i> ¹⁸
Leukocyte activation and adherence to the endothelium
Adherence of the red cell to the endothelium
<i>Nitric oxide depletion by free heme</i> ²¹
Reduction of nitric oxide
Loss of nitric oxide-associated vasodilatation
Upregulation of adhesion molecules

the diameter of the blood vessel, slowing blood flow and trapping dense sickled cells. The increase in blood transit time also increases red cell sickling and, finally, blood vessel occlusion occurs. This produces ischemia and finally necrosis, which causes cytokine release and perpetuates the sickle event.^{7,19,20}

Sickle cell trait

Sickle cell trait is a benign condition produced when a gene containing the HbS mutation is inherited along with a normal β -globin gene, and is described as HbAS. The individual with HbAS is considered to be a carrier of the sickle cell genetic mutation. Two HbAS partners have a 25% risk of having a child with HbSS and this risk remains the same for each pregnancy. The diagnosis of HbAS is made when the quantity of HbA exceeds that of HbS on hemoglobin testing. Individuals with sickle cell trait can suffer an excessive incidence of hematuria and a urine-concentrating defect. This is probably caused by microvascular injury in the vasa recta of the renal medulla, which has a hypoxic acidotic environment conducive to sickling even in the presence of HbA. Nevertheless, HbAS should only be considered as the cause of hematuria when other possibilities have been excluded. There are reports that individuals with sickle cell trait can develop sickle cell crisis and there is an increased incidence of sudden death in some individuals with HbAS. This is probably related to heat exhaustion brought on by rigorous exercise in hot weather. A liberal fluid intake, gradual acclimatization and the avoidance of overexertion is suggested for individuals with sickle cell trait in hot climates.²²

Laboratory features

HbF is the predominant hemoglobin at birth, comprising about 80% of all detectable hemoglobins. HbA usually comprises 20% of all hemoglobins and HbA₂ is normally not detectable to any major extent. By 6 months of age, HbA has become the major hemoglobin and HbF has fallen to about 5–10%, while HbA₂ has reached adult levels but may continue to rise for 1–2 years.

Individuals with HbSS, HbSC, HbS/ β^0 -thalassemia do not produce HbA. Individuals with HbS/ β^+ -thalassemia produce some HbA, usually 3–20%. HbA₂ is elevated in those with an associated β^+ or β^0 thalassemia. HbF may continue to be present at higher than expected levels in those with HbSS.²³

Blood count

The blood count in sickle disease is normal for the first 2 months. The blood count in those with HbSS and HbS/ β^0 -thalassemia will usually demonstrate a moderate anemia by 6–12 months and a reticulocytosis because of hemolysis. A sustained reticulocytosis above 25% is unusual and suggests recovery from an acute event, hypersplenism or, occasionally, a superimposed autoimmune anemia. Individuals with HbSC or HbS/ β^+ -thalassemia may be normal or have mild anemia. Individuals with higher HbF levels tend to have higher hemoglobin levels.²³

Blood film

The red cells in HbSS vary in size and shape. There is increased polychromasia, red cell fragments, and a variable number of hypochromic or target cells. The characteristic dense sickled cells occur in variable amounts. They are not usually present for the first few months of life because of the high HbF level. The number of sickled cells is variable and ranges from only an occasional finding to 30–40% of all red cells.²⁴ Some investigators report an increased number of sickled cells during a sickle crisis but this has not been confirmed by all.²⁵ In addition to the classical sickled cell there are other cells, often called ‘boat-shaped’ that are elongated and pointed at one or both ends. Howell–Jolly bodies are usually found by 1 year of age and represent evidence of hyposplenism. The presence of many target cells and hypochromia may indicate coexistent α -thalassemia trait. Those individuals who are taking hydroxycarbamide therapy often exhibit a macrocytosis.

The peripheral blood of individuals with HbSC shows less polychromasia and Howell–Jolly bodies are usually not seen. Target cells are a common feature. Sickled cells are not often seen but ‘boat cells’ are common. The characteristic feature is the presence of SC poikilocytes. These are misshapen cells that contain irregularly shaped crystals that jut out at various

angles or they may appear similar to sickle cells but on closer inspection have a straight-sided crystal present.²⁴

Individuals with HbS/ β^+ -thalassemia have only occasional boat-shaped cells and no sickle cells. They have more thalassemic features, including hypochromic microcytic cells, sometimes with basophilic stippling, and frequent target cells.

Other investigations

Patients with HbSS and HbS/ β^0 -thalassemia will have evidence of hemolysis such as elevated lactate dehydrogenase and bilirubin levels and low haptoglobin levels.

Sickle solubility test

This is a simple, quick test to detect the presence of HbS. A sample of the patient’s red cells is mixed with a deoxygenating substance. If the solution becomes turbid, the presence of HbS is suggested, although this needs to be confirmed by more definitive testing. A positive solubility test does not distinguish HbAS, HbSC, HbSS or HbS/ $\beta^{+/-}$ -thalassemia. It may give a false-negative result in children less than 6 months of age and is not recommended in this age group. It may also be negative in extreme anemia or following blood transfusion. False-positive results can occur in those with elevated white cell counts and with hyperproteinemic or hyperlipidemic states because of plasma turbidity, and for this reason the use of plasma-free red cells is recommended.

Definitive testing (Table 10.4)

Hemoglobin electrophoresis relies on the fact that different hemoglobins will separate from each other when exposed to a charge gradient and can be visualized using a staining process. Acid and alkaline medium is used to further characterize the hemoglobins, which have differing mobilities in different media. Hemoglobin electrophoresis is difficult to interpret and may be imprecise in the neonate.

High-performance liquid chromatography (HPLC) has now superseded hemoglobin electrophoresis as the first-line test for variant hemoglobins. This technology involves the capture of positively charged hemoglobin molecules onto a negatively charged solid column, followed by their elution into a liquid phase and capture at a rate that depends on

Table 10.4 Methodologies used for hemoglobin identification.

Hemoglobin electrophoresis
High-performance liquid chromatography
Isoelectric focusing
Mass spectrometry
DNA testing

their charge. Some hemoglobins (e.g., HbF) will elute quite quickly, whereas others (e.g., HbS and HbC) take some minutes. The speed of elution and the quantity of hemoglobin present is calculated using a computerized program.

Isoelectric focusing is often used as a confirmatory test if a hemoglobin variant is detected on HPLC. It gives a pattern similar to that of conventional hemoglobin electrophoresis but allows better separation and definition of hemoglobin variants. It relies on the fact that the net charge of a protein or hemoglobin depends on the pH in the surrounding solution. Various hemoglobins are separated on the gel according to the point where they have no net charge (isoelectric point).

All variant hemoglobins should be characterized using two different methodologies. Sometimes it proves impossible to definitively identify a mutant hemoglobin using any of the above techniques. DNA analysis can be useful to identify the mutant hemoglobin by determining the type of mutation and the gene it affects (e.g., α - or β -globin genes).

Neonatal screening

Early diagnosis facilitates parental education and the introduction of preventive vaccination and antibiotic programs. Universal neonatal screening is now undertaken in many American states and in the UK. It is performed using a blood spot technique from a heel-prick, often when blood is taken for inherited metabolic disease screening. Blood can be taken by direct venipuncture or by umbilical cord blood sampling. The latter may give inaccurate results if contaminated by maternal blood and is least favored.

Surgery and sickle cell disease

Patients with SCD may require surgery because of the complications associated with this disease, e.g., gallstones and avascular necrosis of the femoral head, or for completely unrelated complaints. Surgery and general anesthesia in SCD are not without complications. Early reviews reported a perioperative mortality rate of 10% and a postoperative complication rate of up to 50%.²⁶ This was due, at least in part, to anemia, an increased tendency for red cells to sickle because of hypoxia and hypoperfusion, and because of the complications of SCD such as renal impairment and pulmonary disease. The cooperative study of surgery and anesthesia issued its findings in 1995 for the period 1978–88, during which 1079 surgical procedures were performed on 717 patients. Cholecystectomy and splenectomy accounted for 24% of all surgery; 93% of the patients had preoperative blood transfusion. The overall mortality rate within 30 days of surgery was 1.1% but no death was reported in patients under the age of 14 years. Sickle complications were more likely to occur with regional than with general anesthesia.²⁷ A more recent study

of laparoscopic versus open splenectomy or cholecystectomy in children found that acute chest syndrome (ACS) occurred in 20% of cases. Importantly, laparoscopic surgery did not reduce the incidence of complications and was associated with a longer operating time.²⁸ Another study found that a history of pulmonary disease identified patients at risk for sickle-related events following adenotonsillectomy.²⁹

It was accepted for many years that blood transfusion was a necessary prerequisite for all but the most minor of surgical or anesthetic procedures. The aim was to reduce the percentage of sickle hemoglobin to 30% in order to reduce the ability to sickle and to correct anemia.²⁶ Blood transfusion could be administered by two methods: exchange transfusion or by giving a number of transfusions over a period of weeks. Some centers adopted a more conservative approach and transfused to correct anemia without aiming to reduce the HbS level. In 1988 a multicenter study was commenced to address the question of perioperative care and to attempt to define whether aggressively transfusing to achieve an HbS level under 30% or simple 'top-up' transfusion was the best transfusion policy. The necessity of administering blood was not addressed. The results demonstrated that chest syndrome developed in 10% of patients and resulted in two deaths (0.33%), but the frequency of serious complications was similar in both transfusion groups (30%) and the incidence of transfusion-related complications was greater in the group aggressively transfused to HbS < 30%. It was concluded that simple transfusion to a hemoglobin level of 10 g/dL was as effective as aggressive transfusion.²⁶ In the case of HbSC, a study of outcomes demonstrated that individuals undergoing abdominal surgery without transfusion had a sickle-related complication rate of 35%, whereas those who received transfusion preoperatively had no sickle-related complications. This prompted the recommendation that individuals with HbSC undergoing abdominal surgery should receive blood transfusion but that transfusion was not necessary for simple procedures such as myringotomy.³⁰ New understanding of the pathophysiology of SCD and newer anesthetic techniques suggests that blood transfusion may not always be necessary. A randomized controlled trial comparing 'top-up' transfusion to no transfusion is long overdue.

Irrespective of the decision to transfuse or not, there are some simple precautions that are applicable to every child undergoing surgery.

- Ensure that the child is well hydrated for a minimum of 8 hours prior to surgery. Intravenous hydration should continue during and following surgery.
- Ensure that he/she remains adequately oxygenated during and following the procedure using supplemental oxygen. Some centers have used positive airway pressure for those undergoing abdominal surgery but most children find this unacceptable when fully awake.
- Ensure that the surrounding ambient temperature is adequate at all times.

- Intraoperative monitoring should include temperature, blood pressure, electrocardiographic features and oxygen levels. Postoperatively, blood pressure and oxygen levels (with pulse oximetry) should continue to be monitored.

- Incentive spirometry and physiotherapy should be undertaken once the child is awake.

Some surgical procedures require the use of a tourniquet. Logically, this should create a static reservoir of sickled red cells, because of the hypoxic and acidotic conditions, which can be released back into the system when the tourniquet is removed.^{22,23} Some have advocated prior exchange transfusion to reduce the potential risk.²³ In practice the use of a tourniquet does not appear to cause problems.^{31,32}

years.^{33–36} It is suggested that weight deficit tends to be greater than height deficit.³³ The Jamaican cohort study found that differences in weight between infants with HbSS and HbAA had emerged by the first year of life and reached significance in girls at 12 months and boys by 21 months.³⁷ There is a 1–2 year delay in sexual development and bone age may be delayed by as much as 4 years.^{23,34} Most individuals will attain their expected height centile by adulthood but weight may remain below the appropriate growth centile.²² Specific height and weight growth reference curves have been derived for children with SCD aged 0–18 years in order to identify coincidental growth problems.³⁸ No specific endocrine abnormality has been identified in individuals with SCD.

Children with SCD have increased resting energy expenditure, possibly due to anemia and increased cardiac output and this may contribute to poor growth.³⁹ It has also been suggested that these children may have increased protein requirements and are at risk of protein-energy malnutrition. They have marked reductions in fat-free mass and reduced body fat, indicating reduced energy stores.⁴⁰ Interventional studies will be necessary to determine if increased nutritional support can increase body habitus in those with SCD.

Plasma zinc levels are low in adults with symptomatic SCD and urinary loss of zinc is increased. Zinc deficiency reduces helper T cells and cell-mediated immunity. Zinc supplementation has been reported to improve sexual development and growth.⁴¹ It has also reduced the number of bacterial infections, hospitalizations and vasoocclusive episodes.⁴² Nevertheless, routine zinc supplementation has not gained popularity.

Contraception and pregnancy

There is no evidence to suggest that there is an increased risk of infertility in females with SCD. Oral contraceptive agents can be recommended when requested and there is no evidence that they are more hazardous to women with SCD.⁴³ Depot progestogens are a useful alternative for those who cannot take oral preparations. Intrauterine contraceptive devices have an increased risk of uterine and tubal infection and should be used with caution.⁴⁴

The risk of spontaneous miscarriage was reported to be as high as 25% in the past but now appears to be similar to that of the normal population.^{43–45} The incidence of intrauterine growth restriction may be as high as 21% and may be explained by maternal anemia and placental insufficiency from vascular occlusion and fibrosis.^{44,46} Perinatal mortality rates are increased and range between 1 and 8% in the USA and UK, whereas in Africa they are as high as 12–19%. Hypertension and preeclampsia may complicate up to one-third of all pregnancies and an increase in maternal mortality rates for women with SCD is reported.⁴⁴ There is an increased rate of urinary tract infection; urine analysis should be undertaken at least monthly and positive results treated

aggressively. Anemia may be exacerbated and a drop in hemoglobin of more than 20% may necessitate simple 'top-up' transfusion.⁴³ ACS, painful crises and cerebrovascular events have all been reported but the incidence does not appear higher than in the nonpregnant state. There is no proof that prophylactic blood transfusion alters pregnancy outcome and it should be reserved for those patients with a prior history of perinatal mortality, and those with preeclampsia, ACS, new neurologic event, severe anemia and twin pregnancy.⁴³

Infection

The rate of pneumococcal infection is 30–100 times that of normal children and it has been one of the commonest causes of death in children under 5 years of age.⁴⁷ All children with SCD have splenic dysfunction, irrespective of spleen size, and complete dysfunction has developed in most children with HbSS by 2 years of age.⁴⁷ This causes increased susceptibility to encapsulated organisms such as *Streptococcus pneumoniae* (pneumococcus), *Haemophilus influenzae*, and *Neisseria meningitidis*. The National Institutes of Health (NIH) cooperative study of SCD found that 66% of infections in children under 6 years old were due to pneumococcus, whereas 50% of infections in children over 6 years old were caused by Gram-negative organisms. *Escherichia coli* was responsible for 73% of urinary tract infections and *Salmonella* species caused 77% of cases of osteomyelitis.^{48,49} A Jamaican study confirmed these findings and suggested that *H. influenzae* was also predominantly found in children less than 5 years of age, whereas *E. coli* and *Klebsiella* species predominated in children over 10 years of age. In this study, *E. coli* was found almost exclusively in girls.⁵⁰ *Mycoplasma* species may be responsible for up to 16% of ACS cases and *Chlamydia pneumoniae* has also been implicated as a causative agent in others.⁴⁷

Other types of immunologic dysfunction have been noted in children with SCD. There are decreased opsonin levels, which normally promote phagocytosis.^{23,47} The alternative pathway of complement activation is also found to be defective by some investigators⁵¹ though not by others.^{52,53} Abnormal neutrophil kinetics have been noted, with a decrease in marginating pool numbers in favor of increased numbers in the circulating pool, reducing the half-life of the neutrophil.⁵⁴ It is also suggested that cellular immunity, T-helper cell function and interleukin-2 production is adversely affected by zinc deficiency, common in SCD, and that zinc supplementation reduces the incidence of infection.⁴²

Management of infection

Prophylaxis (Table 10.6)

Penicillin prophylaxis should be commenced in the newborn period and continued for at least 5 years. The PROPS II study of 400 children aged 5 years randomized to receive penicillin

or placebo demonstrated no significant difference after 3 years follow-up provided that there was no history of prior pneumococcal infection or splenectomy.⁵⁵ Nevertheless, some clinicians continue penicillin prophylaxis beyond the age of 5 years. An alternative (but unproved) approach for children over 5 years old would be to commence penicillin at the onset of fever, theoretically providing some treatment while the child is on the way to the doctor.⁵⁶ The British Committee for Standards in Haematology (BCSH) guidelines for those with a hyposplenic state suggest that penicillin prophylaxis should continue for life. Those with penicillin allergy should receive erythromycin twice daily.⁵⁷

Pneumococcal vaccination should be administered from 2 months of age. The pentavalent conjugated pneumococcal vaccine (CPV) Prevenar is suitable for children under 2 years. The polyvalent (23-valent) polysaccharide pneumococcal vaccine (PPV) Pneumovax is recommended at 24 months of age. There is no consensus as to whether a further PPV booster should be given and, if so, when and for how long, but a recent study suggested that PPV was 80% effective within 3 years of vaccination and that children with SCD of all ages may benefit from PPV boosted with CPV.⁵⁸ Another study demonstrated higher IgG pneumococcal antibody concentrations when CPV and PPV were given as a combination 2 months apart.⁵⁹ The BCSH guidelines are quite clear and recommend 5-yearly PPV boosters for life.⁵⁷

Hepatitis B vaccination is now a routine practice in many centers and may be commenced at 2 months of age. Influenza should be administered yearly as viral influenza can cause severe morbidity in individuals with SCD.

Acute management

Most antibiotic therapy is commenced empirically before culture reports are available. Empiric antibiotic cover should aim to treat pneumococcal and *H. influenzae* infections. A child with chest infiltrates should, in addition, receive antibiotics that will treat *Mycoplasma* and *Chlamydia* species. Urinary tract infections should be treated with antibiotics that cover Gram-negative organisms. Treatment of osteomyelitis and septic arthritis requires antibiotics specific for *Salmonella* and *Staphylococcus aureus*. If a child has recently returned from Africa and has fever and diarrhea, typhoid fever should be considered.

Parents and clinicians should be aware that a temperature over 38.5°C in a child with SCD should be treated as an emergency. The child should have a full blood profile, cultures (blood, urine and throat), oxygen saturations and possibly chest radiography performed (see Table 10.6). Other investigations, such as lumbar puncture, should be performed if there is evidence of meningitis. Periosteal or joint aspiration should be undertaken if there is evidence of osteomyelitis or septic arthritis.⁶⁰

Anemia

The first four cases of SCD reported in the literature described anemia and jaundice, consistent features of HbSS. Homozygous SCD is a hemolytic disease. The mean red cell survival time is about 12 days. The rate of hemolysis is determined by the degree of HbS polymerization, the number of irreversibly sickled cells, gender and the presence of α^+ -thalassemia.⁶¹ Vigorous exercise also increases the hemolytic rate.⁶² The usual hemoglobin level for those with HbSS is 6–9 g/dL.²³ The individuals are usually asymptomatic at these levels because of a right-shift in the oxygen dissociation curve due to HbS that enhances oxygen delivery to the tissues.²²

When patients are well, the hemoglobin deviates very little and a falling hemoglobin may signify the early onset of renal failure.²³

An acute precipitous drop in hemoglobin can occur in SCD and lead to cardiac failure and death. There are three main reasons for this: acute splenic sequestration (discussed later in this chapter), hyperhemolysis or parvovirus B19 infection.

Hyperhemolysis

Accelerated hemolysis can occur in association with an acute sickle event, most commonly due to infection and ACS.⁵⁶ It is associated with an increased reticulocyte count above baseline values. Malaria can cause severe life-threatening hemolysis and should be considered if there is a history of travel to malaria zones. A sudden unexpected fall in hemoglobin in an individual who has recently received a red cell transfusion should raise the possibility of a hemolytic transfusion reaction and appropriate investigations are required. Glucose 6-phosphate dehydrogenase deficiency often occurs in children with SCD but there is little evidence that it contributes to anemia.

Parvovirus B19

This infectious agent causes profound anemia because of a direct cytotoxic effect on the erythroid precursors, although occasionally other progenitors are also affected. The normal lifespan of a red cell in SCD is much shortened as previously described and any cessation in erythropoiesis will have a marked effect. The patient may have signs of fever, upper respiratory tract infection and/or gastrointestinal symptoms. The reticulocytopenia begins 5 days after exposure and can last 7–10 days. Exacerbation of the anemia occurs shortly after the onset of reticulocytopenia. In the recovery phase patients may be thought to have a hyperhemolytic event because of the association of anemia with a massive reticulocytosis. The diagnosis can be made by measuring parvoviral IgM levels, which will be positive, or by identification of the virus using polymerase chain reaction. There is no recorded case of parvoviral reinfection and protective immunity appears lifelong.^{56,63}

Vasoocclusive events

Most patients with homozygous SCD will experience a painful vasoocclusive event at some point in their life. The degree of severity of disease varies from patient to patient and is only partially explained by HbF levels and other known disease modifiers (see Table 10.2). Vasoocclusive episodes account for over 90% of all emergency hospital admissions and will most likely result in the patient's death either because of acute organ failure or chronic organ damage.^{11,64} Factors that may precipitate sickling and vasoocclusion include

Fig. 10.1 Periosteal reaction, medullary expansion and inflammation in first to fourth metatarsal bones and focal lucency at the head of the third and fourth metatarsal bones in a boy aged 14 months with recurrent dactylitis.

hypoxia, dehydration and cold weather (see Table 10.1).⁵ The following sections detail the organ systems involved either acutely or chronically and give some suggested management strategies.

Bone and joints

Acute problems

Dactylitis (hand–foot syndrome)

Dactylitis is caused by vasoocclusion and necrosis affecting the bone marrow and inner third of the cortex of the small bones of the hands or feet.²³ It occurs most frequently in children aged 6 months to 2 years old. It presents as an acute painful swelling of the dorsum of the hands or feet and extends into the fingers and toes. It is usually associated with fever. It can take at least 1 week to resolve and tends to recur. Radiologic bone abnormalities may take 2 weeks to appear and include periosteal reaction, translucency or opacity of the diaphysis, and occasional bone loss (Fig. 10.1).⁶⁵ Recurrent events can lead to bone deformity or early fusion of the epiphysis resulting in shortened digits. It is suggested that an episode of dactylitis in the first 2 years of life may predict severe manifestations of SCD in later life.¹² Infection should be considered if the symptoms and signs do not resolve with conservative management.

Bones and joints

The common sites of infarction are the spine, pelvis and long bones. Affected vertebrae may exhibit a ‘codfish’ appearance due to collapse of the endplates. The commonest long bones affected are the humerus, tibia and femur.⁶⁶ The distal segment between the diaphysis and metaphysis is most often

involved in children less than 10 years old and there may be local tenderness, warmth and swelling with impaired movement of the adjacent joint.^{23,56} Often the pain is more diffuse and nonspecific and is due to bone marrow infarction and necrosis. The child is often pyrexial and a leukocytosis is usually present, probably due to the underlying inflammatory response. The pain may last several days.

Management

Warmth, hydration and adequate pain relief are the cornerstones of management. Small children may require only non-steroidal antiinflammatory drugs (NSAIDs) whereas older children may also require opiate analgesia (see section on pain management). If the pyrexia persists, particularly if it is associated with fluctuant swelling, osteomyelitis or septic arthritis should be considered.

Chronic bone disease

Osteonecrosis or avascular necrosis (AVN) is painful and disabling. It can occur with all types of SCD but is most common in those with HbSS/ α -thalassemia. The incidence is 2.5 per 100 patient-years for hip and shoulder joints, and AVN of the femoral head has been described in children as young as 5 years of age. The median age of diagnosis among African-Americans is 28–36 years,⁶⁷ among Jamaicans the median age of onset is 20 years,⁶⁸ while among Nigerians the mean age of onset is 13.7 years.⁶⁹ Of those with shoulder disease, 75% will also have hip disease.^{69,70} Shoulder disease can be asymptomatic but hip disease may present acutely with symptoms suggestive of septic arthritis or may have a more insidious course with pain and limitation of movement. The course from early disease to collapse of the femoral head can be as short as 2 years. The cause of AVN is unclear but may be due, in part, to microinfarction of the cancellous bone.²² Plain bone radiographs are normal in early disease but magnetic resonance imaging (MRI) may show bone and bone marrow necrosis. Some evidence suggests that core decompression early in the course of the disease may halt the progression of necrosis at least in the short term and relieve pain and loss of function.^{71,72} Ultimately, joint replacement is usually needed but because these have a limited lifespan and will need to be revised, their use in teenagers and young adults should be postponed if possible. This makes MRI surveillance and early intervention with core decompression an attractive option.

Abdomen

Acute splenic sequestration

Acute splenic sequestration is a major cause of mortality in children with SCD. The mortality rate for a first event was 12% in a Jamaican series and 20% for those with recurrent disease.⁷³ It is caused by intrasplenic trapping of red cells and is defined as a hemoglobin decrease of at least 2 g/dL associated with a markedly elevated reticulocyte count and acutely

enlarging spleen.⁵⁶ The attacks are often associated with viral or bacterial infection. Recurrent splenic sequestration is common and occurs in at least 50% of those who survive the first episode.⁷³ Sequestration can occur in children as young as 5 weeks but is seen most often in children between the ages of 3 months and 5 years. We have noticed splenic sequestration occurring in children as old as 10 years who are receiving disease-modifying therapy such as chronic blood transfusion or hydroxycarbamide, possibly because these treatment modalities delay splenic fibrosis. It is also reported in older children and adults with HbSC and HbSS/ β^+ -thalassemia.^{74,75}

Management

Early diagnosis is important and parental instruction in abdominal examination and the detection of splenomegaly has become one of the cornerstones of management.⁷⁶ The treatment of splenic sequestration is directed towards the correction of hypovolemia with blood transfusion. The aim of transfusion is to raise the hemoglobin to 7 g/dL; however, as some of the red cells sequestered in the spleen will be released as the spleen regresses, the final hemoglobin will often be higher than predicted on the basis of the volume of red cells administered.⁷⁷

Recurrence may be prevented by splenectomy or perhaps by chronic transfusion. We have not found chronic transfusion to be effective even when the HbS level is less than 20%. Kinney *et al.*⁷⁸ have reported similar findings in patients receiving blood transfusion whose HbS was less than 30%. A study by Wright *et al.*⁷⁹ found that mortality or bacteremic episodes did not differ between children post splenectomy and a control group and recommended that splenectomy should not be deferred due to concerns about infection risk. However, the recommendations of the NIH are that patients who have life-threatening splenic sequestration requiring transfusion should have a splenectomy shortly after the event or be placed on a chronic transfusion program. Further recommendations are that children less than 2 years who have had a severe episode should be placed on chronic transfusion to keep the HbS below 30% until splenectomy can be considered over the age of 2 years.⁵⁶

Abdominal painful crisis

This is a term used to describe any complication in which abdominal pain is prominent and not caused by any other obvious intraabdominal pathology.²³ It usually affects younger children. The pain may be mild and transient to severe and generalized, sometimes with features of intestinal obstruction. Radiologic investigation has, in some cases, found a localized nonfunctioning segment of bowel that recovers function after 3–4 days of conservative management,²³ but often there is no discernible cause.

Hepatic sequestration

This is a rare condition in children and is analogous to splenic

sequestration. It is recognized by rapid hepatic enlargement in association with a falling hemoglobin and rising reticulocyte count. The bilirubin level increases and alkaline phosphatase may also be elevated. The transaminases may be normal. Exchange transfusion is recommended because of the risk of hyperviscosity with simple transfusion.⁸⁰

Acute hepatic necrosis

Acute hepatic necrosis and failure can occur in the absence of viral liver disease and in association with other sickle cell-related vasoocclusive events. Exchange transfusion can bring about a rapid improvement in clinical and biochemical parameters.⁸¹

Gallstones

There is an increased incidence of gallstones in individuals with SCD. They may develop before the age of 4 years and have been reported in 17–33% of patients aged between 2 and 18 years and in over 50% of the adult population.⁸² Coexistent α -thalassemia decreases the chance of developing gallstones, possibly because it reduces the rate of hemolysis.⁸³ Fever, nausea, vomiting and abdominal pain are nonspecific features of cholecystitis and careful evaluation is necessary to exclude other potential causes, as gallstones are not always symptomatic. Laparoscopic cholecystectomy is the treatment of choice for symptomatic gallstones.⁵⁶

Renal manifestations

The environment of the renal medulla is hypoxic, acidotic and hypertonic, all of which promote HbS polymerization. This makes the medulla particularly susceptible to injury.⁸⁴

Hyposthenuria, an inability to concentrate urine properly, is the commonest renal abnormality. It may present with enuresis, often at night. It also makes individuals with SCD more susceptible to dehydration than normal individuals.⁸⁵ Other abnormalities frequently found include impaired renal acidification, decreased potassium secretion and hematuria.⁸⁶ Hematuria occurs most often in males and is usually unilateral, arising from the left kidney in 80% of cases.

Proteinuria is an early manifestation of sickle nephropathy and affects at least 6% of children with SCD. It is associated with lower hemoglobin concentrations, higher mean corpuscular volume and higher white cell counts.⁸⁷ The nephrotic syndrome is estimated to occur in 4% of patients with SCD and renal failure seems virtually inevitable once nephrotic syndrome intervenes.⁸⁸ Angiotensin-converting enzyme (ACE) inhibitors decrease urinary protein excretion and may delay the onset of nephropathy.⁸⁹

Renal failure

Acute renal failure has been reported in 10.3% of patients hospitalized with SCD.⁹⁰ It can arise as a result of dehydration during a sickle cell crisis or secondary to rhabdomyolysis,

sepsis and drug nephrotoxicity. Rhabdomyolysis is a common finding in patients who develop multiorgan failure syndrome (i.e., renal, pulmonary and hepatic failure) during a painful vasoocclusive episode but it may respond dramatically to aggressive red cell exchange.⁹¹

The overall prevalence of chronic renal failure in SCD is about 4.5% and is age related. Predictors of chronic renal failure include hypertension, proteinuria, hematuria, increasingly severe anemia, nephrotic syndrome and inheritance of the Bantu phenotype.⁹² Factors that may slow disease progression include avoidance of NSAIDs, use of ACE inhibitors and control of hypertension. Renal transplantation is an appropriate form of renal replacement in those with end-stage renal disease. Patient and graft survival results are comparable to those obtained in other groups of patients.⁹³ However, recurrence of hyposthenuria and nephropathy after transplant has been described.

Priapism

Priapism is a sustained, painful, involuntary erection and is a well-recognized complication of SCD. It is due to vasoocclusive obstruction to venous drainage of the penis. It is classified as 'prolonged' if it lasts more than 3 hours and 'stuttering' if it lasts more than a few minutes but less than 3 hours and resolves spontaneously. Stuttering priapism may recur and become prolonged. Prolonged priapism is a urologic emergency. Recurrent prolonged episodes ultimately lead to fibrosis and impotence. It may affect more than 30% of males with SCD. Recently, polymorphisms in a gene (*KLOTHO*) that regulates endothelial growth factor expression and endothelial nitric oxide release has been implicated in the etiology of priapism.⁹⁴ The mean age at the time of the initial episode has been reported as 12 years and the probability of experiencing priapism by the age of 20 years was 89%.⁹⁵

Management

The patient should attempt to urinate as soon as the priapism begins and take extra fluids and analgesia. If the priapism lasts longer than 2 hours, the patient should be encouraged to seek medical attention. Conservative management includes analgesia, hydration, anxiolytic therapy and possibly exchange blood transfusion. This is usually effective in young children and should be tried first. If the penile shaft fails to soften, then aspiration and irrigation of the cavernosa may be successful. Early surgical intervention is necessary in adults as medical treatment is less successful.⁵ Shunting may be necessary to prevent recurrent episodes. Recently, an oral α -adrenergic agent, etilefrine, has been found effective in preventing recurrence.^{96,97} There is anecdotal evidence that hydroxycarbamide may prevent priapism but further studies are needed.⁹⁸

Leg ulcers

Between 10 and 20% of individuals with SCD will develop painful indolent leg ulcers usually over the lateral or medial malleolus. Occasionally they are found on the dorsum of the foot or over the tibia. They can be single or multiple. Some will heal quickly whereas others may be present for years.

There is no definitive treatment for leg ulcers. The area should be kept clean and infection treated promptly. A variety of dressings have been tried and no single one has shown superiority. Intravenous arginine butyrate has produced rapid healing of ulcers,⁹⁹ but a role for hydroxycarbamide seems unclear because it is implicated in ulcer formation in patients with myeloproliferative disease.¹⁰⁰

Pulmonary manifestations

Acute chest syndrome

ACS is the second most common cause of hospitalization in patients with SCD and is responsible for 25% of deaths.¹⁰¹ The incidence ranges from 24.5 events per 100 patient-years in young children to 8.8 events per 100 patient-years in older adults. Fever, cough, chest pain and pulmonary infiltrates on chest radiography are the common presenting features and the condition may rapidly progress to life-threatening respiratory insufficiency and total 'white out' on chest radiographs (Fig. 10.2).²¹ The most common etiologic factors are infection, pulmonary fat embolism or pulmonary infarction but it may be multifactorial. The commonest infective organisms isolated in children are virus, *Mycoplasma pneumoniae* and *Chlamydia pneumoniae*. Pulmonary infarction is the sole cause of ACS in 20% of cases but is a major factor in all events.¹⁰¹ Factors influencing the frequency of ACS include the degree of anemia, low HbF levels, high steady-state white

Fig. 10.2 Right midzone and basal infiltrate in a boy aged 5 years with acute chest syndrome.

cell count, younger age group, seasonal variation (especially in the young) and bronchoreactive lung disease. Higher hemoglobin levels and winter season increases the frequency of episodes. Bronchoreactive lung disease is common in individuals with SCD and is present in 43% of children during the steady state. It often worsens during ACS and may contribute to progressive lung injury.^{101,103} Hemoglobin levels may drop by at least 1 g/dL during the event and the white cell counts double. A platelet count of less than $200 \times 10^9/L$ is a strong predictor of morbidity and mortality.¹⁰¹ The patient may become more unstable during the first few days following admission; 15% of all patients require intubation and the average mortality rate is 3%, rising to 9% in those over 18 years of age.

Management

Supplemental oxygen should be administered to those whose oxygen saturation is less than 95%. Hydration is important but overhydration can worsen the condition. Adequate pain relief should be administered but oversedation avoided. Incentive spirometry has been shown to be beneficial in the prevention and management of ACS. Airways hyperreactivity is treated with bronchodilators. Intravenous broad-spectrum antibiotics including a macrolide or quinolone should be administered. Top-up blood transfusion, to achieve a final hemoglobin of 10 g/dL, has been shown to be effective in children with ACS and should be administered if there is evidence of hypoxemia.^{56,104} In severe cases exchange transfusion may be necessary. Mechanical ventilation may be necessary for those with life-threatening respiratory failure and use of extracorporeal membrane oxygenation may be beneficial.¹⁰⁵ Dexamethasone and inhaled nitric oxide also show promise but further study is necessary to determine their role.^{106,107}

Chronic pulmonary disease

Chronic pulmonary disease is a disease of adults with SCD and affects up to 32% of patients.¹⁰⁸ The true incidence is unknown as the early stages of disease are asymptomatic. The etiology is multifactorial and includes lung damage from ACS, chronic oxygen desaturation or sleep hypoventilation, repeated episodes of thromboembolism, and hemolytic anemia-associated pulmonary hypertension due to reduced nitric oxide/arginine levels.^{56,101,109} Survival for those with symptomatic sickle cell-related pulmonary hypertension appears to be shorter than for those with primary pulmonary hypertension, with reports suggesting a 2-year mortality of 50% compared with a 2.8-year median survival for those with primary pulmonary hypertension.¹¹⁰ The HbF level, white cell or platelet count and the use of hydroxycarbamide appears unrelated to the development of pulmonary hypertension.¹⁰⁸ A recent study of infants aged 3–30 months found evidence of early abnormal lung function in those with HbSS

that had a possible relationship to airways reactivity.¹¹¹ This suggests that the injury which culminates in later pulmonary damage may begin at a very early age and may require early intervention if progression is to be halted. The HUG-Infant trial may give some information on the role of hydroxycarbamide as an early intervention strategy. The use of arginine supplementation may also be of benefit.¹¹²

Cerebrovascular disease

Stroke

Children with SCD have a 200-fold increased risk of stroke, with a prevalence rate of 11%.^{113,114} The incidence of ischemic stroke is highest in children aged 1–9 years, whereas intracranial hemorrhage is most common in adults. Cerebral infarction may occur as a result of fibrous proliferation of the intima affecting the distal internal carotid, proximal middle cerebral artery and the proximal anterior cerebral artery. This leads to vasooclusion and the development of collaterals.¹¹⁵ Patients with a history of stroke typically have infarcts in the cortex and deep white matter. The patterns of infarction include wedge-shaped lesions of large-vessel territories, border zone infarctions particularly of the middle cerebral artery territory, and small punctate lesions of the deep white matter.¹¹⁶ High white cell count, low hemoglobin levels, and recent episodes of ACS have all been associated with high risk of infarction.¹¹⁵ Specific HLA types (DPB1*0401, A*0102, A*2612) may also be associated with small- and large-vessel stroke but further evaluation is required to confirm this preliminary finding.¹¹³

Management

The child should undergo evaluation with computed tomography or MRI to determine the cause of the neurologic deficit. Intravenous hydration should be given. Exchange blood transfusion should be undertaken as soon as possible, aiming to reduce HbS to less than 30%. This usually requires a one-volume exchange. A chronic transfusion program should be instituted to maintain HbS less than 30% as studies have shown that untransfused patients have a stroke recurrence rate as high as 70% whereas it is about 10% in a transfused group of patients.²² The duration of a chronic transfusion program is unclear as strokes have recurred when transfusions have stopped even after 5–12 years of therapy.¹¹⁷ Recently, it has been suggested that hydroxycarbamide overlapping blood transfusion for some months and then continued alone may be an alternative to blood transfusion for long-term stroke prevention.^{118,119}

Prevention

Transcranial Doppler ultrasonography (TCD) measures blood flow through intracranial blood vessels. Blood flow velocity is higher through stenotic vessels. The STOP study

screened patients with HbSS and HbS/ β^0 -thalassemia, aged 2–16 years, using TCD. Time-averaged mean velocities were measured in the middle cerebral, distal internal carotid and anterior cerebral arteries. Flow rates of 200 cm/s were considered abnormal. Those with abnormal flow were randomized to a blood transfusion group, aiming to keep HbS below 30%, or an observation group. After 24 months, 10 cerebral infarctions had occurred in the observation group compared with only one in the transfusion group and the study was closed.¹¹⁹ This has led to the recommendation that all children aged 2–16 years be screened by TCD and chronic transfusion strongly considered if abnormal.⁵⁶

Silent infarction

MRI has identified silent infarcts in at least 17% of children who have not had a clinical stroke.¹²¹ These children perform poorly on psychometric testing and are educationally disadvantaged.¹²² A multivariate analysis identified low pain event rate, leukocyte count above $11.8 \times 10^9/L$, the Senegal sickle haplotype and a previous history of seizures as risk factors for silent infarction.¹²¹ Silent infarcts are prominent in children under 4 years, with a possible incidence of 11%.¹²³ Those children with abnormal TCD and MRI seem at increased risk of stroke or new silent infarction and chronic transfusion appears to reduce this risk.¹²⁴ However, the relationship between abnormal TCD and silent infarction is not clear. Wang *et al.*¹²³ demonstrated that of the 17 patients they identified as having silent infarction, only four had abnormal TCD and one had a conditional result.¹²³ Further study is required to confirm the preliminary data that blood transfusion has a role in the management of silent infarction, particularly in those with normal TCD. Recently it has been suggested that nocturnal hypoxemia may also have a role in the development of cerebral events and it is suggested that screening for, and management of, this problem may be an effective alternative to prophylactic blood transfusion.¹²⁵

Eye disease

Sickle cell vasoocclusion can affect the vascular bed within the eye, often with devastating consequences. There are two main types of eye disease described in SCD: nonproliferative and proliferative disease.

Nonproliferative disease

Conjunctival vascular occlusions are more marked in HbSS and HbS/ β^0 -thalassemia and consist of sacular or multiple short comma-shaped capillary segments often packed with red cells.²³ Iris atrophy can occur as part of a more generalized anterior segment ischemia or as an isolated finding with papillary irregularity and white patches on the iris. Other findings include retinal pigmentary changes, abnormalities of the retinal vasculature, macula, choroids and optic disk.

They are apparent by ophthalmoscopy but rarely have visual sequelae.⁵⁶

Proliferative disease

This is more common in those individuals with HbSC disease and affects 5–10% of all those with SCD. It involves the growth of abnormal vascular fronds, most likely due to peripheral retinal arteriolar occlusions and ischemia stimulating angiogenesis.⁵⁶ They can vary from small vessel loops to large complex lesions occupying a large segment of the retinal periphery.²³ It can occur as early as 8 years of age and affects males more frequently than females.²³ Sudden blindness may occur because of vitreous hemorrhage and from mechanical traction created by chronic enlarging fibrovascular retinal membranes.⁵⁶

Management

All children with sickle cell hemoglobinopathies should have yearly dilated eye examination carried out by an ophthalmologist experienced in retinal disease. Any individual who experiences a change in vision should have an immediate ophthalmologic consultation. Treatment is usually reserved for those with proliferative retinopathy and consists of laser photocoagulation or cryotherapy to induce regression of the neovascular tissue. Surgery is required for retinal detachment or nonresolving vitreous hemorrhage.⁵⁶

General management strategies (Table 10.6)

The management of acute sickle events includes rapid assessment that should include blood pressure and pulse oximetry measurements. Blood testing is usually required as many children appear well even if they have increasing anemia. Blood testing should include full blood count, reticulocyte estimation and blood film. Blood chemistry measurement of urea, sodium, potassium, creatinine and bilirubin may be useful. Blood, urine and throat cultures are required if the child has a fever and chest radiography can be useful as early chest syndrome may have few clinical signs. Intravenous hydration is often required but 0.9% 'normal' saline is best avoided because of the large salt load. Dextrose 5% or dextrose 2.5% + 0.45% saline are preferred options. Broad-spectrum antibiotics are commenced in ill pyrexial children. Macrolide antibiotics are added for those with chest signs and other specific antibiotics should be considered depending on the clinical presentation.

Blood transfusion can be life-saving. It should be considered if the hemoglobin level falls below 6 g/dL. Simple 'top-up' transfusion restores blood volume in acute splenic sequestration and improves oxygenation in ACS with evidence of hypoxemia. Exchange transfusion is of benefit in severe chest crisis, stroke or transient ischemic episode, and acute hepatic sequestration or hepatic necrosis. Exchange

transfusion should be considered for prolonged unresolving priapism in children. The blood given should be fully ABO, Rhesus and Kell matched as a minimum requirement. All children with SCD should have extended red cell phenotyping undertaken when they are older than 6 months of age. Administration of phenotypically matched red cells will reduce the incidence of alloimmunization.

Pain management

Recurrent episodes of acute severe pain are the hallmarks of SCD. Different individuals have different mechanisms for dealing with pain and pain perception depends on a series of poorly understood interactions between physical and psychologic factors. A formal pain assessment should be made using one of the pain assessment tools appropriate to the patient's age and cognitive abilities, e.g., Wong-Baker Faces Pain Rating Scale. Initial management should be aimed at providing rapid and adequate pain control, which should be maintained using parenteral or oral analgesia. Provision for extra bolus analgesia should be made for breakthrough pain. Analgesia is administered using a 'step-up analgesic ladder' template, starting with paracetamol (acetaminophen) and NSAIDs (if not contraindicated by liver or renal disease) for mild pain, moving on to a mild opioid in addition to NSAIDs and paracetamol, and finally for severe pain a strong opioid is given with NSAIDs.¹²⁶ Antiemetic medication and laxatives should be prescribed with opioids. Adjunctive therapy, including massage, distraction and anxiolytic medication, may be beneficial. Pain score, blood pressure, pulse, respiratory rate, oxygen saturation and level of consciousness should be monitored regularly.

Long-term surveillance strategies

It has been suggested that many of the individuals who develop multiorgan failure had, for most of their lives, been considered to have mild SCD.¹¹ The surveillance regimen suggested here is designed to allow early identification of organ dysfunction. The specific pathophysiology in many cases remains unclear but it is hoped that early therapeutic intervention can halt disease progression. Controlled clinical trials are required in many cases to determine the most appropriate treatment modalities.

Long-term therapeutic options

Blood transfusion

Acute indications for blood transfusion are discussed above. The role of chronic blood transfusion is to suppress endogenous red cell production and reduce HbS to less than 30%. Red cells that are leukocyte depleted and phenotypically matched for Rhesus, Kell and Duffy antigens are usually

administered every 3–4 weeks. Indications for chronic transfusion therapy include:

- primary stroke prevention in those with abnormal TCD;
- secondary stroke prevention;
- anemia associated with chronic renal failure;
- severe debilitating pain;
- complicated pregnancy (twin or previous fetal loss).

Possible indications for chronic transfusion therapy include:

- silent infarction;
- splenic sequestration while awaiting surgery;
- priapism;
- pulmonary hypertension.

Blood transfusion is not without complication and the benefits of transfusion must be weighed against these complications. Acute transfusion reactions may occur. Alloimmunization can occur in 30% of patients and antibodies to K, E, C and Jkb accounted for 82% of alloantibodies in one study.¹²⁷ Delayed hemolysis can occur 6–10 days following transfusion and can mimic or precipitate an acute sickle event. The direct Coombs test is usually negative but hemoglobinuria is a frequent finding.¹²⁸ The risks of viral transmission have diminished with improved blood banking procedures, although there is a new and as yet poorly defined risk of prion transmission. Iron overload is a definite risk with prolonged transfusion therapy. Iron stores must be monitored, usually by measuring serum ferritin, and iron chelation instituted once ferritin levels exceed 1000 ng/mL.⁵⁶

Hydroxycarbamide

Hydroxycarbamide is a ribonucleotide inhibitor that impedes DNA synthesis by preventing the formation of deoxyribonucleotides. All the mechanisms of action in SCD have not been fully elucidated but some properties have been noted. It increases HbF levels and reduces neutrophils, monocytes and reticulocytes.¹²⁹ It improves red cell hydration and deformability¹²⁶ and reduces red cell endothelial adherence.¹³¹ It may also generate nitric oxide, a potent vasodilator.²²

Initial studies of hydroxycarbamide in adults suggested that it reduced the frequency of painful crises, ACS, blood transfusions and hospitalizations.¹²⁹ A recently published 9-year follow-up study of the original group now confirms a 40% reduction in mortality.¹³² Similar studies in children confirmed its efficacy and lack of life-threatening events,^{133,134} and a 9-year follow-up study has shown sustained HbF levels without effects on growth or increased numbers of acquired DNA mutations.¹³⁵ One of the unanswered questions is whether hydroxycarbamide given prior to the onset of chronic organ dysfunction could prevent damage. Preliminary data suggested benefits even in young children and now that the cooperative study of hydroxycarbamide in infants (HUG-Infants) has commenced, its findings will be eagerly awaited.¹³⁶ Hydroxycarbamide is potentially mutagenic and carcinogenic and both cancer and leukemia have been

reported in patients receiving the drug. It remains unclear if the incidence of cancer is higher in this group than in the general population.¹³⁷

Hematopoietic cell transplantation

Stem cell transplantation is the only current therapy that has the potential to cure SCD. There have been about 200 transplants from HLA-identical siblings worldwide and there is an 85% survival, free of SCD, with a follow-up in some cases of 11 years. There is a 5% transplant-related mortality and 5% of patients experience chronic graft-versus-host disease. Neurologic complications such as seizures can occur during transplant and may in part be related to hypertension. The current indications for stem cell transplant are:⁵⁶

- availability of a fully HLA-matched sibling donor;
- patient age < 16 years with HbSS or HbS/ β^0 -thalassemia;
- previous stroke;
- abnormal MRI or neuropsychologic function;
- recurrent chest syndrome or stage I/II sickle lung disease;
- recurrent vasoocclusive episodes;
- sickle nephropathy;
- AVN of multiple joints.

Volunteer unrelated transplants, umbilical cord blood and nonmyeloablative transplants are the subject of clinical trial. Currently, there are no comparative studies of blood transfusion, hydroxycarbamide or stem cell transplantation that would permit recommendation of one intervention over the others.

The Future

Drug therapies that specifically target one aspect of the sickle pathologic process are being developed (Table 10.7). Drugs

Table 10.7 Experimental therapies for the management of sickle cell disease.

Agents to increase HbF
Butyrate
Decitabine
Nitric oxide promoters
Nitric oxide
Arginine
Citrulline
Red cell membrane channel blockers
Magnesium
Arginine
Clotrimazole derivatives
Endothelial interactions/decreased activation
Antiadhesion molecules
Sulfasalazine
Combinations

such as arginine that increase the availability of nitric oxide are undergoing phase I studies and have shown some benefit in pulmonary hypertension.¹³⁸ Agents such as decitabine, which act by hypomethylation of the γ -globin genes, produce a rise in HbF levels and have shown effect even in individuals previously resistant to hydroxycarbamide.¹³⁹ Short-chain fatty acids and their derivatives enhance γ -globin gene expression and can induce significant HbF increase.¹³⁷ Clotrimazole derivatives and magnesium inhibit erythrocyte membrane electrolyte fluxes and can prevent red cell dehydration, thus reducing HbS concentration and polymerization. Antibodies targeting endothelial adhesion mechanisms have been developed in rat models and are now awaiting further development. Alternatives to sibling transplantation are being actively pursued as few patients have fully matched sibling donors and advances in this area can be expected. Gene therapy is still at the developmental stage and is moving slowly. It is unlikely that any major advance will be seen in the near future. Our knowledge of the mechanisms underlying the sickling process has grown enormously over the past 10 years; however, one suspects there is much left to understand, particularly in the area of vascular biology about this complex disease.

Hemoglobin variants and the rarer hemoglobin disorders

Andreas E. Kulozik

Introduction

Hemoglobin is a tetrameric protein complex consisting of two pairs of globin chains with a combined molecular mass of 64 400 Da. One type of globin chain is coded at the tip of the short arm of chromosome 16 where the α -globin gene cluster containing the embryonic ζ and the adult α_2 and α_1 genes is located.¹ The other type is coded on the short arm of chromosome 11 (11p14) by the β -globin gene cluster containing the embryonic ϵ , fetal γ and δ , and adult β genes.¹ Each of the four subunits is covalently bound to the ferroporphyrin heme as a ligand. The structure and function of hemoglobin enable it to be soluble and stable in the erythrocyte, and to allow uptake, transport and release of large quantities of oxygen under physiologic conditions.

As of January 2005, 896 functionally relevant and functionally silent hemoglobin variants have been described and

deposited in the hemoglobin variant database.² This chapter reviews aspects of normal hemoglobin structure and function and describes the less common pathologic hemoglobin anomalies.

Hemoglobin structure

Primary structure

The globin chains are coded in the α - and β -gene cluster (Fig. 11.1) and contain 141 and 146 amino acids respectively.³ The strong evolutionary and functional kinship of these proteins is reflected by the high degree of sequence homology. The α - and ζ -chains show identity at 84 of 141 residues (60%). The homology of the ϵ , γ , δ and β genes is even more striking, with an identity of 94 of 146 residues (64%). The heme is bound covalently between the iron and the proximal F8 His

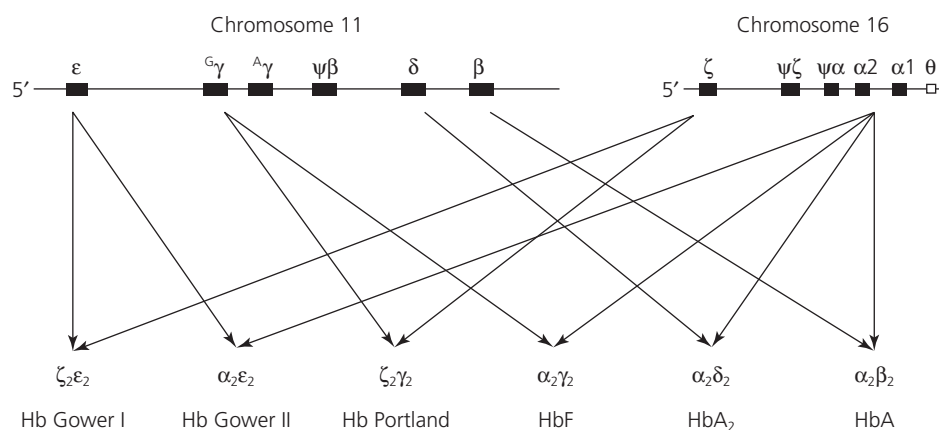

Fig. 11.1 The α - and β -globin gene clusters on chromosomes 11 and 16. The β -globin gene cluster contains the embryonic ϵ -, fetal γ -, and adult δ - and β -globin genes. In addition, there is a nonexpressed pseudogene ($\psi\beta$) with significant sequence homology to the β gene. The α -globin gene cluster contains the embryonic ζ - and adult α -globin genes. In addition, there are various pseudogenes ($\psi\zeta$, $\psi\alpha$, θ). Different hemoglobins are produced in the course of ontogeny; all contain two α - or ζ -chains and two β - or β -like chains (embryonic stage: Hb Gower I, Hb Gower II, Hb Portland; fetal stage: Hb F; postnatal and adult stage: HbA₂, HbA).

at position 87 in the α -chain and at position 92 in the β -chain. The functionally important residues, such as those at the α - β interfaces or at the heme-binding sites, are especially highly conserved.

Secondary structure

The globin chains are wound up into segments of α -helices that are interrupted by non-helical configurations where the polypeptide chains bend.³ The helices, with 3.6 amino acids per turn, are stabilized by H-bonds between the carbonyl and amino groups of residues four positions apart. The β -chain consists of eight helical segments (designated A–H). The α -chain is similar, although the D helix has been deleted in the course of evolution by a functionally neutral mutation.⁴ The residues can be assigned to their position in the helices and the degree of homology between globin chains is particularly striking when the alignment is oriented at the secondary structure. For example, the heme-binding histidines at positions 87 in the α -chain and 92 in the β -chain are at position 8 in the F helix (F8) in both globin chains. Homologous positions in the globins are therefore best represented by the helical designation rather than by their numerical position in the primary structure.

Tertiary and quaternary structure

Much of the information available about the three-dimensional structure and the function of hemoglobin has been obtained by X-ray crystallography.⁵⁻¹⁰ Tertiary structure refers to the steric relationship of residues within the individual globin chain, whereas quaternary structure refers to subunit interactions. Both determine the functionally important three-dimensional structure of the entire tetrameric protein-heme complex and are therefore dealt with together.

The helices of the individual globin chains form a compact spherical structure (Fig. 11.2). The residues facing outward are mainly polar, whereas those facing inwards are mainly non-polar. This distribution is responsible for both the excellent solubility of hemoglobin and its high degree of stability by blocking the influx of water into the central part of the complex.

Near to the surface, the heme molecule is suspended between the proximal and distal histidines at position F8 and E7. The six electrons in the outermost orbital of the ferrous iron (Fe^{2+}) coordinate with the four nitrogens of the pyrrole molecule, the imidazole nitrogen of His F8 and the oxygen. Additionally, there are multiple contacts to mainly non-polar residues of the heme pocket between the E and F helices, but also to residues of the C, G and H helices. The porphyrin ring is held in this pocket by 60 hydrophobic bonds, conferring a high degree of stability. The functional importance of these contact points is highlighted by their strong evolutionary conservation and by the effect of amino acid substitutions that result in unstable hemoglobin variants.

Fig. 11.2 Tertiary structure of the β -globin chain. The α -helices are designated A–F from the N- to the C-terminal. Modified with permission from Ref. 84.

The four subunits are assembled to form an ellipsoidal measuring $6.4 \times 5.5 \times 5.0$ nm. In the center of the tetrameric complex runs a twofold, dyad axis of symmetry, which means that any part of the molecule will superimpose on an identical counterpart if rotated by 180° around this axis (Fig. 11.3).¹¹ The α and β chains have two interfaces between each other, one between the α_1 (α_2) and β_1 (β_2) and the other between the α_1 (α_2) and β_2 (β_1) chains. The $\alpha_1\beta_1$ ($\alpha_2\beta_2$) contact is established by about 40 van der Waals and H-bonds involving 16 α -chain and 17 β -chain residues.³ The characteristic of the $\alpha_1\beta_2$ contact is that there are two possible conformations that are assumed while oxygenated or deoxygenated. The deoxy form is tight (T-form) with about 40 van der Waals and H-bonds,³ whereas the oxy form is relaxed by about 0.7 nm and established by only 22 van der Waals and H-bonds (R-form). Consequently, oxyhemoglobin is less stable than deoxyhemoglobin. This allosteric movement at the $\alpha_1\beta_2$ interface is also paramount to the cooperative effect of oxygen binding. Calculations of conformational energies and direct structural analyses suggest that oxygen binding to the T-form puts an increased strain on the $\alpha_1\beta_2$ ($\alpha_2\beta_1$) interface that can be relieved by the conformational change to the R-form, which can then more readily accept more oxygen at the other hemes in the complex. Mechanistically, the transition from the T-form to the R-form requires oxygen binding according to a "symmetry rule," i.e., whenever oxygen binding creates a

Fig. 11.3 Quaternary structure of hemoglobin in the T (solid line) and R (dotted line) quaternary conformations. The α_1/β_1 contact remains unchanged, whereas the α_1/β_2 contact rotates by about 15° when the allosteric switch occurs. Modified with permission from Ref. 11.

tetramer with at least one ligated subunit on each dimeric half-molecule ($\alpha_1\beta_1$ or $\alpha_2\beta_2$), quaternary switching occurs.¹²

The T-form is further stabilized by chloride and 2,3-diphosphoglycerate (2,3-DPG), which confer intra- and inter-subunit salt bonds. Cl^- establishes two bonds between the N-terminal Val of α_2 to α_2 131 Ser and α_1 141 Arg and also neutralizes repulsive forces of positively charged residues in the central cavity.¹³ 2,3-DPG is a polyanion that associates with the positive charges of the N-terminal amino groups of Lys 82 and of the histidines 2 and 143 of the β -chains. When 2,3-DPG is lost during oxygenation, Cl^- and H^+ ions are ejected from the central cavity.

Hemoglobin function

The chief function of hemoglobin is to take up oxygen in the lungs and transport it to the peripheral tissues, where it is unloaded in exchange for CO_2 . The quantities of oxygen transported are enormous: 1 mol of hemoglobin can bind

Fig. 11.4 Sigmoid binding curve of HbF and HbA at high and low 2,3-diphosphoglycerate (2,3-DPG) concentrations. The hyperbolic binding curves of myoglobin and HbH, which do not show a cooperative effect on oxygen binding, are shown for comparison. Modified with permission from Ref. 84.

4 mol of O_2 ; as 1 mol of a gas at standard temperature and pressure is 22.4 L, 1 g of hemoglobin can bind 1.39 mL of O_2 . At a hemoglobin concentration of 15 g/dL, 100 mL of blood can thus transport ~ 20 mL of O_2 .

The basic mechanism is the cooperative effect of the subunits, which is structurally based on the allosterism of the R-form and T-form. This means that binding of oxygen induces allosteric changes in particular at the $\alpha_1\beta_2$ contact that facilitate the uptake of further oxygen molecules (homotropism). This cooperative effect is modified by the influence of other molecules, such as 2,3-DPG, H^+ , Cl^- and CO_2 (heterotropism). The physiologic corollary of this cooperative effect is the sigmoid binding curve of hemoglobin, i.e., oxygen is rapidly loaded and unloaded at physiologic oxygen tensions (Fig. 11.4).

Homotropic interactions of oxygen binding

A powerful model of oxygen binding was proposed by Monod *et al.*¹⁴ which was later modified.¹² According to this model, the R-form and the T-form are in equilibrium and differ in their oxygen affinity. The binding of the ligand to the individual subunit causes the tertiary structure to relax. When one subunit of each $\alpha_1\beta_1$ and $\alpha_2\beta_2$ dimer is oxygenated, the quaternary switch to the R conformation occurs, facilitating oxygen loading of the remaining two subunits. This basic shift of the equilibrium induced by the ligand itself is modified heterotropically by CO_2 , 2,3-DPG and chloride as detailed below.

Heterotropic interactions of oxygen binding

Bohr effect

Bohr, Hasselbalch and Krogh showed in 1904 that oxygen

affinity is reduced by CO_2 . The major mechanism of the Bohr effect is the formation of carbonic acid from CO_2 and H_2O , catalyzed by carbonic anhydrase ($\text{CO}_2 + \text{H}_2\text{O} \leftrightarrow \text{H}_2\text{CO}_3$); carbonic acid readily dissociates into HCO_3^- and H^+ . HCO_3^- is rapidly exported into the plasma in exchange for Cl^- , thus decreasing intracellular pH. The protons stabilize the T-form by forming H-bonds, predominantly at β 146 His but also at β 94 Asp, α 122 His and the N-terminal amino groups.^{15–18} On oxygenation these protons are extruded, breaking the salt bonds and changing the pK_a from 8.0 in deoxyhemoglobin to 7.1 in oxyhemoglobin.^{8,19–21} The Bohr effect therefore facilitates gas exchange, because oxygen affinity is decreased and oxygen unloaded at high concentrations of CO_2 , i.e., in the peripheral tissues. Conversely, when CO_2 is exhaled in the lungs and intracellular pH rises, oxygen affinity is increased, which favors oxygen uptake.

A smaller portion of the CO_2 is directly bound to reactive amino groups to form carbamino complexes that also stabilize the T-form. However, in comparison to the Bohr effect, carbamino formation is probably of much less significance in terms of controlling allosterism and cooperative oxygen binding.²²

Interaction with chloride

Chloride is transported into the red cell when bicarbonate is exported during protonation and deoxygenation (see above). Chloride reinforces the stabilization of the T-form by neutralizing electrostatic repulsion by an excess of positive charges in the central cavity of the molecule.^{13,23,24} Additionally, Cl binding at the N-terminus of the α -chains appears to stabilize protonation and the T-form, thus modulating allosterism. Upon oxygenation, chloride is released together with the protons that are required for the reverse carbonic anhydrase reaction. The efficiency of the Bohr effect is reduced to about half in a chloride-depleted system, demonstrating the physiologic importance of the chloride interaction.²⁵ Clinically, the importance of the interaction of chloride with positively charged residues is demonstrated by the variants with altered oxygen affinity and additional or missing positive charges in the central cavity of the molecule.¹³

Interaction with 2,3-DPG

2,3-DPG is a polyanion with a high affinity for positively charged residues in the hemoglobin complex. It is a potent modifier of oxygen affinity^{26,27} and forms H-bonds with the N-terminal amino groups, the imidazole of β 143 His, and the amino groups of β 82 Lys in the T-conformation. In the R-conformation, these interactions are much weaker.^{28,29} 2,3-DPG thus stabilizes deoxyhemoglobin and reduces oxygen affinity. The higher oxygen affinity of HbF in comparison to HbA is due to a sequence difference between the γ and

β chains: β 143 His corresponds to γ 143 Ser, which is an uncharged amino acid that does not bind to 2,3-DPG.

The concentration of intracellular 2,3-DPG can be upregulated in conditions of chronic hypoxia, thus reducing oxygen affinity and increasing oxygen availability in peripheral tissues. This is also one of the compensatory mechanisms of chronic anemia.

Hemoglobin variants

Adult hemoglobins

HbA

After completion of the fetal to adult switch (see below), HbA ($\alpha_2\beta_2$) is the predominant hemoglobin. HbA is posttranslationally glycosylated at the N-terminal valine and at internal lysine residues. This is a two-step reaction, first quickly and reversibly transforming the Hb-NH_2 group to an aldimine and then slowly and irreversibly to a ketoamine. The post-translational modifications can be identified as fast-eluting fractions (HbA_{1a-c}) on column chromatography (Fig. 11.5). One of these fractions (HbA_{1c}) can be readily quantified and is a useful marker for the long-term metabolic control of patients with diabetes mellitus. In rare cases of substitutions of the N-terminal Val residue, HbA can be acetylated, in this respect resembling HbF. In cation exchange chromatography, these variants may be mistakenly identified as raised HbA_{1c} .^{30–32}

Fig. 11.5 Quantitation of HbF and HbA_{1c} by fast protein liquid chromatography (Mono S[®] HR 5/5, Pharmacia). Modified with permission from Ref. 84.

HbA₂

About 2.5% of adult hemoglobin is HbA₂ ($\beta_2\delta_2$). Functionally, HbA₂ is identical to HbA, although due to its low level of expression it is physiologically irrelevant and total lack of its synthesis has no clinical effect.

The δ -chain is highly homologous to the β -chain and differs by only 10 amino acids. Because of the difference in charge, HbA₂ can be easily separated from HbA by electrophoresis or chromatography. The δ -globin gene is located immediately 5' of the β -globin gene (see Fig. 11.1) and switched on roughly in parallel to the β gene. The much lower level of δ -globin expression results from the following.

- 1 Reduced transcriptional activity of the δ -globin gene, which is caused by the relative inefficiency of its promoter³³ and probably by the lack of, or a less efficiently functioning, enhancer in the second intron.³⁴
 - 2 Reduced δ -globin mRNA stability.³⁵
 - 3 A lesser affinity of δ -globin chains for α -globin chains.³⁶
- This characteristic is exploited for the diagnosis of heterozygous β -thalassemia. When β -globin chains are present in low concentrations, δ -globin chains are able to form tetramers with α -chains and HbA₂ levels thus increase. Conversely, in α -thalassemia, HbA₂ may be decreased.

Fetal hemoglobin

Structure and function

Structurally and functionally, fetal hemoglobin (HbF; $\alpha_2\gamma_2$) is similar to HbA. However, there are some significant differences. The amino acid sequence of the γ -chain differs from the β -chain at 39 residues; 22 of these occur at the external surface, explaining the different electrophoretic/chromatographic behavior and the increased solubility of HbF. Four substitutions are located at the $\alpha_1\beta_1$ ($\alpha_1\gamma_1$) interface, which results in the increased stability of HbF. The $\alpha_1\beta_2$ ($\alpha_1\gamma_2$) contacts are identical in both HbA and HbF, which is reflected by similar cooperative effects of oxygen binding in both hemoglobins. The substitution β 143 His \rightarrow γ 143 Ser causes a diminished interaction of HbF with 2,3-DPG, thus increasing oxygen affinity of fetal red cells.³⁷ The diagnostically important increased resistance of HbF to alkali (see below) can be explained by the β 112 Cys \rightarrow γ 112 Thr and β 130 Tyr \rightarrow γ 130 Trp substitutions.³⁸

HbF is structurally heterogeneous. The γ -globin chains are coded for by two closely linked genes that are located between the ϵ and the δ genes within the β -globin gene cluster (see Fig. 11.1). The amino acid sequence that is coded for by the more 5' gene differs from that of the 3' gene at position 136, where the 5' gene codes for a glycine ($^G\gamma$) and the 3' gene for an alanine ($^A\gamma$) residue.³⁹ During fetal life, about 75% of the HbF contains $^G\gamma$ chains, whereas the small amounts of HbF present in adult life contain predominantly $^A\gamma$ chains.⁴⁰

In addition to these allelic differences, the $^A\gamma$ gene contains a common polymorphism coding for either Ile ($^A\gamma^I$) or Thr ($^A\gamma^T$) at position 75.⁴¹ The major posttranslational modification of HbF is by acetylation at the N-terminal Gly, which results in a more negatively charged component (HbF₁).

Diagnostic and therapeutic relevance

Following the fetal to adult hemoglobin switch during the first 6 months of life there are only trace amounts of HbF in the peripheral blood.⁴² The discovery of a method to differentiate fetal from adult red cells by acid HbA elution⁴³ and the identification of fetal red cells in the maternal circulation post partum was part of the logical foundation for anti-D prophylaxis in Rh-negative mothers (see Chapter 10). Practically, this method is useful for the estimation of fetomaternal blood transfusion.⁴⁴

Increased HbF levels occur in both hemoglobin disorders and acquired hematopoietic diseases. In sickle cell disease (see Chapter 11), HbF is raised as a result of selective survival of F cells. In patients from Saudi Arabia and India, HbF synthesis is increased and associated with a milder clinical phenotype.^{45,46} The sickle cell mutation in Asia occurred on a different genetic background from that in African patients.⁴⁷ There is probably more than one genetic factor responsible for the raised HbF levels, which are both probably linked and not linked to the β -globin gene cluster.^{48–51} The clinical benefit of hydroxycarbamide in the treatment of sickle cell disease is related to an increase of HbF, although HbF-independent factors probably play an additional important role.⁵²

In patients with homozygous β -thalassemia, the increase of the relative HbF is pathognomonic (see Chapter 15). While HbF synthesis per cell is not increased in most patients, in absolute terms F cells are produced in larger numbers than normal by the greatly expanded bone marrow. These cells subsequently survive selectively because the imbalance between α -chain and non- α -chain synthesis is less marked in F cells than in cells not expressing γ -globin.⁵³ If genetic determinants that increase globin gene expression per cell are present, such as point mutations of the γ -globin gene promoters or deletions of the β -globin gene cluster,⁵⁴ the clinical and hematologic manifestations of homozygous β -thalassemia can be considerably ameliorated and adult individuals with hereditary persistence of HbF and 100% HbF can be perfectly healthy (see Chapter 15). Pharmacologic attempts to reactivate HbF synthesis have been promising but have not been shown to be applicable to most patients in large-scale trials.^{55–57}

There are a multitude of acquired conditions associated with an increase of HbF. This is invariably so in, and is a diagnostic feature of, juvenile chronic myeloid leukemia, Fanconi anemia and erythroleukemia.^{58–62} Raised HbF levels can be commonly seen, but are not of specific diagnostic value, in other myeloproliferative disorders and during the

Fig. 11.6 Developmental changes in globin synthesis.

hematologic recovery following bone marrow transplantation or intensive chemotherapy.⁶³

Embryonic hemoglobins

During weeks 2–14 of embryonic life the yolk sac produces three different hemoglobins: $\zeta_2\epsilon_2$ (Hb Gower I), $\alpha_2\epsilon_2$ (Hb Gower II), and $\zeta_2\gamma_2$ (Hb Portland).^{64–66} The ϵ -chains are homologous to the β and γ chains and are coded for by a single gene at the 5' end of the β -globin gene cluster (see Fig. 11.1). The ζ -chain is homologous to the α -chain and is coded for by a single gene at the 5' end of the α -globin gene cluster (see Fig. 11.1). All three embryonic hemoglobins show allosterism, a cooperative effect on oxygen binding, and sensitivity to 2,3-DPG, but they exhibit a higher oxygen affinity than HbA and a decreased Bohr effect.⁶⁷ Under normal conditions these hemoglobins are not detectable during fetal or postnatal life. However, in deletional α^0 -thalassemia, embryonic hemoglobins can be found at later stages of development.^{68–70}

Developmental changes

The individual globin genes are activated to high levels of expression selectively in erythroid cells and programmed to be predominantly expressed at specific developmental stages. In both clusters on chromosomes 11 and 16 the globin genes are arranged in the order of their expression during development (see Fig. 11.1). About 14 days following conception, Hb Gower I and II, Hb Portland, and a little later HbF, begin to be synthesized in the yolk sac. By about 8 weeks the embryonic genes are silenced and HbF becomes the predominant hemoglobin and is synthesized in the fetal liver and spleen, and increasingly also in the bone marrow. HbA is made in small amounts during this period. At around birth, γ -globin chain and HbF synthesis are substituted by β -globin

Fig. 11.7 Starch gel electrophoresis of hemoglobins at the adult (lane 1), embryonic (lane 2), and fetal (lane 3) stages of development.

chain and HbA synthesis. Postnatally, the bone marrow becomes the only site of normal erythropoiesis (Figs 11.6 and 11.7).⁷¹

In the α -globin gene cluster there is a genetic embryonic (ζ) to fetal/adult (α) switch, whereas the β -globin gene cluster performs an embryonic (ϵ) to fetal (γ) and a fetal to adult (β) switch in gene expression. These switches are important paradigms of ontogenetic gene regulation and have therefore been the subject of intense study by biologists. The motivation for the medical sciences to study the fetal to adult hemoglobin switch results from the interest in reactivating γ -globin gene expression as a therapeutic option for the hemoglobinopathies.

The mechanisms responsible for the developmental specificity of hemoglobin synthesis are dependent on specific sequences within both the promoters and remote regulatory sequences.^{72–75} These DNA sequences interact with erythroid-specific and ubiquitous transcription factors, which results in the activation or silencing of the individual genes.

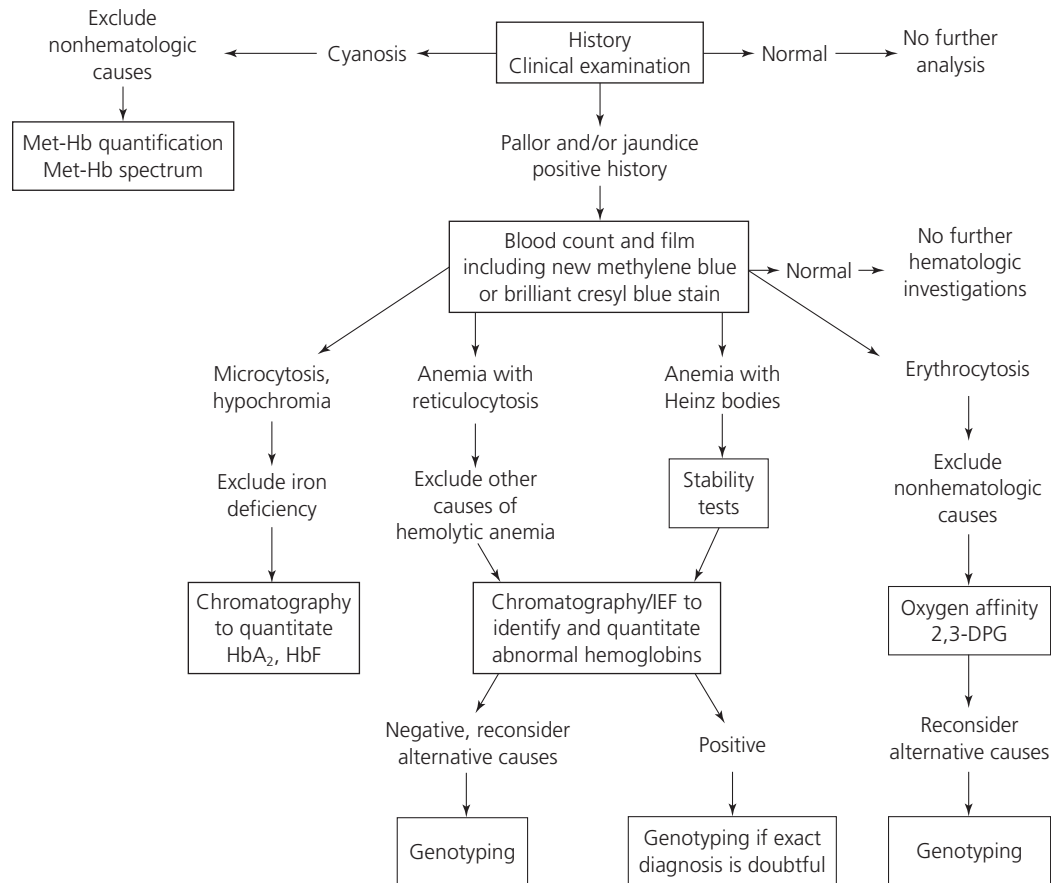

Fig. 11.8 Strategy for the analysis of the hemoglobinopathies. 2,3-DPG, 2,3-diphosphoglycerate; IEF, isoelectric focusing; Met-Hb, methemoglobin.

Experiments in transgenic mice and the analysis of naturally occurring mutants suggest that the individual genes can be either autonomously regulated or require competition with other genes of the cluster.^{54,76–81}

Methods of hemoglobin identification

The practical approach to hemoglobin analysis is summarized in Fig. 11.8. The laboratory hematologist needs to be informed about relevant clinical details, in particular any recent erythrocyte transfusions, results of routine hematology, and iron status. The blood needs to be anticoagulated with EDTA or citrate and, except for the analysis of highly unstable variants or HbH in the diagnosis of α -thalassemia, can be stored for a few days. Generally, a blood volume of 5 mL is sufficient to perform all necessary analyses.

Routine hematology

This should include a complete blood count, including erythrocyte indices and reticulocytes, and careful examination of a blood film.

Cytologic tests

These tests are valuable, simple, and reproducible but are relatively labor-intensive as they are not automated.

HbF cells (Kleihauer technique)

This technique is based on the acid elution of HbA but not HbF from single cells.⁴³ The thin film is fixed and dried in 80% ethanol and then incubated for 5 min in a citrate-phosphate buffer at pH 3.2 and 37°C. The slide is then rinsed and stained with hematoxylin and eosin. HbA cells appear as empty ghosts, whereas HbF cells are stained (Fig. 11.9). If HbF cells are not present, there is no need to quantitate HbF by more sensitive techniques such as alkali denaturation or chromatography.

Inclusion bodies

HbH cells and Heinz bodies that reflect denatured hemoglobin can be identified by incubation for 30 min at room temperature of a drop of blood with a drop of brilliant cresyl blue or new methylene blue.⁸² Microscopically, Heinz bodies are coarse and rather plump and located peripherally against the membrane, whereas HbH inclusions are smaller

Fig. 11.9 Kleihauer technique. Acid elution of HbA and demonstration of HbF in single red cells: (A) cord blood; (B) normal adult blood; (C) maternal blood after fetomaternal transfusion. Modified with permission from Ref. 84.

Fig. 11.10 Heinz bodies in a brilliant cresyl blue-stained film of a patient with Hb Köln.

and more evenly distributed within the cell. The Kleihauer technique (see above) is also useful for the demonstration of inclusion bodies (Fig. 11.10).

Sickle test

This test was used to demonstrate HbS in blood films and is now dispensable, because hemoglobin electrophoresis or chromatography are more useful quantitative methods and can distinguish heterozygotes, homozygotes, and compound heterozygotes.⁸²

Denaturation tests

HbF

Denaturation by alkali is the classic technique for determining HbF quantitatively.⁸³ In principle, this is based on the increased stability of HbF over HbA in the presence of alkali due to the amino acid substitutions at positions 112 (β Cys \rightarrow γ Thr) and 130 (β Tyr \rightarrow γ Trp). The detailed protocol of alkali denaturation of a cyanmethemoglobin solution has to be followed accurately with respect to the concentrations of hemoglobin solution, NaOH, and ammonium sulfate, as well as to the timing and temperature. The method is reliable for

low HbF concentrations. At higher concentrations (>20%) the alkali denaturation method tends to underestimate, because some of the HbF is coprecipitated with the HbA.

Unstable variants

If an unstable variant cannot be specifically identified by electrophoretic, chromatographic, or isoelectric focusing techniques, its presence may be demonstrated as Heinz bodies or by an increased denaturation by heat or isopropanol.⁸² For the heat denaturation test a buffered cyanmethemoglobin solution is incubated at 69.5°C for 6 min, which results in the precipitation of unstable variants. For the isopropanol test the hemolysate is incubated with 17% buffered isopropanol at 37°C, which also results in the precipitation of unstable hemoglobins. If the specific identification of the variant is not possible by standard techniques, DNA analysis is probably the most economic diagnostic procedure to be employed next.

Solubility test

This method is still used by some laboratories to discriminate HbS from other rarer variants with the same electrophoretic behavior. However, DNA analysis is now the more efficient method to identify the variant.

Spectral analysis

This is a method to identify HbM anomalies that show a characteristic methemoglobin spectrum at 450–650 nm (Fig. 11.11). The hemolysate is transformed completely into methemoglobin by potassium ferricyanide and the absorption compared to a normal control with an identical concentration and pH.⁸⁴

Oxygen affinity

The oxygen dissociation curve can be measured by using commercially available tonometers. In principle, red cells are deoxygenated and suspended at a low concentration at a defined temperature and pH. Oxygen at known P_{O_2} is then added stepwise and the amount of oxyhemoglobin measured by spectrometry (see Fig. 11.4).

Fig. 11.11 Methemoglobin spectrum of HbM Saskatoon (curve 1), HbM Boston (curve 2), and HbM Milwaukee (curve 3) in comparison to normal methemoglobin (curve 4). Modified with permission from Ref. 84.

Hemoglobin electrophoresis

The identification of hemoglobin variants by electrophoretic techniques depends on the introduction of a charge difference by the amino acid substitution. Commonly used routine methods are alkaline cellulose acetate and acid agar-gel electrophoresis of hemolysates.⁸² Although the commoner variants are detected with these methods, 45 of all pathologic hemoglobin variants are not associated with a charge difference and are therefore electrophoretically silent. Furthermore, electrophoretic methods are generally unreliable for the quantitation of hemoglobin variants. An exception is the technically difficult and laborious starch bloc electrophoresis that results in particularly sharp bands that allow reproducible quantitative measurements (see Fig. 11.7).⁸⁴

Isoelectric focusing

A pH gradient is generated in a polyacrylamide gel, separating the loaded hemoglobins according to their pK_a . In contrast to hemoglobin electrophoresis, this method does not rely on the charge and many variants not detectable by electrophoretic methods can be identified by isoelectric focusing.⁸⁵ The technical effort associated with isoelectric focusing can be much reduced by using immobilized pH gradients in polyacrylamide gels, which can be used to detect common (Fig. 11.12) and rare (Fig. 11.13) variants with a high degree of sensitivity and specificity.⁸⁶

Fig. 11.12 Immobilized pH gradient of common hemoglobin variants. Kindly provided by Dr P. Sinha.

Fig. 11.13 Immobilized pH gradient of Hb Okayama (arrow) (lanes 1 and 3) and a normal control with HbA_{1c} in the same position (lane 2). Kindly provided by Dr P. Sinha.

Chromatography

With these methods, hemoglobin variants can be reliably identified and quantitated. Recently, in larger laboratories, high-performance liquid chromatography and fast protein liquid chromatography techniques have largely superseded the formerly used DEAF-Sephadex chromatography (see Fig. 11.5). Apart from their high degree of accuracy and reproducibility, chromatographic methods can also be used to prepare samples for further biochemical and biophysical analysis.

Mass spectrometry

This method has recently been introduced to accurately determine the molecular weight of globin chains. The likely amino acid substitution can thus be predicted without protein sequencing. This method complements DNA sequencing in that it detects posttranslational modifications.⁸⁷ However, the immense cost of the equipment and the special expertise required limit this technique to specialized laboratories.

Fig. 11.14 Characterization of an unstable variant by DNA sequence analysis. The G7G→GAG mutation in codon 98 can be demonstrated directly and the Val→Glu amino acid substitution of Hb Mainz deduced according to the genetic code.

DNA analysis

The invention of the polymerase chain reaction (PCR)^{88,89} caused a revolution in clinically applied molecular biology. PCR-amplified DNA can also be subjected to various diagnostic procedures such as allele-specific oligonucleotide hybridization, restriction enzyme analysis,^{90,91} or automated direct sequencing.⁹² The structure of variant hemoglobins and the amino acid substitution can thus be indirectly determined (Fig. 11.14), although posttranslational modifications detectable by biochemical analysis do, of course, remain unidentified.^{87,93–96} Molecular genetic techniques are particularly useful in prenatal diagnosis.⁹⁷

Rare hemoglobin disorders

Unstable variants (congenital Heinz body hemolytic anemia)

Hemoglobin is a highly organized complex whose function and stability is dependent on the subtle arrangement of the various structural features described above. Many mutations thus lead to some degree of instability that can be recognized by *in vitro* testing but do not result in significant clinical consequences. The clinical definition of unstable hemoglobinopathies therefore refers to congenital Heinz-body

hemolytic anemia (CHBA) only.^{98,99} A continuously updated list of the variants can be found in the globin database.²

Pathogenesis

The common pathway for unstable hemoglobin denaturation is the relaxation of the strict steric organization, which then favors the R configuration and thus the oxygenated state. In oxyhemoglobin, ferrous iron is more likely to be oxidized to the ferric form ($\text{Hb Fe}^{2+} + \text{O}_2 \rightarrow \text{Hb Fe}^{3+} + \text{O}_2^-$). Both the superoxide anion and hydrogen peroxide can induce the generation of more methemoglobin. As ferriheme has a lower affinity for globin, this in itself may lead to heme loss and rapid denaturation.^{100,101} Additionally, the distortion of the quaternary configuration allows the E7 histidine directly but reversibly to bind to the oxidized heme (reversible hemichrome). If on further distortion other residues bind to the oxidized heme, this is irreversible and results in denaturation and finally precipitation as a Heinz body. These become attached to the inner surface of the red cell membrane and cause trapping in the spleen where the inclusions are removed or hemolysis occurs. In addition to this rather mechanical view of splenic hemolysis, autologous antibodies have been reported to bind to modified membrane constituents.^{102,103}

Many unstable variants can be detected electrophoretically (see Fig. 11.15). However, if instability is severe in the so-called hyperunstable hemoglobins, protein-based analytical techniques are not sufficient (see below). In some such variants the clinical features are remarkably mild.¹⁰⁴ In others, there is marked ineffective erythropoiesis with low reticulocyte counts for the degree of anemia and unbalanced synthesis of α -globin/non- α -globin chains, suggesting that an early step of complex formation such as dimerization may be affected.^{105–110}

There are five different and not mutually exclusive molecular mechanisms destabilizing the three-dimensional structure of the complex. In some variants the mechanism for instability cannot be predicted from the amino acid substitution and X-ray crystallography data are not available.

Destabilization of the globin–heme interaction

Heme is bound to the heme pocket at the surface of the complex where nonpolar residues in the CD, E, F, and FG regions interact hydrophobically with the porphyrin ring. Many of the clinically relevant unstable variants, including the most common Hb Köln (β 98 [FG5] Val → Met), affect these residues resulting in a weaker globin to heme link.^{111,112}

If the F8 histidine is substituted in Hb Istanbul (β 92 His → Gln),¹¹³ Hb Mozhaik (β 92 His → Arg),¹¹⁴ and Hb Newcastle (β 92 His → Pro),¹¹⁵ heme cannot be bound to globin, which results in instability.

The E7 histidine binds directly to molecular oxygen and, together with E11 Val, produces a steric configuration that

prevents access of larger molecules to the heme pocket. If E7 His is substituted by Arg in Hb Zürich (β 63 His \rightarrow Arg), a molecular gap is opened that allows oxidant substances, such as sulfonamide drugs, to attack the ferrous iron, resulting in methemoglobin formation that triggers denaturation. In Hb Zürich, ferrous iron oxidation can be inhibited by CO (e.g., in smokers) resulting in a decrease of Heinz bodies.

A substitution of E11 Val was the first unstable hemoglobin to be characterized at the molecular level.¹¹⁶ This rare variant has been described in four families from the UK, Japan, and Russia, and results in considerable anemia (Hb 5–8 g/dL) with regular transfusion requirements.⁸⁷ In the initial protein analysis, E11 Val was found to be substituted by Asp and was designated Hb Bristol. Subsequent DNA analysis showed a GTG \rightarrow ATG mutation of codon 67, thus replacing the codon of Val with Met, not Asp. Met has therefore been posttranslationally modified to Asp. Posttranslational modifications have also been observed in Hb Redondo (β 92 His \rightarrow Asn \rightarrow Asp), Hb La Roche-sur-Yon (β 81 Leu \rightarrow His \rightarrow β 80 Asn \rightarrow Asp), and Hb Atlanta-Coventry (β 75 Leu \rightarrow Pro \rightarrow β 141 Leu deleted).^{87,93–96}

Disruption of secondary structure

The predominant secondary structure of globin chains is the α -helix, which is crucial for the tight assembly of the tertiary and quaternary structure. Any substitution that inhibits α -helix formation is therefore likely to be associated with clinical manifestations. Proline cannot participate in helix formation and variants introducing this residue are almost always unstable. An exception is the stable variant Hb Singapore (α 141 Arg \rightarrow Pro) where the proline is located at the C-terminal end of the chain, which does not participate in helix formation.¹¹⁷

Substitutions at the hydrophobic core

The interior of the complex is highly hydrophobic. A common mechanism of destabilization is a substitution of a charged for an uncharged amino acid, thus allowing water to enter into the tightly fitting core.¹¹⁸ Similarly, the tight steric fit may be disturbed by the replacement of one hydrophobic residue with another. Finally, if the strong $\alpha_1\beta_1$ interface is relaxed, the internal SH groups may become highly reactive as is the case in Hb Tacoma and Hb Philly.^{119,120}

Amino acid deletions

Deletions of amino acids can have a serious effect on the conformation of the entire complex, which may be so severe that a thalassemic phenotype develops.

Elongation of a subunit

These variants are caused by DNA insertions, by mutations of the translation termination codon (Ter), or by a frameshift in the third exon putting Ter out of frame. If translation is continued into the 3' untranslated region (UTR) of the α -

globin gene, the mRNA becomes unstable and this is associated with a thalassemic phenotype.^{121,122}

Genetics

Unstable hemoglobins are inherited as an autosomal dominant trait with CHBA in the heterozygote. As the clinical consequences are part of the definition of unstable hemoglobinopathies, it is not surprising that β variants are more common than α variants. Each of the two β -globin alleles directs 50% of the total β -globin chain synthesis, whereas there are two α_2 -globin and two α_1 -globin alleles of which α_2 is expressed at about twice the level of α_1 .^{123,124} Each α_2 allele thus accounts for about 30–35% and each α_1 allele for about 15–20% of the total α -chain synthesis. The α_1 variants are therefore mildly expressed phenotypically even when present homozygously.¹²⁵ Also, analogous amino acid substitutions lead to clinically milder presentations in the α -globin than in the β -globin chains. Thus, α -chain variants are less likely to be identified than β -chain variants (e.g., Hb Iwata α F8 His \rightarrow Arg, no anemia, 5% abnormal hemoglobin¹²⁶ vs. Hb Mozhaik β F8 His \rightarrow Arg, Hb 7 g/dL, 32% abnormal hemoglobin and CHBA).¹¹⁴

Variants of the γ -chain are rare. In HbF Poole ($G\gamma$ 130 Trp \rightarrow Gly) there is neonatal (and presumably fetal) hemolytic anemia that disappears with the fetal to adult hemoglobin switch after the first few months of life.¹²⁷ More severe γ -chain variants are not known, probably due to the duplication of the γ genes and to the negative selection bias presumably operating in fetal hemoglobinopathies.

No selective pressure seems to have favored unstable hemoglobins in the course of evolution. Therefore, these variants are generally rare and have often been described in single families only. Spontaneous mutations are not uncommon.

There are single reports of patients who are compound heterozygotes for an unstable variant and a thalassemic mutation. The clinical picture of these cases depends on the degree of instability of the abnormal variant; some are mildly affected,^{128,129} whereas others exhibit severe hemolytic disease.¹³⁰ Homozygotes are also exceedingly rare. A patient with homozygous Hb Bushwick (β 74 (E18) Gly \rightarrow Val) was reported to suffer from chronic anemia caused by a combination of hemolysis and ineffective erythropoiesis that was severely exacerbated at times of infection.¹³¹

Clinical features

The age at presentation and the severity of CHBA depends on the degree of instability and on the type of chain affected. For the reasons discussed above, β -chain variants tend to be more severe than α -chain variants. In severe CHBA, patients may become symptomatic in early childhood. They present either with chronic anemia, a hemolytic crisis associated with fever and/or oxidant stress of sulfonamide medication, or

with an aplastic crisis usually following parvovirus infection.¹³² The urine is often dark due to the presence of bilirubin degradation products (mesobilifuscinuria). Pigment gallstones are also common and may cause colic. Milder unstable variants may not be associated with any clinical symptoms and may only be detected fortuitously.

The findings on clinical examination depend on the severity of the hemolysis. Jaundice and splenomegaly are common. In some, this may be associated with hypersplenism. Cyanosis may be noted in those with a significant methemoglobin concentration (e.g., Hb Freiburg).¹³³ Occasionally, leg ulcers have been described.^{134,135}

The hyperunstable and thalassemic variants can be mild but often cause severe anemia and may present as thalassemia intermedia or even thalassemia major (see below). They differ from other types of CHBA in that Heinz bodies are not necessarily seen, the abnormal hemoglobin cannot be identified by hemoglobin analysis, and the α /non- α ratio is often unbalanced. Ineffective erythropoiesis may be suggested by low reticulocyte counts for the degree of anemia and the degree of plasma transferrin receptor elevation, and by inclusion bodies in the erythroblasts in the bone marrow (Table 11.1).

Laboratory diagnosis

Routine hematology shows signs of hemolytic anemia with reticulocytosis, indirect hyperbilirubinemia, and decreased haptoglobin. Blood films stained with new methylene blue or brilliant cresyl blue show Heinz bodies (see Fig. 11.10). Hemoglobin analysis often demonstrates characteristic findings, allowing the identification of the abnormal variant (Fig. 11.15). Otherwise, DNA analysis will establish the definite diagnosis (see Fig. 11.14).

Treatment

Most patients with CHBA do not require specific treatment. If severe hemolysis is present, folic acid should be supplemented, oxidant drugs avoided, and increased awareness exercised at times of pyrexia. Paracetamol (acetaminophen) or acetylsalicylic acid are generally safe. Sulfonamides should be avoided.

Splenectomy

This is clearly indicated in cases with hypersplenism but has been tried in other patients with varied success. Generally, caution is adequate because of the danger of postsplenectomy septicemia, particularly in young children, and because of postsplenectomy thromboembolism.^{136–138} Penicillin prophylaxis is mandatory and vaccination against *Streptococcus pneumoniae* and *Neisseria meningitidis* is indicated and should ideally be performed 3 months before the operation.^{139,140} The duration of penicillin prophylaxis is controversial and

recommendations are often based on anecdotal reports. Controlled studies are difficult because of the rarity of this complication and the uncertain long-term compliance of patients. However, there are numerous reports of postsplenectomy septicemia occurring many years after the operation and the risk probably depends on the underlying disorder. There are also reports of postsplenectomy pulmonary embolism following the development of polycythemia and pulmonary hypertension in unstable hemoglobinopathies.^{141,142} Priapism following splenectomy in a patient with the hyperunstable Hb Olmsted (β 141 [H19] Leu \rightarrow Arg) has been reported,¹⁴³ which is also a well-recognized complication of splenectomy in thalassemia intermedia.^{144–146}

Cholecystectomy

Gallstones are often asymptomatic and do not generally require treatment. However, in patients with colic or stones in the bile duct, surgical treatment may be warranted.

Hydroxycarbamide

This drug has a definite place in the therapy of adults and children with sickle cell disease^{52,147–150} and possibly in thalassemia intermedia.^{51,152} There has also been a report of two adult patients with severe CHBA who benefited from hydroxycarbamide treatment.¹⁵³

Thalassemic variants

In these variants there is, in addition to the structural abnormality, a net decrease in globin chain synthesis, which may be caused by reduced transcriptional activity, a decrease in mRNA processing efficiency or mRNA stability, or increased posttranslational degradation (see Table 11.1). There are clinical and hematologic characteristics of thalassemia (Fig. 11.16), such as hypochromia, microcytosis, splenomegaly, and anemia due to ineffective erythropoiesis and dyserythropoiesis in the β -chain variants or signs of hemolysis in the α -chain variants.

Pathogenesis and clinical features

The paradigm of this type of hemoglobin variant is Hb Lepore, which contains a $\delta\beta$ fusion chain. This is coded for by a $\delta\beta$ -globin fusion gene that is the result of an unequal cross-over event between the highly homologous δ - and β -globin genes. The cross-over has occurred at three different points: Hb Lepore Boston ($\delta 87\beta 116$),^{154,155} Hb Hollandia ($\delta 22\beta 50$),¹⁵⁶ and Hb Baltimore ($\delta 50\beta 86$).^{157,158} These variants do not differ in their pathogenetic or clinical effect. The transcriptional activity of these fusion genes is controlled by the δ -globin gene promoter containing only a single CACCC-box and is thus much reduced compared with the β -globin gene that contains this regulatory element in duplicate. Heterozygotes

Table 11.1 Thalassemic hemoglobin variants.

Reference	Variant type and name	Mutation	Mechanism
<i>Reduced transcriptional activity</i>			
154–161	Hb Lepore Boston Hb Lepore Hollandia Hb Lepore Baltimore	$\delta\beta$ -globin gene fusion	Transcriptional control by 5-globin gene promoter

for the Hb Lepore anomaly are hypochromic, with about 7–15% of the variant and 2–3% HbF. Compound heterozygotes with a β^0 or a severe β^+ allele on the other chromosome are usually transfusion dependent, as are the rare cases of homozygotes.^{159–161}

The commonest thalassemic hemoglobin variant is HbE

(β 26 Glu \rightarrow Lys), which reaches extraordinarily high gene frequencies in Southeast Asia. Both the β^E mutation and the much rarer variant Hb Knossos (β 27 Ala \rightarrow Ser) cause activation of a cryptic splice site in exon 1 of the β -globin gene and thus defective mRNA processing. In addition, HbE is mildly unstable, which contributes to the reduced

Fig. 11.15 Characterization of unstable variants by starch bloc electrophoresis. Hemolysate of a patient with Hb Köln (A, lane 1) and another with an unidentified unstable hemoglobin (B, lane 2) is compared to a normal control (A, lane 2 and B, lane 1). Modified with permission from Ref. 84.

Fig. 11.16 Peripheral blood film of a splenectomized patient with the highly unstable and thalassemic variant Hb Dresden (β 33–35 Val-Val-Tyr \rightarrow 0–0–Asp) showing marked hypochromia, target cells, and dysplastic normoblasts. Hemoglobin electrophoresis and immobilized pH gradient showed high levels of HbF. The abnormal hemoglobin could not be identified by these methods.

availability of these globin chains. HbE causes hemolysis in the homozygote and thalassemia intermedia or major when in compound with a β^0 -thalassemia mutation. Hb Knossos/ β^0 -thalassemia compound heterozygotes have been described as exhibiting the phenotype of thalassemia intermedia or major.¹⁶²⁻¹⁶⁸

Another example of a variant with impaired splice efficiency is Hb Monroe (β 30 Arg \rightarrow Thr). The G \rightarrow C mutation affects the last nucleotide of the first exon, which is part of the consensus sequence of the splice donor site surrounding the invariant GT dinucleotide.¹⁶⁹ Hb Monroe is a severe

Fig. 11.17 Sequence analysis of the β -globin gene in Hb Dresden. The TGGTCT deletion of a hexanucleotide within codons 33–35 can be readily identified and the structure of the abnormal globin deduced.

β^+ -thalassemia mutation with < 1% residual activity. mRNA stability and globin chain synthesis and stability are reduced in termination codon mutations that cause ribosomal readthrough into the 3'-UTR and an elongation of the α -globin chain (Hb Constant Spring, Hb Icaria, Hb Koya Dora, Hb Seal Rock). Clinically, these defects are typical thalassemia mutations and the variants are detectable in small amounts.^{121,122,170-174}

Finally, a thalassemic phenotype of hemoglobin variants may be caused posttranslationally. In some of these variants the globin chains are markedly unstable and degraded before they can be incorporated into the tetramer. Others cause hyperinstability of the complete hemoglobin molecule. In either case, protein-based analytical techniques are unlikely to be informative and DNA analysis has to be employed (Fig. 11.17). A special type of abnormality that may be classified with this group of variants is characterized by premature translational stop codons in the third β -globin exon, which results in the synthesis of C-terminally truncated and nonfunctional globin chains. In all these mutations, the erythropoietic precursor in the bone marrow has to degrade α - and β -globin chains, which overloads the proteolytic capacity of the system and causes ineffective erythropoiesis.^{105,175,176} The clinical hallmark of these abnormalities is the dominant mode of inheritance of the thalassemic phenotype, which may be mild or severe with chronic transfusion requirements.

Genetics

In these variants typical features of thalassemia are seen in the heterozygote. If expressed in sufficient amounts, the diagnosis may be made by hemoglobin analysis. Otherwise, DNA analysis will identify the gene mutation, enabling the deduction of the amino acid substitution in most cases.

Treatment

Treatment guidelines for thalassemia intermedia and major are described in Chapter 15.

Variants with increased oxygen affinity

In these variants the equilibrium between the R-quaternary and T-quaternary conformation is disturbed and the R form is more readily assumed. The sigmoid oxygen binding curve is shifted to the left, i.e., oxygen uptake in the lungs is facilitated and oxygen release in the peripheral tissues impeded. Many variants with altered oxygen affinity are also unstable to some degree. In contrast to CHBA, the clinical hallmark of variants with altered oxygen affinity is erythrocytosis/polycythemia but not hemolysis. A continuously updated list of the variants can be found in the globin database.²

Pathogenesis

The more the oxygen binding curve is shifted to the left, the more difficult it is for the tetramer to change its quaternary conformation. Generally, this loss of allosterism results in loss of the cooperative and Bohr effects. These variants thus resemble other hemoproteins such as myoglobin, and with an increasing degree of oxygen affinity tend not to function as oxygen carriers. Although there is no hypoxemia, oxygen availability is decreased. This results in erythropoietin production and erythrocytosis as a compensatory mechanism. Most patients with high-affinity variants show normal exercise tolerance, although blood loss or venesection to a numerically normal hemoglobin may result in clinically relevant hypoxia.^{197–200}

Many high-affinity variants have substitutions at the $\alpha_1\beta_2$ interface, where most of the allosteric changes occur. The C-terminal ends of the subunits are also important sites for high-affinity variants because they greatly contribute to the stabilization of the T-conformation forming salt bonds (α 141 Arg, β 146 His) and to the anchoring of the loose end in a pouch between the F and H helices (α 140 Tyr, β 145 Tyr). In addition, 2,3-DPG binding can be affected by changes of β 143 His or β 82 Lys.^{15,201–212}

Genetics

High-affinity traits are autosomal dominant, with α variants usually less apparent than β variants for the reasons discussed

above. Homozygotes or compound heterozygotes with β -thalassemia mutations are rare and expected to be viable only in variants with a moderate increase in oxygen affinity and preserved functional properties. For example, the high-affinity variant Hb Headington (β 72 [E16] Ser \rightarrow Arg) exhibits a moderate decrease in cooperativity and a normal Bohr effect. In compound with $\delta\beta^0$ -thalassemia, a 62-year-old male has been reported to have erythrocytosis but no symptoms related to this abnormality.²¹³ Rather more severely, a patient with thalassemia intermedia has been reported to be compound heterozygous for $\delta\beta^0$ -thalassemia and Hb Crete (β 129 [H7] Ala \rightarrow Pro), which is an unstable variant with high oxygen affinity but normal Bohr effect.²¹⁴

Clinical features

Most patients are asymptomatic but may present with a violaceous complexion or peripheral cyanosis. Splenomegaly occurs in some patients but is not common. Most commonly, high-affinity variants are detected on a routine blood count showing erythrocytosis. Hyperviscosity-related symptoms do not usually occur, although there are anecdotal reports of exceptions.²¹⁵ In theory, oxygen delivery to the fetus will be affected if the mother's blood contains a high-affinity hemoglobin. In practice, however, this is not the case and for mothers with an exclusive or predominant occurrence of HbF, fetal outcome is normal.^{216–218}

Laboratory diagnosis

The blood count shows erythrocytosis to be the commonest abnormality. The hemoglobin ranges between 17 and 22 g/dL. In some patients, leukocytosis has been reported and polycythemia vera must be carefully excluded in these cases.

Only about 50% of all high-affinity variants are detectable electrophoretically. The diagnosis can be established by measuring the oxygen dissociation curve of the hemolysate²¹⁹ and by DNA analysis.

Treatment

Variants with high oxygen affinity cause benign changes in the hematologic parameters. Erythrocytosis is the mode of compensation for decreased oxygen availability. Phlebotomy should therefore not generally be performed but exceptions may be the rare cases with symptoms related to hyperviscosity. It is important to establish the correct diagnosis in order to avoid inappropriate therapy.²²⁰

Variants with decreased oxygen affinity

Pathogenesis

In these rare variants the T-conformation is stabilized, thus

impeding oxygen uptake and facilitating oxygen unloading. This right shift of the oxygen binding curve leads to good oxygen availability to the peripheral tissues but a less active hematopoietic stimulus, and slight anemia is a possible feature.

Clinical features

Heterozygous individuals are healthy but may have slight anemia without functional consequences. Cyanosis due to incomplete oxygen loading is a feature of some low-affinity variants such as Hb Kansas (β 102 Asn \rightarrow Thr), Hb Beth Israel (β 102 Asn \rightarrow Ser) and Hb St Mande (β 102 Asn \rightarrow Tyr). However, exercise tolerance is not affected, because of the facilitated oxygen delivery.^{221–224} As there are no functionally significant clinical symptoms, treatment is not required.

HbM anomalies

The HbM anomalies are rare variants that occur throughout the world. They are characterized by amino acid substitutions of the heme iron-binding region that cause permanent and virtually complete oxidation of the heme iron to the ferric (Fe^{3+}) form. HbM variants are therefore unable to carry oxygen and have a typical methemoglobin absorption spectrum. Instability is not a prominent feature of the M hemoglobins, which also differentiates M hemoglobins from the unstable variants with a high rate of spontaneous oxidation, such as Hb Freiburg, Hb Tübingen, and Hb St Louis. Heterozygotes are cyanotic without any other clinical symptoms.

Pathogenesis

Normal hemoglobin is slowly oxidized to methemoglobin at a calculated rate of 3% daily. There are five known adult and two fetal HbM variants (Table 11.2). Six of these are His \rightarrow Tyr substitutions of the proximal (F8) or the distal (E7) heme-binding site. Tyr forms a covalent bond with ferric iron which is thus stabilized.²²⁵ In HbM Milwaukee, the hydrophobic Val at position β 67 is substituted by the polar Glu, which binds covalently to the ferric heme iron exactly one helical winding carboxy-terminal of His E7.²²⁶ Methemoglobin formation stabilizes the R-quaternary conformation, which

obliterates hemoglobin function both directly by blocking oxygen loading of the affected subunits and indirectly by increasing oxygen affinity of the normal subunits, thus impeding oxygen delivery.^{227,228}

Normally, methemoglobin is efficiently reduced to ferro-hemoglobin by the NADH-dependent cytochrome b_5 reductase and to a much lesser extent by the NADPH-dependent flavin reductase.^{229–234} The normal methemoglobin concentration is $< 1\%$. Three of the five known adult M hemoglobins cannot be enzymatically reduced and the other two are oxidized too fast for the enzyme to be effective.²³⁵ Clinical tolerance of methemoglobin depends on the acuteness of its formation, very much analogous to the tolerance of anemia. In chronic cases, such as those with M hemoglobins or those with cytochrome b_5 reductase deficiency,²³⁶ methemoglobin concentrations of up to 40% are well tolerated. In contrast, when methemoglobinemia develops suddenly following intoxication with oxidant drugs or chemicals, symptoms of hypoxia may start at levels of 20%.²³⁷ Toxic methemoglobinemia is most likely to occur in infants, whose cytochrome b_5 reductase is only about half as active as that of adults.²³⁸

Genetics and clinical features

M hemoglobins are inherited in an autosomal dominant fashion, although spontaneous mutations are common. Heterozygotes are cyanotic without impairment of physical abilities. The lower levels of α HbM than β HbM can be explained by the presence of four α -globin but only two β -globin genes in the genome (see above). Homozygotes have not yet been described. Newborns with HbFM variants present with transient cyanosis that disappears with the fetal to adult hemoglobin switch.

Laboratory diagnosis

In alkaline hemoglobin electrophoresis, M hemoglobins may be detected as a grayish-green band that migrates slightly more slowly than HbA. At pH 7.0, HbM can be separated from normal methemoglobin following ferricyanide oxidation. The absorption spectrum of HbM at pH 6.8–7.0 is characteristically changed in comparison to normal

Table 11.2 HbM anomalies.

	Structure	Hb (g/dL)	Variant (%)	Hematology
HbM Boston ²²⁵	α 58 (E7) His \rightarrow Tyr	15	25–32	Cyanosis
HbM Iwate ²³⁹	α 87 (F8) His \rightarrow Tyr	17	20–27	Cyanosis
HbM Saskatoon ²⁴⁰	β 63 (E7) His \rightarrow Tyr	13–16	35–40	Cyanosis and some degree of hemolysis
HbM Hyde Park ²⁴¹	β 92 (F8) His \rightarrow Tyr	10–12.5	25–40	Cyanosis and some degree of hemolysis
HbM Milwaukee ²⁴²	β 67 (E11) Val \rightarrow Glu	14–15	26–40	Cyanosis
HbFM Osaka ²⁴³	γ 63 (E7) His \rightarrow Tyr			Cyanosis of the newborn
HbFM Fort Ripley ^{244,245}	γ 92 (F8) His \rightarrow Tyr			Cyanosis of the newborn

Acquired: toxins, drugs

methemoglobin, although DNA analysis is probably the most efficient method to confirm the diagnosis.

Treatment

The most important treatment is to establish the diagnosis (Table 11.3) and to reassure the patient and parents of the normal physical prognosis. Unnecessary and possibly dangerous diagnostic procedures to exclude heart and lung disease must be avoided. Redox agents such as methylene blue or ascorbic acid have no effect.

Cyanosis occurs at levels of normal deoxyhemoglobin > 5 g/dL. It follows that acquired conditions that result in inadequate oxygenation are the commonest causes of cyanosis. In severe polycythemia, cyanosis may occur in the absence of hypoxemia. Methemoglobinemia or sulfhemoglobinemia are rare causes of cyanosis (>1.5 g/dL methemoglobin; >0.5 g/dL sulfhemoglobin) and may be inherited or acquired.

Red cell membrane abnormalities

Patrick G. Gallagher

The erythrocyte membrane provides a protective layer between hemoglobin and other intracellular components and the extracellular environment. It facilitates the transport of cations, anions, urea, water, and other small molecules in and out of the cell, but denies entry to larger molecules, particularly if they are charged. It is a sturdy yet flexible container, consisting of a lipid bilayer studded with numerous integral proteins and an underlying proteinaceous membrane skeleton. With only a limited capacity for repair or self-renewal, it lasts the entire 120-day lifespan of the normal red cell. This chapter summarizes the structure and functions of the normal red cell membrane and reviews the major red cell membrane abnormalities that cause human disease.

Membrane lipids

Components

Lipids comprise about 50% of the weight of the erythrocyte membrane. The average human red cell contains about 455 million lipid molecules, all found within the lipid bilayer of the plasma membrane. Phospholipids and unesterified cholesterol, present in nearly equimolar concentrations, predominate, but there are small amounts of glycolipids, primarily globoside, the parvovirus receptor.¹⁻⁴ The major phospholipids are phosphatidylcholine, phosphatidylethanolamine, sphingomyelin, and phosphatidylserine. Small quantities of phosphatidic acid, phosphatidylinositol and lysophosphatidylcholine are also found. The typical phospholipids, with the exception of sphingomyelin and lysophosphatidylcholine, are composed of a glycerol backbone with two medium-chain fatty acids attached via an ester or vinyl linkage. The composition of fatty acids partially determines the properties of the various phospholipids and can affect membrane properties.⁵ A family of red cell enzymes with specificity for each phospholipid class is thought to maintain the precise fatty acyl composition characteristic

of that class.⁶ Lysophospholipids, the precursors of phospholipids, have a single fatty acid attached to the first position of the glycerol backbone.

Phosphoinositides are phospholipids with a phosphoinositol-containing polar head group, which may be mono-phosphorylated (phosphatidylinositol-4-monophosphate) or bi-phosphorylated (phosphatidylinositol-4,5-bisphosphate).⁷ Although representing only 2–5% of membrane phospholipids, phosphoinositides have considerable biologic activity and are involved in maintaining red cell shape and deformability.⁸ Some membrane proteins, including proteins involved in complement regulation, are anchored to the red cell membrane through a phosphoinositol lipid domain.⁹ This allows these proteins to move laterally in the membrane, preventing complement-mediated membrane damage. Phosphoinositol-anchored proteins are lost through the release of lipid-enriched vesicles from the cell during the membrane remodeling that accompanies reticulocyte maturation or cell aging. This process of vesiculation and loss of complement regulatory proteins is accelerated in sickle cell anemia by repeated cycles of sickling, making these cells sensitive to complement-mediated lysis.¹⁰

Organization and dynamics

Under physiologic conditions, the lipid bilayer is in a liquid state allowing both the transmembrane proteins and the cell surface molecules to move in the plane of the membrane. Bilayer fluidity is influenced by several factors, including temperature, which determines the phase transition between a liquid and gel state, the content of free cholesterol (the rigid sterol ring of which decreases lipid bilayer fluidity), and the length and the degree of unsaturation of phospholipid fatty acids. The saturated fatty acids have a relatively rigid backbone, resisting motion, while unsaturated fatty acids have relatively unrestricted movements, thereby increasing the fluidity of the lipid bilayer.

Phospholipids are asymmetrically distributed throughout

the membrane. Phosphatidylserine and phosphatidylethanolamine are primarily in the inner leaflet, while sphingomyelin and phosphatidylcholine are concentrated in the outer half of the bilayer. This asymmetric distribution of phospholipids is a dynamic system involving a constant exchange (“flip-flop”) between the phospholipids of the two bilayer leaflets.^{11,12} In pathologic states, outward exposure of phosphatidylserine, such as occurs in sickle cell disease, β -thalassemia, diabetes and other disorders, leads to activation of blood clotting via conversion of prothrombin to thrombin and red cell attachment to macrophages of the reticuloendothelial system, marking them for destruction.^{13–17} Factors maintaining normal phospholipid asymmetry include a “flippase” or aminophospholipid translocase, which is responsible for magnesium ATP-dependent translocation of phosphatidylserine and phosphatidylethanolamine from the outer leaflet to the inner one; a “floppase” or phospholipid translocase, which moves phospholipids from the outer leaflet to the inner one; and a calcium-dependent phospholipid “scramblase”, which facilitates bidirectional movements of phospholipids in the bilayer.^{18–21}

Changes in the asymmetric distribution of phospholipids have profound effects on red cell shape and other properties. Increasing flip-flop rates perturb phospholipid asymmetry. Examples include an increase in cytosolic calcium, which induces phospholipid scrambling, oxidative cross-linking of membrane proteins, or, in deoxygenated sickled red cells, uncoupling of the lipid bilayer from the underlying skeleton at the tips of the sickle cell spicules.

Glycolipids and cholesterol are intercalated between membrane phospholipids with their long axes perpendicular to the bilayer plane.²² Cholesterol molecules are distributed evenly across the bilayer but glycolipids are localized to the outer leaflet where they contribute to the structure of the blood group antigens. The shape of the lipid bilayer is responsive to slight variations in the surface area of either the inner or outer leaflet, termed the “bilayer couple effect”. This effect predicts that erythrocyte membrane shape changes are the result of expansion of one lipid leaflet compared with the other and that commensurate alteration of the unperturbed leaflet can compensate for such expansion, restoring the normal biconcave shape.²³ Increasing the surface area of the inner leaflet produces a stomatocytic change in shape whereas increasing that of the outer leaflet transforms the cell into an echinocyte.

There is an increasing realization that lipids exist in different domains within each of the bilayer leaflets.^{24,25} Large lipid-rich macroscopic domains have been observed in the membrane. Lipids have also been found in protein-bound microscopic domains. Recently, the presence of lipid-associated domains associated with the detergent-resistant fraction of the membrane, termed “lipid rafts” by some, has been described.²⁶ The precise functions of these specific domains have yet to be elucidated. It has been suggested that

lipid rafts play a role in facilitating malarial invasion of the erythrocyte.^{27–29}

Lipid renewal pathways

Mature erythrocytes are unable to synthesize fatty acids, phospholipids, or cholesterol and thus exchange pathways are the mechanism of lipid modification of red blood cells. In the circulation, erythrocyte cholesterol is rapidly exchanged with unesterified cholesterol from plasma lipoproteins.³⁰ The outer bilayer phospholipids, phosphatidylcholine and sphingomyelin, are slowly exchanged with plasma lipids. Phosphatidylserine and phosphatidylethanolamine, located in the inner bilayer, do not participate in lipid exchange. Another potential lipid renewal pathway is fatty acid acylation. This is an ATP-dependent process in which fatty acids combine with lysophosphatides to remake the native phospholipids, renewing damaged or lost fatty acid side-chains. The composition of red cell phospholipids is quite distinct from that of plasma phospholipids, suggesting that specific pathways exist in red cells to remodel phospholipids to optimize their function. Dietary changes have only a minimal effect on the composition of red cell membrane phospholipids.³¹ In contrast, it is likely that oxidant damage, particularly to unsaturated fatty acid groups, can alter membrane structure and function. Removal of oxidized fatty acids and replacement by normal fatty acids appears to be essential for red cell survival.

Membrane proteins

The red cell membrane contains about a dozen major proteins and hundreds of minor ones. The major proteins of the red cell membrane (Fig. 12.1 and Table 12.1) and their disorders have been intensively studied. Membrane proteins may be classified as either integral, i.e., penetrating or crossing the lipid bilayer and interacting with the hydrophobic lipid core, or peripheral, i.e., interacting with integral proteins or lipids at the membrane surface but not penetrating into the bilayer core.

Components

The integral membrane proteins include glycophorins A, B, C, and D, which possess membrane receptors and antigens, and transport proteins such as band 3, the erythrocyte anion exchanger.^{32–34} The glycophorins, which provide most of the negative surface charge red cells require to avoid sticking to each other and to the vascular wall, carry receptors for *Plasmodium falciparum* and various viruses and bacteria, and serve as conduits for transmembrane signaling.³⁵ Band 3, the major integral protein of the red cell, serves many functions, including as a chloride–bicarbonate exchanger, a binding site for a variety of enzymes and cytoplasmic membrane

Fig. 12.1 Erythrocyte Membrane. A model of the major proteins of the erythrocyte membrane is shown: α and β spectrin, ankyrin, band 3 (the anion exchanger), 4.1 (protein 4.1) and 4.2 (protein 4.2), actin and glycophorin. components, and a participant in regulation of red cell deformability, intermediary metabolism, senescence, and shape.^{36,37} Other integral proteins include the Rh proteins, Kell and Duffy antigens, glucose, urea and amino acid transporters, Na⁺/K⁺-ATPase, Ca²⁺-ATPase, Mg²⁺-ATPase, various kinases and phosphatases, acetylcholinesterase, decay accelerating factor, complement proteins, and receptors for transferrin, insulin, insulin-like growth factors, thyroid hormone, parathyroid hormone, β -adrenergic agonists, cholinergic agents, diphtheria toxin, ceruloplasmin and opiates.

Peripheral membrane proteins include the structural proteins of the spectrin-based erythrocyte membrane skeleton and enzymes such as glyceraldehyde 3-phosphate dehydrogenase. The membrane skeleton is composed of an intricately interwoven meshwork of proteins and is largely responsible for the biconcave disk shape of the red cell.^{38–40} It comprises approximately half the membrane protein mass and is primarily composed of spectrin. Spectrin is composed of two subunits, α and β spectrin, encoded by separate genes, that both contain 106 amino acid α -helical “spectrin repeats” composed of triple helices connected by short connecting regions. The α - and β -spectrin chains intertwine in an antiparallel manner to form 100-nm long heterodimers, which self-associate head to head to form tetramers and oligomers. These higher-order molecules provide significant flexibility and structural support for the lipid bilayer, helping maintain cellular shape. Disruption of spectrin self-association leads to membrane instability, altered membrane deformability and mechanical properties, and abnormal erythrocyte shape.

The primary linkage of spectrin to the erythrocyte membrane is mediated by the binding of spectrin to ankyrin, which in turn binds to band 3.⁴¹ Protein 4.2 binds to band 3 and probably binds to ankyrin, possibly promoting their interaction.⁴² Disruption of the spectrin–ankyrin–band 3 linkage or the band 3–protein 4.2 interaction leads to membrane loss and the phenotype of spherocytosis.

A second linkage of spectrin to the plasma membrane is mediated by its association with a multiprotein “junctional complex” that includes spectrin, protein 4.1, and actin.⁴³ Protein 4.1, a protein with numerous erythroid and non-erythroid isoforms,⁴⁴ interacts with spectrin and actin as well as proteins in the overlying lipid bilayer, including band 3, glycophorin C, p55, calmodulin, CD44, pIC1n, CASK, mature parasite-infected antigen, and phosphatidylserine. Other important peripheral membrane proteins include p55 (which interacts with protein 4.1 and glycophorin C), the β subtype of actin, adducin, a heteromer of structurally related proteins, α -adducin, β -adducin or γ -adducin, which plays a role in the early assembly of the spectrin/actin complex by capping the ends of fast-growing actin filaments and by recruiting spectrin to the ends of actin filaments, dematin, tropomyosin, and tropomodulin. Disruption of the protein–protein interactions of the junctional complex also leads to membrane defects and inherited hemolytic anemia.

Membrane synthesis

Membrane proteins are synthesized early in the differentiation of erythroid progenitor cells. Events controlling membrane synthesis and assembly are poorly understood. There is considerable *in vitro* evidence suggesting that spectrin and ankyrin are assembled onto the membrane in only small amounts until band 3 is synthesized and introduced into the bilayer, providing an attachment site for ankyrin, spectrin, and the other skeletal proteins in sequence.⁴⁵ These data suggested a pivotal role for band 3 in membrane assembly. However, creation of a band 3 knockout mouse has led to reexamination of the role of band 3 in membrane protein assembly, because nearly normal amounts of skeletal proteins are present in the erythrocyte membranes of these mice despite the total absence of band 3.⁴⁶ Further studies have shown that protein 4.2 can assemble on the membrane in the absence of band 3. There is asymmetric synthesis of α and β spectrin, the former exceeding the latter by several fold. Proteins not incorporated into the membrane are rapidly degraded and lost. Similarly, large excesses of protein 4.1 are generated relative to the amount actually incorporated into the membrane skeleton. Overall, membrane protein biosynthesis and incorporation can be viewed as a somewhat inefficient process.

Membrane deformability

The normal red cell has a biconcave disk shape in the resting state, but in circulation it assumes elliptical, parachute-like, or other shapes in response to circulatory shear forces. Its ability to deform is determined by the surface area–volume ratio, cytoplasmic viscosity, and membrane material properties.⁴⁷ A decrease in the surface area–volume ratio, as is seen in spherocytes, reduces deformability and may impede passage of the red cell through constricted areas of the microcirculation, as found in the spleen. Changes in cytoplasmic viscosity are usually the result of osmotic movement of water into or out of the red cell. Movement of water into the cell decreases cytoplasmic viscosity but causes an increase in cell volume without affecting surface area, thus adversely affecting deformability. Movement of water out of the cell increases cytoplasmic viscosity and consequently decreases deformability. Optimal deformability is noted at physiologic plasma osmolality (290 mosmol). Membrane material properties are complex, as the membrane behaves as a solid, semisolid or liquid depending on the duration and strength of the deforming force exerted. The force required to increase surface area is primarily determined by the lipid bilayer, whereas most other behaviors such as elasticity, elastic recoil, and yield shear stress are determined by the intrinsic and cytoskeletal protein network.⁴⁸ Many of the proteins of the red cell membrane are subject to posttranslational modification by phosphorylation, glycosylation, myristylation, fatty acid acylation, sulfhydryl-mediated oxidation, calmodulin,

calpain-mediated proteolysis, and other processes that affect membrane properties in various ways.

Membrane transport

Water, urea, glucose, anions, and many other molecules move across the red cell membrane. This discussion is limited to cations, as disorders of cation transport are those most frequently associated with various human red cell disorders.^{49,50} The normal red cell has an internal cation content quite different from that of the surrounding plasma.⁵¹ The red cell K^+ concentration is high (~140 mmol/L cell water) compared with plasma K^+ concentrations of 4–5 mmol/L, whereas the red cell Na^+ concentration is low (~10 mmol/L cell water) compared with the plasma Na^+ concentration of about 140 mmol/L.⁵² These concentration gradients lead to a small passive movement across the lipid bilayer of Na^+ into and K^+ out of the cell. Cation homeostasis is maintained by the active transport of Na^+ out of and K^+ into the cell with a 3 : 2 stoichiometry that exactly equals the normal passive movement of these cations. The Na^+/K^+ -ATPase pump responsible for active transport couples the hydrolysis of ATP to the movement of Na^+ and K^+ . The pump is a multimer composed of a catalytic α subunit and smaller β and γ subunits. Two other cation transport pathways are of importance, the Gardos channel and K/Cl cotransport. The Gardos channel is activated by increased intracellular Ca^{2+} , usually the result of ATP depletion, and promotes loss of intracellular K^+ and ultimately cell dehydration.⁵³ The volume-activated K/Cl cotransport pathway, also leads to cell dehydration secondary to the loss of K^+ .⁵⁴ Both these pathways have been targeted to prevent cellular dehydration and sickling in sickle cell disease.^{49,55} Finally, mechanical stretching of the membrane may lead to cation loss, a process likely to be of importance in the cellular dehydration that follows sickling deformation of hemoglobin SS red cells. The molecular basis of this pathway is unknown.

Fetal and neonatal red cell membranes

The membranes of fetal and neonatal erythrocytes differ from those of adult cells.⁵⁶ Increased myosin, cholesterol, and lipid phosphorus, and decreased aquaporin have been observed,^{56–58} but the functional significance of these observations is unknown. Increased potassium loss, reduced chloride/bicarbonate exchange, and decreased water transport are other features of neonatal red cells.⁵⁹ The blood group antigen systems of neonatal cells are not fully developed and there are expression differences in the Ii antigen of band 3. There is significant variation in size and shape of neonatal cells. Thus irregularly shaped cells such as poikilocytes, acanthocytes, and burr cells are much more common on peripheral blood smears from neonates than on those from adults. There is a striking loss of surface area as neonatal

red cells age⁵⁷ and this, along with cation loss and dehydration, creates a subpopulation of dense, poorly deformable, older cells destined for early destruction, contributing to the shortened life of the neonatal erythrocyte.⁶⁰ The neonatal erythrocyte exhibits decreased deformability, reflected in increased osmotic resistance, which normalizes by 4–6 weeks of age. The practical correlate of this observation is that osmotic fragility curves generated from control neonatal erythrocytes should be used when testing a neonate for hereditary spherocytosis (HS) (see below). The performance of osmotic fragility testing need only be delayed in cases when there is potential for confusion between HS and spherocytosis from other causes, e.g., ABO incompatibility.

Hereditary spherocytosis

The hallmark of this group of heterogeneous disorders is the presence of spherocytes on the peripheral blood smear.^{61,62} Hemolysis is commonly accompanied by anemia of variable severity. Inheritance is autosomal dominant in two-thirds to three-quarters of patients. In the remainder, inheritance is autosomal recessive or due to a *de novo* mutation.^{63–66} The incidence of HS is about 1 in 2500–4000 in northern European populations, but this is likely to be an underestimate as mild cases are often not diagnosed.⁶⁷ In other parts of the world, the disease is thought to be less common, although comprehensive population survey data are unavailable.

Clinical features

Anemia in HS may be absent, mild, moderate, or severe to the point of threatening life.⁶³ Patients with “typical” HS suffer from mild to moderate anemia.

- *Mildly affected individuals* exhibit no anemia, have modest reticulocytosis, and may not be detected until adolescence or adult life. They maintain normal hemoglobin levels in the face of accelerated erythrocyte destruction by virtue of an erythropoietin-driven increase in erythropoiesis.⁶⁸
- *Moderately affected individuals* are more anemic, have higher reticulocyte counts and elevated serum bilirubin levels, may require occasional transfusions, and are usually detected in infancy or childhood. As noted in the earliest descriptions of HS, mild intermittent jaundice may be the only symptom of the disease. Splenomegaly develops in most patients, with the spleen occasionally reaching large dimensions.
- *Severely affected individuals* have marked hemolysis, anemia, hyperbilirubinemia, splenomegaly, and typically require regular red cell transfusions, particularly during infancy and early childhood.⁶³ Some of these infants present in the first few months of life with severe life-threatening hemolysis.⁶⁹ In the most severe cases, there is prenatal onset; hydrops fetalis and *in utero* demise may occur.⁷⁰ As in other chronic

hemolytic anemias, exacerbations of anemia may be aplastic, hemolytic, or megaloblastic in origin.

- *Aplastic crisis* may occur as a result of transient marrow suppression by parvovirus B19 or other viral infections. Parvovirus B19 selectively infects erythroid precursors and inhibits their growth. The ensuing anemia, often severe, may be the first manifestation of HS. Multiple family members with undiagnosed HS who are infected with parvovirus have developed aplastic crises at the same time, leading to descriptions of “outbreaks” of HS. Infection with parvovirus is a particular danger to susceptible pregnant women because it can infect the fetus, leading to fetal anemia, hydrops fetalis, and fetal demise.

- *Increased hemolysis* may accompany viral illnesses, probably as a consequence of concomitant splenomegaly associated with the illness (the crucial role of the spleen in spherocyte destruction is discussed below).

- *Megaloblastic anemia* may be superimposed on the chronic hemolytic anemia of HS due to an unmet increased demand for folate to support erythropoiesis. This typically occurs in patients with increased folate demands, i.e., those recovering from an aplastic crisis, pregnant women, and the elderly. Megaloblastic crisis in pregnancy has been reported as the first manifestation of HS.

When detected in the neonatal period, HS is frequently accompanied by jaundice, requiring treatment with phototherapy or exchange transfusion.⁶³ This is thought to be due to coinheritance of Gilbert syndrome. In the neonatal period, spherocytosis on the peripheral blood smear and reticulocytosis are often minimal or even absent.⁷¹

Complications

A common complication is the formation of bilirubinate gallstones, found in at least half of adult patients with HS. Gallstones have been detected in infancy, but they are most likely to be found in older children and young adults.⁷² The coinheritance of Gilbert syndrome markedly increases the risk for gallstones.^{73,74} Because of their high incidence, HS patients should be periodically examined by ultrasound for the presence of gallstones, beginning early in childhood.

Rare complications or associations include leg ulcers and/or dermatitis that heal after splenectomy, gout, extramedullary hematopoietic tumors,^{75,76} spinocerebellar degenerative syndromes, hypertrophic cardiomyopathy, and movement disorder with myopathy. A number of cases of HS and hematologic malignancy, including myeloproliferative disorders and leukemia, have been reported. It has been suggested that persistent hematopoietic stress predisposes to the development of these disorders.

Laboratory diagnosis

Many cases of HS are initially suspected because spherocytes

are found on the peripheral blood smear in a patient with a family history of HS (Fig. 12.2). Spherocytes are a feature of many hemolytic anemias, so their identification on the peripheral blood smear alone is not sufficient to establish a diagnosis of HS (see below). Typical HS patients have obvious spherocytes lacking central pallor on peripheral blood smear. Less commonly, only a few spherocytes are present or, in severe cases, there are numerous small dense spherocytes and bizarre erythrocyte morphology with anisocytosis and poikilocytosis. Molecular studies have shown that specific morphologic findings are associated with certain membrane protein defects, such as “pincered” erythrocytes (band 3), spherocytic acanthocytes (β spectrin), or spherostomatocytes (protein 4.2) (Fig. 12.2).

Routine blood counts in HS reveal anemia and reticulocytosis to varying degrees, with most patients exhibiting mild to moderate anemia. Despite the increased percentage of reticulocytes with a larger volume than mature red cells, mean corpuscular volume (MCV) is normal or slightly low. The most helpful red cell index is mean corpuscular hemoglobin concentration (MCHC), which is usually elevated, reflecting red cell dehydration.⁷⁷ When combined with elevated red cell distribution width (RDW, >14), an elevated MCHC (>35 g/dL) suggests the diagnosis of HS. In unsplenectomized children, MCHC >35 g/dL and RDW >14 has a sensitivity of 63% and specificity of 100% for the diagnosis of HS.⁷⁸ Measurement of MCV by light scatter analysis provides a histogram of MCHCs that has been claimed to identify nearly all patients with HS.

The reduced surface area–volume ratio characteristic of spherocytes increases their susceptibility to osmotic lysis in hypotonic solutions. This is the basis of the osmotic fragility test, in which red cells are suspended in buffered salt solutions of decreasing tonicity and the degree of hemolysis determined (Fig. 12.3). Incubation of blood specimens for 24 hours in the absence of metabolic substrate accentuates the osmotic fragility of spherocytes and makes easier the distinction of this disease from others. Surprisingly, even after incubation, up to 15% of samples have normal osmotic fragility.⁷⁷ The finding of increased osmotic fragility is not unique to HS and is also present in other conditions associated with spherocytosis. In nonsplenectomized HS subjects, a “tail” of the osmotic fragility curve may be present, indicating a subpopulation of particularly fragile red cells conditioned by splenic stasis. This subpopulation of cells disappears after splenectomy. The relative contributions of cell dehydration and surface area deficiency can be accurately determined by osmotic gradient ektacytometry, available only in specialized laboratories.⁷⁷

Other tests used in the diagnosis of HS are not widely used (e.g., glycerol lysis test, pink test, hypertonic cryohemolysis, and skeleton gelation test). The former two tests, which employ glycerol to retard the osmotic swelling of red cells, are preferred in some laboratories because they are easy to

Fig. 12.2 Peripheral blood smears in hereditary spherocytosis (HS). (a) Two blood smears of typical moderately severe HS with a mild deficiency of red cell spectrin and ankyrin. Although many cells have spheroidal shape, some retain a central concavity. (b) HS with pincered red cells (arrows), as typically seen in HS associated with band 3 deficiency. Occasional spiculated red cells are also present. (c) Severe atypical HS due to severe combined spectrin and ankyrin deficiency. In addition to spherocytes, many cells have irregular contour. (d) HS with isolated spectrin deficiency due to a β -spectrin mutation. Some of the spherocytes have prominent surface projections resembling spherocanthocytes. Reproduced with permission from Gallagher PG, Jarolim P. Red cell membrane disorders. In: Hoffman R, Benz EJ Jr, Shattil SJ et al. (eds) *Hematology: Basis Principles and Practice*, 4th edn. Philadelphia: WB Saunders, 2005, pp. 669–91.

perform and can be adapted to microsamples. Flow cytometric analysis of eosin-5-maleimide binding to erythrocytes, which reflects relative amounts of Rh-related integral membrane proteins and band 3, has recently been explored as a screening test for HS diagnosis.⁷⁹ Specialized testing, such as membrane protein quantitation, ektacytometry, and genetic analyses, are available for studying difficult cases or when additional information is desired.

Other laboratory manifestations in HS are markers of ongoing hemolysis. Reticulocytosis, increased bilirubin, increased lactate dehydrogenase, increased urinary and fecal urobilinogen, and decreased haptoglobin reflect increased erythrocyte production or destruction.

Differential diagnosis

Acquired immune hemolytic disease is the condition that

most closely resembles HS. It can be ruled out by the absence of a family history of hemolytic anemia, the presence of a positive direct antiglobulin test or other manifestations of autoimmune disease, and a relative lack of exacerbation of hemolysis in the incubated osmotic fragility test. In the neonate, some cases of ABO incompatibility may be excluded by mother/infant blood group typing, and by a negative antiglobulin test of newborn red cells. Other diseases in which spherocytes may be seen, such as unstable hemoglobinopathies, glucose 6-phosphate dehydrogenase (G6PD) deficiency, microangiopathic hemolytic anemia, or clostridial sepsis, is distinguished from HS by differences in clinical course, red cell morphology, and clinical laboratory tests specific for each disease. The mechanism of spherocyte production is usually loss of membrane surface area in excess of loss of cell volume. Membrane loss may be secondary to oxidant injury, as in G6PD deficiency or hemoglobin H disease.

Fig. 12.3 Osmotic fragility curves in hereditary spherocytosis (HS). The shaded area is the normal range. Results representative of both typical and severe HS are shown. A “tail”, representing very fragile erythrocytes that have been conditioned by the spleen, is common in many HS patients prior to splenectomy. Reproduced with permission from Dacie J. Hereditary spherocytosis. In: *The Haemolytic Anaemias*. Edinburgh: Churchill Livingstone, 1985, pp. 134–215.

In immune hemolytic anemia, interaction of membrane–antibody complexes with the reticuloendothelial system leads to membrane loss through phagocytosis. Venoms may contain phospholipases or other membrane-active enzymes that induce spherocyte formation. Various types of mechanical hemolytic anemia may generate spherocytes in the process of erythrocyte fragmentation. With the exception of autoimmune hemolytic anemia, spherocytes are rarely the

sole or dominant morphologic abnormality noted in these conditions. Macrospherocytes may be seen when red cell water content is increased and the cell swells, as is the case in hereditary hydrocytosis.

Pathophysiology

The molecular basis of HS is heterogeneous and thus it is likely that the loss of membrane surface area is a consequence of several molecular mechanisms whose common denominator is a weakening of protein–protein interactions that link the membrane skeleton to the lipid bilayer, leading to microvesiculation, loss of membrane surface area, decreased surface area–volume ratio, and spherocytosis (Fig. 12.4). Defects of spectrin, ankyrin, or protein 4.2 lead to reduced density of the membrane skeleton, causing destabilization of the lipid bilayer with the resultant loss of band 3-containing microvesicles. Abnormalities of band 3 result in band 3 deficiency, leading to loss of the lipid-stabilizing effect of band 3 and releasing band 3-free microvesicles from the membrane. Both pathways ultimately result in the loss of membrane material with a reduction in membrane surface area. The ensuing decrease in membrane surface area with formation of spherocytes is paralleled by a decrease in erythrocyte deformability that predisposes the cells to splenic entrapment and conditioning.

The spleen plays a secondary, but important, role in the pathobiology of HS. Splenic destruction of abnormal erythrocytes with decreased deformability is the primary cause of hemolysis experienced by patients with HS.⁸⁰ Reticulocytes are not spherocytic, indicating that the spherocytic change in shape appears after reticulocyte maturation in the circulation.

Fig. 12.4 Pathophysiology of hereditary spherocytosis. The primary defect in hereditary spherocytosis is a deficiency of membrane surface area. Decreased surface area may be produced by two different mechanisms. (a) Defects of spectrin or ankyrin lead to reduced density of the membrane skeleton, destabilizing the overlying lipid bilayer and releasing band 3-containing microvesicles. (b) Defects of band 3 or protein 4.2 lead to band 3 deficiency and loss of its lipid-stabilizing effect. This results in the loss of band 3-free microvesicles. Both pathways result in membrane loss, decreased surface area, and formation of spherocytes with decreased deformability. These deformed erythrocytes become trapped in the hostile environment of the spleen where splenic conditioning inflicts further membrane damage, amplifying the cycle of red cell membrane injury. Reproduced with permission from Gallagher PG, Jarolim P. Red cell membrane disorders. In: Hoffman R, Benz EJ Jr, Shattil SJ et al. (eds) *Hematology: Basis Principles and Practice*, 3th edn. Philadelphia: WB Saunders, 2000, pp. 576–610.

Repeated passages through the splenic cords, a process termed “splenic conditioning”, promotes membrane loss leading to a reduction in surface area–volume ratio and a progressively more spheroid red cell. Reflecting this process, red cells obtained from the splenic vein have greater osmotic fragility than those obtained from the splenic artery. The more spheroidal the red cell, the greater the likelihood that its lack of deformability will prevent its passage through the narrow fenestrations of the splenic cords. Some of these conditioned red cells reenter the systemic circulation, as revealed by the “tail” of the osmotic fragility curve (see Fig. 12.3), indicating the presence of a subpopulation of cells with markedly reduced surface area. After splenectomy, this red cell population disappears.

Detained in the fenestrations of the splenic sinuses, the red cell is subjected to an acidotic, metabolically unfavorable environment where oxidants are prevalent and phagocytic reticuloendothelial cells are ubiquitous. Secondary lesions, such as 2,3-diphosphoglycerate (2,3-DPG) depletion, occur in this setting. Nondeformable spherocytes accumulate in the red pulp, which becomes grossly enlarged. The central importance of the spleen in the production and destruction of spherocytes is most clearly seen when the spleen is removed surgically, for this procedure virtually eliminates hemolysis and anemia in moderately severe cases and eliminates the need for transfusion and partially corrects the anemia in severe cases.

Molecular genetics

HS is the clinical consequence of mutations in the genes encoding ankyrin, band 3, α and β spectrin, or protein 4.2.^{81–83} The molecular basis of HS is heterogeneous and is frequently classified based on findings after quantitation of membrane proteins from HS patients. These abnormalities are combined deficiency of spectrin and ankyrin, isolated deficiency of spectrin, deficiency of band 3, and deficiency of protein 4.2.⁸⁴

Combined deficiency of spectrin and ankyrin

Combined spectrin and ankyrin deficiency is the most common abnormality of the erythrocyte membrane in approximately half to two-thirds of typical HS patients. Ankyrin is the primary binding site on the membrane for the spectrin-based membrane skeleton. Thus ankyrin deficiency leads to a proportional decrease in spectrin assembly on the membrane despite normal spectrin synthesis. Most ankyrin defects are private point mutations in the coding region of the ankyrin gene associated with decreased mRNA accumulation, i.e., deletion, frameshift, or nonsense mutations.^{83,85} In some cases, mutations of the ankyrin promoter leading to decreased ankyrin expression have been found.⁸⁶ Approximately 15–20% of ankyrin gene mutations reported are *de novo* mutations.^{66,87}

A few patients with atypical HS associated with karyotypic abnormalities involving deletions or translocations of the ankyrin gene locus on chromosome 8p have been described. Ankyrin deletions may be part of a contiguous gene syndrome, with manifestations of spherocytosis, mental retardation, typical facies, and hypogonadism.⁸⁸

Isolated spectrin deficiency

The reported mutations of isolated spectrin deficiency include defects of both α and β spectrin. Since α spectrin is synthesized in excess and β -spectrin synthesis is rate limiting for membrane assembly of spectrin tetramer, it is not surprising that mutation of a single β -spectrin allele is sufficient to cause spherocytosis while both α -spectrin alleles must be affected for the same to occur.

Mutations of the β -spectrin gene have been identified in a number of patients with dominantly inherited HS associated with spectrin deficiency.^{89,90} With rare exceptions, these mutations are private and are associated with decreased β -spectrin mRNA accumulation. β -Spectrin^{Kissimmee}, a point mutation located in the highly conserved region of β spectrin involved in the interaction with protein 4.1, is dysfunctional in its *in vitro* binding to protein 4.1 and thereby the linkage of spectrin to actin.⁹¹

In recessive HS associated with isolated spectrin deficiency, the defect involves α spectrin.^{62,92,93} In normal erythroid cells, α spectrin is synthesized in large excess of β spectrin. Thus, subjects with one normal and one defective α -spectrin allele are expected to be asymptomatic, because α -spectrin production remains in excess of β -spectrin synthesis, allowing normal amounts of spectrin heterodimers to be assembled on the membrane. Patients who are homozygotes or compound heterozygotes for α -spectrin defects may suffer from severe HS.^{94,95}

Deficiency of band 3

Deficiency of band 3 is found in a subset of HS patients who present with a phenotype of mild to moderate dominantly inherited HS with mushroom-shaped or “pincered” red cells. Most, if not all, of these patients also have concomitant protein 4.2 deficiency, and a reduction in red cell anion transport proportional to the band 3 deficiency. More than 50 different band 3 mutations associated with HS have been reported.⁸² These mutations are spread throughout band 3 in both the cytoplasmic domain and the membrane-spanning domains. Many of these are frameshift or nonsense mutations associated with complete or near-complete absence of mutant allele mRNA in reticulocytes.^{96,97} A number of band 3 missense mutations clustered in the membrane-spanning domain that replace highly conserved arginines have been described.⁹⁸ In these HS cases, the mutant band 3 most likely does not fold and insert into the endoplasmic reticulum and ultimately into

the erythrocyte membrane after synthesis. Finally, alleles have been identified that influence band 3 expression and that, when inherited in *trans* to a band 3 mutation, aggravate band 3 deficiency and worsen the clinical severity of disease.⁹⁹

Deficiency of protein 4.2

HS associated with isolated protein 4.2 deficiency is an autosomal recessive condition that is usually found in individuals of Japanese ancestry.¹⁰⁰ In these cases, an almost total absence of protein 4.2 from the erythrocyte membranes of homozygous patients is detected. Protein 4.2-deficient erythrocytes may also have a decreased content of ankyrin and band 3. Protein 4.2 deficiency also occurs in association with band 3 mutations, probably as a result of abnormal binding of protein 4.2 to the cytoplasmic domain of band 3.¹⁰¹

Treatment

Splenectomy cures or markedly improves the anemia in most patients with HS.^{63,77,92} Even patients with severe HS exhibit significant clinical improvement, with the degree of spectrin deficiency in HS erythrocytes correlating with the response to splenectomy (Fig. 12.5). After splenectomy, erythrocyte lifespan normalizes, transfusion requirements are decreased or eliminated, and the risk of cholelithiasis is reduced. Reticulocyte counts fall to normal or near normal, spherocytosis and altered osmotic fragility persist, but the “tail” of the osmotic fragility curve, created by conditioning of a subpopulation of spherocytes by the spleen, disappears.

Laparoscopic splenectomy is now the surgical method of choice, resulting in less postoperative discomfort, quicker recovery time, shorter hospitalization, and decreased costs.^{102,103} Even huge spleens can be removed laparoscopically.

The benefits of splenectomy must be balanced against the immediate and long-term risks of the procedure. Operative complications of splenectomy include local infection, bleeding, and pancreatitis. The most feared long-term complication of splenectomy is overwhelming sepsis, often fatal, with encapsulated bacteria, especially *Streptococcus pneumoniae*.¹⁰⁴ One review of 850 postsplenectomy HS cases comprising mostly infants and children found that 30 (3.52%) developed sepsis and 19 (2.23%) died of infection.¹⁰⁵ Another report of 226 splenectomized HS patients estimated the mortality from overwhelming sepsis to be 0.73 per 1000 years. The mortality rates for the 35 children who underwent splenectomy prior to 6 years of age and for the 191 individuals who were older than 6 at the time of splenectomy were 1.12 per 1000 and 0.66 per 1000 years of life after splenectomy, respectively, both far exceeding the rates in the general population.¹⁰⁴ These rates may overestimate the current risk of sepsis, since most of the participants underwent splenectomy prior to the introduction of the pneumococcal vaccine.

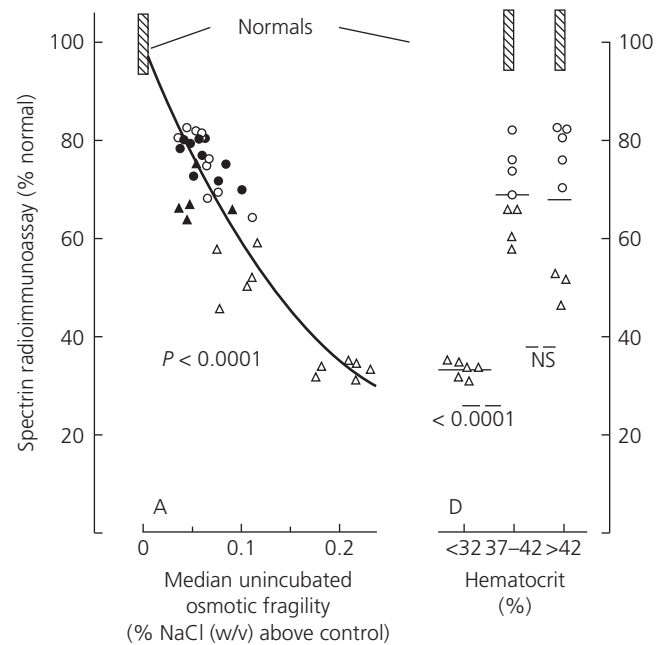

Fig. 12.5 Correlation between spectrin deficiency and unincubated osmotic fragility in hereditary spherocytosis (HS). Spectrin content, as measured by radioimmunoassay, is shown on the vertical axis and osmotic fragility, as measured by NaCl concentration producing 50% hemolysis of erythrocytes, is shown on the horizontal axis. Circles represent patients with typical autosomal dominant HS; triangles represent patients with atypical nondominant spherocytosis. Open symbols represent patients who have undergone splenectomy. The right panel shows the hematocrit of each patient at least 4 months post splenectomy. Reproduced with permission from Ref. 92.

The introduction of pneumococcal, *Haemophilus influenzae*, and meningococcal vaccines and the promotion of early antibiotic therapy for febrile children who have had a splenectomy have led to decreases in the incidence of overwhelming postsplenectomy infection.¹⁰⁶ Some recommend daily oral penicillin prophylaxis, although data to support this are lacking. Others advise having antibiotics available at home for immediate treatment of any significant fever. The emerging risk of penicillin-resistant pneumococcal infections requires vigilance and prompt selection of appropriate antibiotics in ill patients with suspected pneumococcal infection.

In the past, splenectomy was considered “routine” in HS patients. However, the risk of overwhelming post-splenectomy infection, the emergence of penicillin-resistant pneumococci, and growing recognition of increased risk of cardiovascular disease, particularly thrombosis and pulmonary hypertension, have led to reevaluation of the role of splenectomy in HS.^{107,108} Recent HS management guidelines recognize these important considerations and recommend detailed discussion between health-care providers, patient, and family when splenectomy is considered.¹⁰⁹ For instance, splenectomy may pose special risks for individuals living in geographic regions where parasitic diseases such as

Fig. 12.6 Surgical technique used for partial (about 80%) splenectomy. (a) All vascular pedicles supplying the spleen are divided except those arising from the left gastroepiploic vessels. (b) The upper pole of the spleen is removed at the boundary between the well-perfused and poorly perfused tissue. Reproduced with permission from Tchernia G, Gauthier F, Mielot F *et al.* Initial assessment of the beneficial effect of partial splenectomy in hereditary spherocytosis. *Blood* 1993; **81**: 2014.

malaria or babesiosis occur. One approach is to splenectomize patients with severe hemolytic anemia and those suffering from significant signs or symptoms of anemia, including growth failure, skeletal changes, leg ulcers, and extramedullary hematopoietic tumors. Routine use of splenectomy in patients with moderate HS and compensated asymptomatic anemia is controversial. Patients with mild HS and compensated hemolysis can be followed carefully and referred for splenectomy if clinically indicated.

The higher risk of overwhelming sepsis in young children who undergo splenectomy makes it important to defer the operation until at least 6 years of age in all but the most severely affected patients. Recently, partial splenectomy via open laparotomy has been advocated for infants and young children with severe hemolysis and transfusion-dependent anemia (Fig. 12.6).^{110–113} The goals of this procedure are to preserve the immunologic functions of the spleen while reducing the degree of splenic entrapment and destruction of spherocytic red cells and palliating hemolysis and anemia. Long-term data for this procedure are lacking. Rapid regrowth of the spleen may limit its effectiveness. In many cases, complete splenectomy is required, but hopefully at a time when the patients are considerably older and the risk of sepsis is less.

Supportive care with daily oral folic acid is warranted.

Hereditary elliptocytosis

The elliptocytosis syndromes are a heterogeneous group of hereditary erythrocyte disorders that have in common the presence of elongated, oval or elliptical cigar-shaped red cells on peripheral blood smear.¹¹⁴ Inheritance is usually autosomal dominant. The incidence of elliptocytosis in the USA is not greater than 1 in 2000–4000,¹¹⁵ but in malarial regions of Africa it may reach 1.6% of the population¹¹⁶ and in malarial areas of Southeast Asia 30% or higher.

Clinical syndromes

Elliptocytic red cell morphology is the common denominator

in all but the clinically silent forms of this group of patients (Fig. 12.7). Hemolytic anemia ranges from absent to life-threatening. Severe hemolysis is usually a consequence of homozygosity or compound heterozygosity for spectrin self-association site mutations. The clinical features generally fall into one of the following categories as defined by Palek and Jarolim.¹¹⁷

Silent carrier

These individuals are clinically and hematologically normal, but usually have subtle defects in membrane skeletal properties that can be detected in the laboratory. The responsible mutation is most commonly the low-expression spectrin variant, α spectrin^{LELY} (see below), but occasionally one of the structural spectrin mutations usually associated with common hereditary elliptocytosis (HE) may be clinically silent. Silent carriers are usually only detected during analysis of pedigrees containing individuals with more clinically obvious forms of elliptocytosis.

Common hereditary elliptocytosis

This is the most frequent type of HE. Most patients are asymptomatic and come to medical attention only because of the presence of elliptocytes on the peripheral blood smear (Fig. 12.7). Transient hemolytic anemia with more striking morphologic abnormalities (schistocytes, fragments, budding forms, and microcytes) (Fig. 12.7) may be encountered during the neonatal period and infancy, but they usually evolve into typical asymptomatic HE throughout childhood. Episodic hemolysis and morphologic changes like those seen in transient neonatal poikilocytosis may also occur during acute or chronic illnesses characterized by reticuloendothelial hyperplasia,^{118,119} vitamin B₁₂ deficiency,^{120–122} or altered microvasculature.¹²³ Rarely, common HE is associated with lifelong hemolysis. This usually implies the inheritance of an unusually severe spectrin mutation or coinheritance of a low-expression mutation that increases the relative amount of the mutant α -spectrin polypeptide. Homozygous or compound

Fig. 12.7 Peripheral blood smears from subjects with various forms of hereditary elliptocytosis (HE). (a) Simple heterozygote with mild common HE associated with an elliptogenic spectrin mutation. Note predominant elliptocytosis with some rod-shaped cells (arrow) and virtual absence of poikilocytes. (b) "Homozygous" common HE due to doubly heterozygous state for two α -spectrin mutations. Both parents have mild HE. There are many elliptocytes as well as numerous fragments and poikilocytes. (c) Hereditary pyropoikilocytosis: the patient is a double heterozygote for mutant α spectrin and a defect characterized by reduced synthesis of this protein. Note prominent microspherocytosis, micropoikilocytosis, and fragmentation. Only a few elliptocytes are present. Some poikilocytes are in the process of budding (arrow). (d) Southeast Asian (Melanesian) ovalocytosis. The majority of cells are oval, some of them containing either a longitudinal slit or a transverse ridge (arrow). Reproduced with permission from Ref. 117.

heterozygous HE is also often associated with chronic hemolysis, which ranges from moderate to life-threatening and may be accompanied by splenomegaly and other findings of chronic hemolysis.

Hereditary pyropoikilocytosis

Hereditary pyropoikilocytosis (HPP) is the most severe of the elliptocytosis syndromes.^{120,124} The hallmark of this disorder is that the red cells resemble those seen in burn patients and, indeed, are susceptible to budding and fragmentation on heating to 46°C, whereas normal red cells are unaffected at temperatures below 50°C.¹¹⁷ It is now established that HPP represents a subtype of common HE, as evidenced by the coexistence of HE and HPP in the same family and by the presence of the same molecular defect of spectrin. Unlike patients with HE, HPP erythrocytes are also partially deficient in spectrin. In some HPP probands, one HE parent has a structural mutation of α -spectrin while the other parent is fully asymptomatic and has no detectable biochemical abnormality. The asymptomatic parent carries a silent "thalassemia-like" defect of spectrin synthesis, enhancing the relative expression of the spectrin mutant and leading to a superimposed spectrin deficiency in the HPP proband. Other HPP probands have inherited two structural mutations of spectrin from HE parents in a homozygous or compound heterozygous manner. The thermal instability of spectrin originally reported as diagnostic of HPP is not unique for this disorder; it is also found in the erythrocytes of some HE patients.

Hemolytic anemia usually first appears in the neonatal

period and resembles the transient neonatal hemolysis described above in common HE infants. However, in HPP the morphologic abnormalities of the red cells (poikilocytes, spherocytes, fragmentation, and extreme microcytosis) (Fig. 12.7) and the hemolytic anemia is lifelong rather than transient. An abundance of microspherocytes and, often, a paucity of elliptocytes on the peripheral blood smear are features that distinguish HPP from the hemolytic forms of common HE. HPP patients develop splenomegaly, may require transfusions for episodes of anemia, and often require splenectomy. HPP is seen predominantly in black subjects, but it has also been diagnosed in Arabs and Caucasians.

Spherocytic elliptocytosis

Typically seen only in Caucasians, this is a dominantly inherited disorder producing mild-to-moderate hemolysis, splenomegaly, and red cells that range from spherocytes to elliptocytes. The elliptocytes are often few in number and fragmentation, budding and extreme microcytosis are absent, distinguishing spherocytic elliptocytosis from HPP and the other hemolytic forms of common HE.

Southeast Asian ovalocytosis

Common in New Guinea and other malaria-ridden regions of Southeast Asia, Southeast Asian ovalocytosis is a dominant asymptomatic condition that is thought to confer protection against *P. falciparum* infection.^{125,126} The red cells are often described as stomatocytic elliptocytes and have a unique appearance on the peripheral blood smear (Fig. 12.7).

Heterozygotes are not anemic. The homozygous state has never been seen and is thought to be lethal *in utero*.¹²⁷

Diagnosis

A careful inspection of the peripheral blood smear is the first step in identifying the various clinical forms of elliptocytosis. Red cell indices are normal in common HE, whereas profound microcytosis and increased MCHC are features of HPP. Hematologic evaluation of the parents and siblings is usually helpful in defining the pattern of inheritance. Osmotic fragility is increased in HPP and homozygous common HE but normal in the less severe subtypes.¹¹⁷

Specialized testing, such as membrane protein quantitation, tryptic digestion of spectrin, spectrin self-association studies, ektacytometry, and genetic analyses, are available for studying difficult cases or when additional information is desired. Prenatal diagnosis has been accomplished by direct examination of fetal red cells and membrane proteins. If the specific mutation(s) present in the family is known, prenatal diagnosis by analysis of fetal DNA is also feasible.

Pathophysiology

Weakening of membrane skeleton protein interactions by mutations altering protein structure, function, or amount leads to diminished membrane mechanical stability and ultimately, in severe cases, to hemolysis. The α - and β -spectrin mutations near the $\alpha\beta$ -spectrin heterodimer self-association region impair spectrin tetramer formation, while protein 4.1 or glycophorin deficiency affects spectrin-actin-protein 4.1 junctional complex formation and membrane attachment.

Elliptocytes form as the red cell matures, since immature red cells in the HE syndromes do not exhibit any morphologic abnormalities.¹¹⁷ Acquisition of the elliptocytic shape is thought to be the result of the repeated episodes of elliptocytic deformation that all red cells experience during each circulatory cycle. Whereas normal red cells regain a discocytic configuration by a process of elastic recoil, HE red cells become locked into the elliptocytic configuration by disruption of the normally abundant interconnections between the membrane proteins.

The elliptocytic shape *per se* does not necessarily shorten the lifespan of the red cell. For example, Southeast Asian ovalocytes, despite being rigid cells with a membrane mechanical stability greater than normal, have a normal lifespan.¹¹⁷ Although mechanical fragility is impaired, leading to fragmentation and microcytosis, intravascular hemolysis appears to play little role in red cell destruction since hemoglobinuria, hemoglobinemia, or hemosiderinuria are not features of hemolytic elliptocytosis. In fact, considerable hemolysis must occur within the spleen, since splenectomy usually reduces the hemolytic rate.

Alterations in the microcirculation or transient

developmental factors present during fetal and early postnatal life can generate poikilocytosis and hemolysis in individuals with common HE. Transient neonatal poikilocytosis and hemolysis is thought to occur as a consequence of the high concentrations of fetal hemoglobin in neonatal red cells. Because fetal hemoglobin does not bind 2,3-DPG, large amounts of free 2,3-DPG are available in the neonatal red cell to interact with and destabilize the membrane skeleton.¹²⁸ In normal neonatal red cells this does not appear to have a discernible effect on red cell shape or survival, but in red cells whose membrane skeleton is weakened by an inherited defect, the sum of the effects of 2,3-DPG and the inherited defect is sufficient to decrease mechanical stability, producing poikilocytosis and hemolytic anemia. As fetal hemoglobin levels decline over the first few months of life, the contribution of 2,3-DPG to the hemolytic process wanes, hemolysis disappears, and poikilocytes are replaced by the elliptocytes characteristic of common HE.

Molecular genetics

The variable clinical severity of HE is a consequence of mutations in α or β spectrin, protein 4.1, glycophorin C, or band 3. These mutations lead to quantitative or qualitative defects in the mutant protein.^{81,114}

Spectrin mutations

The most common defects in HE are mutations of α or β spectrin.^{129,130} The side-to-side, antiparallel self-association of these proteins into a flexible rod-like $\alpha\beta$ heterodimer forms the building block of the spectrin tetramer.^{33,131} Spectrin heterodimers associate head to head to form spectrin tetramers, the major structural subunits of the membrane skeleton. Spectrin tetramers are interconnected into a two-dimensional lattice through binding, at their distal ends, to actin oligomers with the aid of protein 4.1 at the junctional complex.¹³² Spectrin dimer-tetramer interconversion is governed by a simple thermodynamic equilibrium that under physiologic conditions strongly favors spectrin tetramers.^{133,134} The contact site between the α - and β -spectrin chains of the opposed heterodimers is an atypical triple helical repeat in which one helix is contributed by the NH_2 -terminus of α spectrin and two helices are contributed by the COOH -terminus of β -spectrin.

Most α -spectrin defects are at, or near, the NH_2 -terminus of α spectrin involved in heterodimer self-association site, impairing self-association of spectrin into tetramers (Fig. 12.8).^{129,135} Most α -spectrin mutations are point mutations.¹³⁰ These mutations create abnormal proteolytic cleavage sites that typically reside in the third helix of a repetitive segment and give rise to abnormal tryptic peptides on two-dimensional tryptic peptide maps of spectrin.

Elliptocytogenic β -spectrin mutations are COOH -terminal point mutations or truncations that disrupt the formation

Fig. 12.8 A model of the spectrin self-association site: a triple helical model of the spectrin repeats that constitute the spectrin self-association site. The symbols denote positions of various genetic defects identified in patients with hereditary elliptocytosis or hereditary pyropoikilocytosis. Limited tryptic digestion of spectrin followed by two-dimensional gel electrophoresis identifies abnormal cleavage sites in spectrin associated with different mutations. These cleavage sites are denoted by arrows. Reproduced with permission from Gallagher PG, Tse WT, Forget BG. Clinical and molecular aspects of disorders of the erythrocyte membrane skeleton. *Semin Perinatol* 1990; **14**: 351.

of the combined β triple-helical repetitive segment and consequently the self-association of spectrin heterodimers to tetramers (Fig. 12.8).^{129,130} All these mutations open a proteolytic cleavage site residing in the third helix of the combined repetitive segment, which gives rise to a 74-kDa α I peptide on tryptic peptide mapping of erythrocyte spectrin.

Although most spectrin mutations reside in the vicinity of the $\alpha\beta$ -spectrin self-association site, a few mutations residing in the α II domain have been described. These mutations are asymptomatic in the simple heterozygous state but cause hemolytic anemia, which may be severe, in homozygous patients.^{136–138}

The large number of α -spectrin mutations has allowed correlations to be established between clinical severity and the nature of the mutation. Mutations near the site of dimer-dimer self-association at the NH_2 -terminus of α spectrin are the most likely to interfere with tetramer formation and lead to clinical symptoms. Another important determinant of clinical severity is the amount of mutant spectrin polypeptides present. In general, the greater the percentage of mutant spectrin, the more severe the clinical course. Variation in the amount of mutant spectrin found in members of a given pedigree is sometimes due to homozygous or heterozygous inheritance of the structural mutation, but more often it is due to the presence or absence of a low-expression α -spectrin mutation inherited in *trans* to a single mutant α -spectrin allele.

The commonest example of a low-expression allele is α -spectrin^{LELY}, which is present in 20–30% of α -spectrin alleles in the normal population.^{139,140} The primary mutation, which is in intron 45, leads to variable splicing and loss of exon 46 in about half of the mRNA synthesized. α -Spectrin polypeptides lacking exon 46 sequences do not participate as avidly as do normal α -spectrin polypeptides in dimer and tetramer assembly and are therefore vulnerable to loss by proteolysis.¹⁴¹ The ultimate effect of such a mutation is to reduce the quantity of α spectrin available for assembly into the membrane. Since more α than β spectrin is normally synthesized, a moderate reduction in α spectrin need not alter the number of $\alpha\beta$ -spectrin dimers finally assembled into the membrane. It will, however have the effect of increasing the fraction

of α spectrin to the non-spectrin^{LELY} allele. If this allele bears a mutation that is associated with elliptocytosis, the greater quantity of the mutant spectrin in the membrane will usually be associated with greater clinical severity. In contrast, if the α -spectrin^{LELY} mutation is inherited in *cis* with an elliptocytic mutation, there will be a reduced quantity of the mutant spectrin in the membrane and a milder clinical picture.

Protein 4.1 mutations

Protein 4.1 mutations are a much less common cause of elliptocytosis than spectrin mutations. Protein 4.1 has several domains involved in protein-protein interactions, including a spectrin-binding domain where 4.1 binds to the distal end of the spectrin $\alpha\beta$ heterodimer, markedly increasing the binding of spectrin to oligomeric actin, and an NH_2 -terminal domain, where 4.1 interacts with glycophorin C, phosphatidylinositol, and phosphatidylserine, facilitating the attachment of the distal end of spectrin to the membrane.^{33,132} Studies of 4.1 mRNA from normal erythroid cells have revealed 4.1 isoforms resulting from complex tissue- and developmental stage-specific patterns of alternate mRNA splicing.^{142–147} Alternate translation initiation sites are present in the protein 4.1 mRNA. When an upstream AUG is utilized, isoforms greater than 80 kDa are synthesized. During erythropoiesis, this upstream AUG is spliced out and a downstream AUG is utilized, leading to the production of the 80-kDa mature erythroid protein 4.1 isoform.¹⁴³

Partial protein 4.1 deficiency is associated with mild dominant HE, while complete deficiency (a homozygous state) leads to severe hemolytic HE.^{148,149} Homozygous 4.1(–) erythrocytes fragment more rapidly than normal at moderate shear stresses, an indication of their intrinsic instability.¹²¹ Homozygous protein 4.1(–) erythrocytes also lack p55 and have only 30% of the normal content of glycophorin C. Electron microscopic studies of homozygous 4.1(–) erythrocyte membranes revealed a markedly disrupted skeletal network with disruption of the intramembrane particles, suggesting that protein 4.1 plays an important role in maintenance of not only the skeletal network but also the integral proteins of the membrane structure.¹⁵⁰

Mutations associated with 4.1 deficiency have included a deletion that includes the exon encoding the erythroid transcription start site and mutations of the transcription initiation codon.¹¹⁴ Qualitative defects of protein 4.1 include deletions and duplications of the exons encoding the spectrin-binding domain, leading to either truncated or elongated forms of protein 4.1.

Glycophorin C deficiency

Glycophorin C deficiency with elliptocytosis, the Leach phenotype,^{151,152} is usually due to a large deletion of genomic DNA (~7 kb) that removes exons 3 and 4 from the GPC/GPD locus. In contrast to other forms of HE, which are dominantly inherited, heterozygous carriers are asymptomatic, with normal red blood cell morphology; homozygous subjects have no anemia and only mild elliptocytosis apparent on the peripheral blood film.¹⁵³ Glycophorin C-deficient subjects are also partially deficient in protein 4.1 and lack p55, presumably because these proteins form a complex and recruit or stabilize each other on the membrane.¹⁵⁴ It has been speculated that the protein 4.1 deficiency in Leach erythrocytes is the cause of the elliptocytic shape. In contrast, subjects deficient in glycophorin A, the major transmembrane glycoprotein, are asymptomatic.

Resistance to malaria

As is the case with other erythrocyte variants such as hemoglobinopathies, enzymopathies, and blood group antigens, alterations in red cell membrane structure that lead to elliptocytosis may provide resistance against malaria. This property has been attributed to diminished invasion, poor intraerythrocytic growth, or diminished cytoadherence of infected erythrocytes.¹⁵⁵ A high prevalence of HE in regions where malaria has been or is endemic, such as the approximately 1.6% incidence of common HE in inhabitants of Benin in West Africa, suggests positive evolutionary selection.^{116,156} Convincing data are available for heterozygous Southeast Asian ovalocytosis, which in one study was found in approximately 15% of inhabitants of the Madang area of Papua New Guinea but in only 9% of those who had uncomplicated *P. falciparum* malaria, and in none of those with potentially life-threatening cerebral malaria.¹⁵⁷

Treatment

Most cases of HE require no specific therapy. Supportive care measures such as supplemental folic acid or occasional red cell transfusions for episodes of anemia (usually related to infection) may be helpful. When hemolysis is severe, splenectomy may eliminate the need for regular red cell transfusions and improve the anemia. As in HS, the increased risk of bacterial infection following splenectomy in infancy or early

childhood is a reason to wait until later childhood or adolescence before considering surgery.

Echinocytes and acanthocytes

Echinocytes and acanthocytes are types of spiculated red blood cells. Echinocytes have serrated edges over the entire surface of the cell and often appear crenated in a blood smear. Acanthocytes have only a few spicules of varying size that project from the cell surface at irregular intervals. They appear contracted and dense on stained peripheral blood smears. Wet preparations or scanning electron micrographs can be used to distinguish the two types of cells. Echinocytes can be produced *in vitro* by washing red cells in saline, by interactions between glass and red cells, and by insertion of amphipathic compounds that localize to the exterior leaflet of the lipid bilayer. High pH, ATP depletion, and Ca^{2+} accumulation can also cause echinocytosis. Echinocytes are seen in neonates and in patients with uremia, those who have defects in glycolytic metabolism, after splenectomy, and in some patients with microangiopathic hemolytic anemia. Acanthocytosis and echinocytes may be found in patients with liver damage, abetalipoproteinemia, unusual neurologic symptoms, anorexia nervosa, McLeod and In(Lu) blood groups, myelodysplasia, and hypothyroidism.

Abetalipoproteinemia

Progressive ataxia, atypical retinitis pigmentosa, a celiac syndrome, and acanthocytosis are the primary manifestations of abetalipoproteinemia.¹⁵⁸ Absorption of lipids through the intestine is defective, serum cholesterol levels are extremely low, and serum β lipoprotein is absent in this hereditary disease. The disease is due to failure to synthesize or secrete lipoprotein-containing products of the apolipoprotein B gene, the B apoproteins B100 and B48, or to defects in the microsomal triglyceride transfer protein, required for secretion of apoprotein B-containing lipoproteins.^{159–161} A wide spectrum of clinical manifestations may be observed depending on the extent to which apolipoprotein B-mediated metabolic processes are affected. All patients have some degree of neurologic impairment and acanthocytes. The acanthocytic shape is not present in young erythrocytes but accumulates with cell aging. In severe cases, up to 50–90% of the erythrocytes are acanthocytes. Despite the profound morphologic abnormality, anemia may be absent or manifest as a very mild normocytic anemia with normal or slightly elevated reticulocyte counts.

In the abetalipoproteinemic acanthocytic erythrocyte, the outer leaflet of the red cell membrane is markedly enriched in sphingomyelin, mirroring the altered plasma lipid profile of these patients presumably due to lipid exchange. In contrast to the spur cell anemia of liver disease (see below),

erythrocyte membrane cholesterol is normal or slightly increased. The molecular basis of the acanthocytic shape is unknown but is presumed to be due to an increase in surface area of the outer leaflet of the lipid bilayer relative to the inner leaflet.

Patients may become deficient in vitamin E due to fat malabsorption, rendering their acanthocytic red cells susceptible to hemolysis following *in vitro* incubation in dilute solutions of hydrogen peroxide. Whether vitamin E deficiency influences the various clinical manifestations of this disease is not known. However, children who have chronic liver disease and develop vitamin E deficiency have been reported to develop acanthocytosis as well as neurologic dysfunction. Retinal and neuromuscular abnormalities may be stabilized by the administration of vitamin E.

Chorea-acanthocytosis

This syndrome is characterized by acanthocytes, normolipoproteinemia, and progressive neurologic disease beginning in adolescence or adult life.¹⁶² The neurologic manifestations are varied and include limb chorea, progressive orofacial dyskinesia, tongue-biting, muscle wasting, and hypotonia. The relationship between the red cell changes and neurologic manifestations is unclear. Recent cloning of the chorein gene and identification of mutations in affected patients have not significantly extended our understanding of the pathophysiology of this disorder.^{2,163,164} Chorein does not belong to any known gene family.

Other neuroacanthocytosis syndromes

Neuroacanthocytosis is the term applied to a group of disorders with great phenotypic and genetic heterogeneity.^{165,166} In addition to the chorea-acanthocytosis syndrome described above and the X-linked McLeod syndrome described below, acanthocytosis is found in other neurodegenerative disorders including Huntington disease-like 2 and pantothenate kinase-associated neurodegeneration, formerly known as Hallervorden-Spatz syndrome and its allelic variant HARP syndrome (*hypobetalipoproteinemia, acanthocytosis, retinitis pigmentosa, pallidal degeneration*).^{167–172} Variants of all these disorders have been found, including syndromes with chorea-acanthocytosis and myopathy and with chorea-acanthocytosis, spherocytosis and hemolysis. The etiology of the acanthocytic phenotype in these disorders is unknown. Further investigation of the precise defect in the red cell may provide insights into the pathophysiologic processes affecting the brain.

Miscellaneous disorders

A variety of additional disorders are associated with either acanthocytes or echinocytes.

Anorexia nervosa

Patients with anorexia nervosa may have acanthocytes on peripheral smear.¹⁷³ The mechanisms responsible have not been defined and considerable variation in the number of acanthocytes exists between patients. Anemia is rare and is usually hypoplastic and not hemolytic. It is accompanied by other cytopenias, attributed to malnutrition and starvation.

Liver disease

Patients with liver disease may develop either target cells or spur cells. Those with target cells have a reversible disorder primarily related to the increased unesterified cholesterol content of the plasma associated with lecithin-cholesterol acyltransferase (LCAT) inhibition (see below) and do not have hemolysis. In contrast, patients with advanced hepatocellular disease have 20–30% acanthocytes in their peripheral blood and moderate-to-severe hemolysis. Echinocytes and target cells may also be present. In contrast to target cells, where there is a proportionate increase in red cell cholesterol and phospholipid, in spur cells or acanthocytes associated with hepatocellular liver disease there is not only an increase in both cholesterol and phospholipid but a dramatic increase in the ratio of cholesterol to phospholipid. The precise impact of this imbalance of lipids on membrane properties and the profound hemolysis associated with this condition has not been determined. In addition to these quantitative lipid abnormalities, a defect in the remodeling of membrane phospholipids is present. To add additional complexity to the picture, some patients with advanced hepatocellular liver disease, particularly children, develop spur cells but do not have abnormalities in membrane lipids.

Vitamin E deficiency

Echinocytes and occasional acanthocytes are a feature of vitamin E deficiency. Previously noted in premature infants due to feeding of formulas with inadequate vitamin E content and very high polyunsaturated fatty acids, this condition is now limited to patients who have fat malabsorption, often related to liver disease, abetalipoproteinemia, or cystic fibrosis.¹⁷⁴ Parenteral administration of vitamin E will correct the deficiency in patients with impaired gastrointestinal absorption of this vitamin.

Blood group abnormalities

Acanthocytes have been associated with certain abnormalities of the blood group systems. In McLeod syndrome, an X-linked inherited anomaly of the Kell blood group system, red cells, leukocytes, or both cell types react poorly with Kell antisera but behave normally in other blood group reactions. Affected cells lack XK, a membrane protein that is linked to

Kell, a zinc endopeptidase that carries the Kell antigens.^{175–177} Males have variable acanthocytosis (8–85%) and mild compensated hemolysis. Females have only occasional acanthocytes and very mild or no hemolysis. Some patients with McLeod syndrome develop a neuropathy or myopathy. Psychiatric symptoms, seizures, and peripheral neuropathy with muscle denervation have also been reported. The XK gene is less than 500 kb from the chronic granulomatous disease (CGD) locus. Thus some males with chromosomal deletions involving this region have both McLeod syndrome and CGD. It is important to identify these patients because if they are transfused, they may develop antibodies compatible only with McLeod red cells.

The commonest cause of the null Lutheran phenotype Lu(a–b–) is the presence of an inhibitor called In(Lu) that partially suppresses expression of Lu_a and Lu_b, rendering these antigens undetectable by standard agglutination tests. About 1 in 5000 individuals inherits this dominantly acting inhibitor. Patients with this inhibitor have normal, poikilocytic, or acanthocytic red cells but no hemolysis.

Uremia

Echinocytes are found in the blood smear of patients who develop uremia and hemolysis. These are secondary to an extra corpuscular factor that appears to affect red cell metabolism and results in elevated levels of intracellular calcium, a factor known to induce echinocytosis. Red cells from patients with uremia survive normally when infused into nonuremic recipients.

Other disorders

Approximately 50% of patients with hypothyroidism have a small number (0.5–2%) of acanthocytes on peripheral blood smears. Due to the high incidence of hypothyroidism relative to other disorders causing acanthocytosis, it has been suggested that thyroid testing be considered in patients with acanthocytosis.¹⁷⁸

Target cells

Target cells are red cells that have an increased surface area–volume ratio. The redundant membrane creates what appears to be a hyperchromic bull's-eye in the center of the red cell when viewed on a stained peripheral blood smear. Target cells are generated either by increasing the membrane lipid content and thus the surface area or by decreasing cell volume. The latter is the consequence of decreased hemoglobin synthesis (thalassemia or iron deficiency), the presence of certain structural mutations of hemoglobin (S, C, D, E), or of primary disorders of cell hydration. Generally, an increase in membrane surface area does not affect red cell

survival, while reduced volume from cellular dehydration or reduced hemoglobin synthesis often may.

Target cells are often seen in the peripheral blood smear of patients who have obstructive liver disease, reflecting a balanced increase in phospholipids and cholesterol.^{179,180} Unesterified cholesterol in the plasma increases in concentration as a result of the inhibition of LCAT by bile salts. The central role of abnormal plasma lipids in the formation of target cells can be shown *in vitro* by incubation of normal red cells in plasma from patients with obstructive liver disease or, conversely, by incubating target cells in normal plasma. In the former situation, target cells are formed and in the latter they disappear. This is the basis for the observation that in patients with HS who develop temporary obstructive jaundice as a result of gallstones, the hemolytic process improves and osmotic fragility may become normal. In this setting, the increase in membrane surface area normalizes the previously abnormal surface area–volume ratio of spherocytes.

Target cells are also seen in hereditary LCAT deficiency, a rare disease due to a mutation in the LCAT gene.^{181,182} Plasma unesterified cholesterol and phospholipid concentrations are increased. The disorder, which exhibits an autosomal recessive mode of inheritance, is characterized by anemia, corneal opacities, hyperlipemia, proteinuria, chronic nephritis, and premature atherosclerosis. A moderate normochromic normocytic anemia accompanied by prominent target cell formation and decreased red cell osmotic fragility is noted. Serum and red cell lipids are improved *in vivo* when LCAT is provided by infusions of normal plasma.

In the first few weeks following splenectomy, target cells appear, reaching levels of 2–10%. Like other target cells, membrane lipids are increased, osmotic fragility is decreased, and the mean surface area–volume ratio is increased.^{117,183} The spleen normally removes excess membrane from red cells, a process called splenic conditioning. The exact mechanism responsible is not defined, although the reduction in red cell lipid content suggests that lipases may be involved. After splenectomy, red cells may eventually lose their excess lipid by conditioning in nonsplenic sites, gradually leading to the disappearance of target cells.

Disorders of hydration and cation transport

The hereditary stomatocytosis syndromes are a group of inherited disorders characterized by erythrocytes with a mouth-shaped (stoma) area of central pallor on peripheral blood smear (Fig. 12.9).^{184–186} Stomatocytosis is associated with abnormalities in red cell hydration and cation transport that lead to changes in red cell volume, which may be either increased (hydrocytosis) or decreased (xerocytosis), or in some cases near normal. The pathobiology of the stomatocytic shape is poorly understood and the molecular basis

Fig. 12.9 Red cell morphology in disorders of cell hydration: (a) hereditary xerocytosis; (b) hereditary hydrocytosis. Reproduced with permission from Ref. 184.

of this group of disorders is unknown. Primary disorders of cellular metabolism or hemoglobinopathies may produce a secondary abnormality of cell hydration that contributes to the hemolytic process. This section focuses on the primary disorders of cell hydration.

Xerocytosis

Clinical features

The dehydrated stomatocytosis syndromes, also known as xerocytosis or dessiccytosis, are characterized by contracted and spiculated red cells, variable numbers of stomatocytes, and target cells on peripheral blood smear.¹⁸⁵ Little or no anemia is usually found, although red cell lifespan may be considerably shortened.¹⁸⁷ Splenomegaly and other markers of chronic hemolysis are uncommon. Inheritance has usually been autosomal dominant. A clinical syndrome of xerocytosis, perinatal ascites, nonimmune hydrops fetalis, and pseudohyperkalemia has been described in several kindreds.^{188, 189}

Laboratory findings

The hallmark of xerocytosis is red cell dehydration, which is most easily detected by examination of the red cell indices (high MCHC) or the osmotic fragility curve (increased osmotic resistance). These tests serve to separate xerocytosis from spherocytosis, where the MCHC may be elevated but osmotic fragility is usually increased. A simple test may reveal resistance of xerocytes to heat-induced budding and fragmentation.¹⁹⁰ Target cells and occasional bizarre red cells where the hemoglobin is puddled at each pole are seen on the peripheral blood smear (Fig. 12.9).¹⁹¹ The reticulocyte count is often increased to a level higher than that expected for the degree of anemia. Ultimately, the diagnosis of xerocytosis depends on recognizing the abnormalities listed above and eliminating from consideration other diseases such as hemoglobinopathies or pyruvate kinase deficiency that may produce similar abnormalities.

Pathophysiology

The basic red cell abnormality in xerocytosis is passive loss of intracellular K^+ in excess of accumulation of intracellular Na^+ , leading to a gradual decline in total intracellular cations and an obligate loss of cell water to maintain osmotic balance. Active transport of cations via the Na^+/K^+ -ATPase pump does not restore cation homeostasis but rather exaggerates the defect, since the fixed stoichiometry of the pump (3 Na^+ out, 2 K^+ in) leads to a further net loss of cations from the cell.¹⁹² A primary pathway for cellular dehydration in hemoglobinopathies (HbSS and HbSC disease) is volume-dependent KCl cotransport. This pathway has not been characterized extensively in xerocytes, but in one family there was evidence that it was abnormal.¹⁹³ The dehydrated xerocyte is rigid due to its increased cytoplasmic viscosity¹⁹⁴ and perhaps also to intrinsic membrane rigidity induced by complexing of globin to spectrin.¹⁹⁵ The rigidity of the xerocyte may contribute to its shortened lifespan by increasing its sensitivity to shear-induced hemolysis in the circulation.¹⁹⁶ Xerocytes resemble HS erythrocytes in their proclivity to vesiculation and loss of membrane surface area after metabolic depletion *in vitro*.¹⁹⁷ Like other dehydrated red cells, xerocytes are susceptible to injury by exogenous oxidants, a susceptibility that can be prevented by prior rehydration of the cells.^{195, 198}

The primary molecular event responsible for xerocytosis is unknown. The gene for xerocytosis has been mapped to 16q23–q24.¹⁹⁹ Isolated pseudohyperkalemia is allelic to xerocytosis and also shows linkage to this region.¹⁹⁹

Treatment

No specific treatment is available or usually required. Splenectomy is of little or no benefit, and in some cases may

be deleterious, predisposing to life-threatening thrombotic episodes (see below).

Hydrocytosis (stomatocytosis)

Clinical features

Mild-to-moderate lifelong hemolytic anemia, often accompanied by splenomegaly, jaundice, and other complications of hemolysis, are seen in hydrocytosis.^{184,200} Some affected individuals develop evidence of iron overload, even in the absence of blood transfusions.²⁰¹ Hydrocytosis is a rare disorder but in informative pedigrees, inheritance has been autosomal dominant.^{4,202–206}

Laboratory findings

As implied by the name, cell water is increased in hydrocytes, causing them to swell and appear on the peripheral blood smear as stomatocytes (Fig. 12.9). The swollen waterlogged cells can also be recognized by the unusually high MCV (often > 120 fL) and low MCHC seen in this condition. The osmotic fragility of hydrocytes is increased. Unlike normal red cells, hydrocytes are low in K^+ and high in Na^+ . The total monovalent cation content (Na^+ and K^+) of hydrocytes is greater than that of normal red cells. Increased osmotic fragility is found in both hydrocytosis and HS, but the two disorders are easily distinguished on the basis of their morphology, red cell indices, and red cell monovalent cation content.

Pathophysiology

Like xerocytosis, hydrocytosis is caused by an abnormality in passive monovalent cation flux. The dominant abnormality is increased passive influx of Na^+ , which is not matched by an equivalent outflow of K^+ . Active cation transport by the Na^+/K^+ -ATPase pump, although greatly increased, is unable to prevent the accumulation of intracellular Na^+ and the resulting increase in monovalent cation content causes osmotic movement of water into the cell, cell swelling, and transformation from diskocyte to stomatocyte morphology. Metabolic depletion, by preventing ATP generation for the Na^+/K^+ -ATPase pump, inhibits active transport of Na^+ out of the cell and accelerates water accumulation and cell swelling. The favorable effect of splenectomy on the rate of hemolysis is most likely due to removal of the organ where metabolic depletion of red cells is most likely to occur.

The molecular basis for hydrocytosis is not known. Red cells from many patients lack or are deficient in stomatin, an integral membrane protein also present in lipid rafts. The precise function of stomatin is unknown but it has been hypothesized to be involved in lipid rafts of the plasma membrane and a multimeric signaling complex of the actin

cytoskeleton, mechanosensation, nociception, and a membrane-bound proteolytic process. Mutations have not been found in stomatin cDNA from patients with hydrocytosis and the stomatin mRNA content of reticulocytes is normal.²⁰⁷ A stomatin knockout mouse had no erythroid phenotype.²⁰⁸ A homozygous stomatin mutation has been described in a child with severe multisystem disease with a dyserythropoietic, sideroblastic erythroid, not hydrocytosis, phenotype.²⁰⁹

Cryohydrocytosis, another condition associated with abnormal cation transport and overhydrated red cells, is distinguished from hydrocytosis by the profound increase in cation permeability that occurs *in vitro* at low temperature (4°C).²¹⁰ A similar susceptibility to cold-induced cation permeability in which K^+ loss predominates and xerocytes instead of hydrocytes are present has also been described.

Treatment

Splenectomy may decrease the hemolytic rate^{6,211} but is to be avoided if possible because of an unusually high risk of serious thrombotic complications and chronic pulmonary hypertension after splenectomy.²⁰⁰ This has been attributed to increased erythrocyte–endothelial cell adhesion due to erythrocyte phosphatidylserine exposure.^{212,213} Fortunately, the majority of patients are able to maintain an adequate hemoglobin level, so that splenectomy is not required.

Other disorders with stomatocytosis

Hydrocytosis and xerocytosis represent the extremes of a spectrum of red cell permeability defects. Patients with features of both conditions have been reported, with variability in the severity of permeability defects, stomatin deficiency, hemolysis, anemia, and numbers of stomatocytes.^{185,186,210,214} These patients have been categorized as “intermediate” syndromes. These observations suggest that hereditary stomatocytosis is a complex collection of syndromes caused by various molecular defects. As detailed below, in some cases these defects have been elucidated.

Rh deficiency syndrome

Stomatocytosis is also present on peripheral blood smears of patients with Rh deficiency syndrome. Erythrocytes from these rare individuals have either absent (Rh_{null}) or markedly reduced (Rh_{mod}) Rh antigen expression. There is mild to moderate hemolytic anemia. Rh proteins are part of a multi-protein complex that includes two Rh proteins and two Rh-associated glycoproteins (RhAG).²¹⁵ Other proteins that associate with this complex include CD47, LW, glycophorin B, and protein 4.2.^{216,217} The Rh–RhAG complex interacts with ankyrin to link the membrane skeleton to the lipid bilayer.

Rh_{null} erythrocytes have increased osmotic fragility, reflecting dehydration and reduced membrane surface area. K^+

transport and Na⁺/K⁺ pump activity are increased, possibly because of reticulocytosis. Phospholipid asymmetry is also altered. Though the clinical syndromes are the same, the genetic basis of the Rh deficiency syndrome is heterogeneous, and at least two groups have been defined. The “amorph” type is due to defects involving the *RH30* locus encoding the RhD and RhE polypeptides.^{218,219} The “regulatory” type of Rh_{null} and Rh_{mod} phenotypes results from suppressor or “modifier” mutations at the *RH50* locus. When one chain of the Rh–RhAG complex is absent, the complex is either not transported to the membrane or is assembled at the membrane.

Familial deficiency of high-density lipoproteins

Familial deficiency of high-density lipoproteins leads to accumulation of cholesteryl esters in many tissues. Hematologic manifestations include a moderately hemolytic anemia with stomatocytosis. Erythrocyte membranes have low free cholesterol content, leading to a decreased cholesterol/phospholipid ratio and a relative increase in phosphatidylcholine.

Sitosterolemia

Sitosterolemia is a recessively inherited condition associated with early-onset xanthomatosis, atherosclerosis, and elevated plasma levels of plant sterols. Defects in the *ABCG5* or *ABCG8* cotransporters lead to increased intestinal absorption and decreased biliary elimination of all sterols, particularly plant sterols. Hematologically, the patients present with macrothrombocytopenia and a stomatocytic hemolytic anemia.^{218,219}

Acquired stomatocytosis

Stomatocytes have been found in several acquired conditions, including neoplasms, cardiovascular and hepatobiliary disease, alcoholism, and therapy with drugs, some of which are known to be stomatocytogenic *in vitro*. Sometimes, the percentage of stomatocytes on the peripheral blood smear may approach 100%. However, the clinical significance of these findings is unclear.

Thalassemias

Nancy F. Olivieri and David J. Weatherall

Introduction

The thalassemias, a heterogeneous family of inherited disorders of hemoglobin synthesis, were first recognized independently in the USA and Italy in the years between 1925 and 1927.¹ The word "thalassemia" owes its name to an attempt, mistaken as it turned out later, to relate the diseases to Mediterranean populations; *thalassa* is from the Greek word for "sea".

It is now apparent that the thalassemias are the world's commonest monogenic diseases and are widespread among races ranging from the Mediterranean region, through the Middle East and Indian subcontinent, to Southeast Asia. Many countries in these regions have, over the last 30 years, gone through a remarkable demographic change in the pattern of their illnesses. With improvements in hygiene and public health measures, very high infant and childhood mortalities due to infection and malnutrition have fallen. In the past, babies born with serious genetic blood diseases would have been unlikely to survive the first years of life, but the scene has now changed dramatically. As these countries undergo this demographic transition, the majority of these children are now surviving long enough to come to diagnosis and to require management. And because the symptomatic treatment of thalassemia is expensive, this change in the pattern of childhood illness will place an increasing drain on the resources of countries in which the disease occurs at a high frequency.²

These diseases are also assuming an increasing importance in the clinical practice of pediatricians in the richer countries.

Genetics and classification

Genetic control of hemoglobin synthesis

A great deal is known about the structure, genetic regulation

and synthesis of hemoglobin. Only those aspects of particular importance for an understanding of the thalassemias are summarized here. Readers are referred to more extensive reviews and monographs.^{3–6}

Different hemoglobins, each adapted to the particular oxygen requirements at each stage of development, are synthesized in the embryo, fetus and adult. All hemoglobins have a similar tetrameric structure, consisting of two different pairs of globin chains, each attached to a heme moiety. Adult and fetal hemoglobins have α chains combined with β chains (HbA, $\alpha_2\beta_2$), δ chains (HbA₂, $\alpha_2\delta_2$) and γ chains (HbF, $\alpha_2\gamma_2$). In embryonic life, α -like chains called ζ chains combine with γ chains to produce Hb Portland ($\zeta_2\gamma_2$), or with ϵ chains to form Hb Gower 1 ($\zeta_2\epsilon_2$), and α and ϵ chains combine to form Hb Gower 2 ($\alpha_2\epsilon_2$). Fetal hemoglobin is itself heterogeneous; there are two kinds of γ chains, which differ in their amino acid compositions only at position 136, where they have either glycine or alanine. Those γ chains with glycine are called $^G\gamma$ chains and those with alanine $^A\gamma$ chains. The $^G\gamma$ and $^A\gamma$ chains are the products of separate ($^G\gamma$ and $^A\gamma$) loci.

The different globin chains are controlled by two main families of globin genes (Fig. 13.1). The β -like globin genes are arranged in a linked cluster on chromosome 11, which is distributed over approximately 60 kb (kilobase or 1000 nucleotide bases). They are arranged in the order 5' to 3' (left to right) ϵ - $^G\gamma$ - $^A\gamma$ - $\psi\beta$ - δ - β . The symbol ψ is used to describe a pseudogene, probably a burnt-out evolutionary remnant of a once-active gene. The α -like globin genes also form a cluster, in this case on chromosome 16. They are distributed in the order 5'- ζ - $\psi\zeta$ - $\psi\alpha 1$ - $\alpha 2$ - $\alpha 1$ -3'.

In order to appreciate the molecular basis for the thalassemias, it is important to understand, at least in outline, something of the structure of the globin genes, how they are regulated, and how their products are synthesized and unite with heme to form hemoglobin molecules in the red cell precursors.^{4,6}

Each globin gene consists of a string of nucleotide bases that are divided into coding sequences, called exons, and

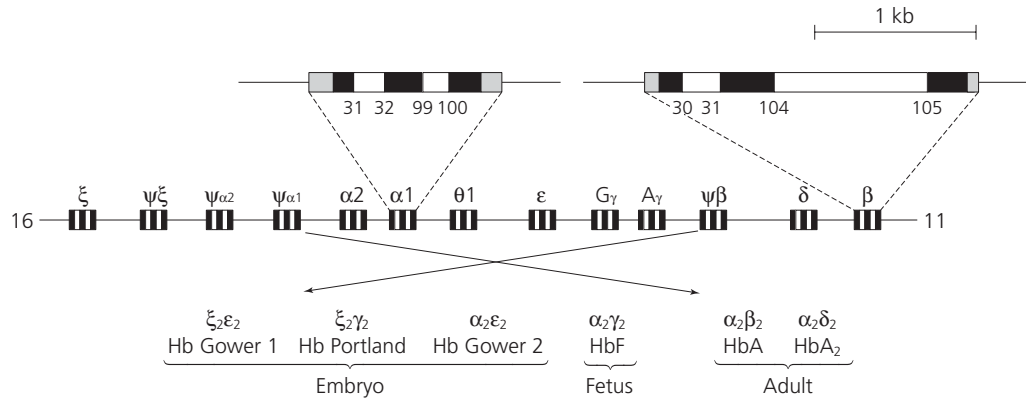

Fig. 13.1 Genetic control of human hemoglobin synthesis. The α - and β -globin gene clusters on chromosomes 16 and 11 are shown, together with the different hemoglobins produced in embryonic, fetal and adult life. In the extended representations of the α 1- and β -globin genes the exons are shown in dark shading, the introns unshaded, and the 5' and 3' noncoding regions are shown in light shading.

noncoding regions known as intervening sequences (IVS) or introns. In the 5' (left-hand) noncoding or flanking regions of globin genes, there are blocks of nucleotide homology, which are found in similar positions in many species. Three such regions, called promoter elements, play a major role in the transcription of the structural genes. The globin gene clusters contain other elements that play an important part in promoting erythroid-specific gene expression and in coordinating the changes in globin gene activity at different stages during development. These include enhancers, i.e., sequences that increase gene expression despite being located at a variable distance from a particular gene, and “master” regulatory sequences, called the locus control region (LCR) in the case of the β -globin gene family and HS40 in the case of the α -gene complex, which lie upstream from the globin gene clusters and are responsible for their activation in erythroid tissue. Each of these regulatory sequences has a modular structure comprising an array of short nucleotide motifs that represent binding sites for transcriptional activators or repressors, molecules involved in the activation or repression of globin gene production in different cell types and at different stages of development.

Each of these regulatory regions binds a number of erythroid-specific factors, including GATA-1 and NF-E2, thereby activating the LCR, which renders the entire β -globin gene cluster transcriptionally active. It seems likely that the LCR and HS40 regions come into apposition with the promoter regions of each of the globin genes in turn and, together with a complex collection of transcription factors and other proteins, form an initiation complex so that individual genes are transcribed.

When a globin gene is transcribed, messenger RNA (mRNA) is synthesized from one of its strands by the action of RNA polymerase. The primary transcription product is a large mRNA precursor, which contains both intron and exon sequences (Fig. 13.2). While in the nucleus this molecule undergoes a remarkable series of modifications; the introns

are removed and the exons are spliced together. This is a multistep process that requires certain structural features of the mRNA precursor, notably the nucleotides GT at the 5' end and AG at the 3' end of intron–exon junctions. We will discuss the importance of these sequences when we consider the mutations that cause thalassemia. The mRNAs are now modified at both their 5' and 3' ends and move into the cytoplasm of the red cell precursor to act as a template for globin chain production.

Amino acids are transported to the mRNA template on carrier molecules called transfer RNAs (tRNAs). There are specific tRNAs for each amino acid. The order of amino acids in a globin chain is determined by a triplet code, where three bases (codons) code for a particular amino acid. The tRNAs also contain three bases, or anticodons, that are complementary to the mRNA codons for particular amino acids. Hence the tRNAs carry amino acids to the template, find the right position by codon/anticodon base pairing, and initiate globin chain synthesis. When the first tRNA is in position, a complex is formed between several protein initiation factors and the subunits of the ribosome that is to hold the growing peptide chains together on the mRNA as it is translated. A second tRNA moves in alongside and the two amino acids are united by a peptide bond; the globin chain is now two amino acid residues long. This process is continued as the message is translated, from left to right, until a specific codon for termination is reached, whereupon the finished globin chain drops off the ribosome mRNA complex and the ribosomal subunits are recycled. The finished globin chain combines with heme and three of its fellows to form a definitive hemoglobin molecule.

The developmental switches from embryonic to fetal and fetal to adult hemoglobin production are synchronized throughout the different organs of hemopoiesis that function at various times of development.^{4,6} The way in which these switches are regulated is not yet completely understood. It is believed that the LCR becomes spatially related sequentially

Fig. 13.2 A schematic representation of gene action and protein synthesis. Reproduced from Weatherall DJ, Clegg JB, eds. *The Thalassemia Syndromes*, Blackwell Science Ltd, 2001.

to the ϵ , γ and finally δ and β chains at different times during fetal development. Why this happens is not clear, although it is possible that there are specific DNA-binding proteins involved in the activation or repression of these genes at different developmental stages.

Classification

The thalassemias can be defined as a heterogeneous group of genetic disorders of hemoglobin synthesis, all of which result from a reduced rate of production of one or more of the globin chains of hemoglobin. This basic defect results in imbalanced globin chain synthesis, which is the hallmark of all forms of thalassemia.¹

The thalassemias can be classified at different levels. Clinically, it is useful to divide them into three groups: the severe transfusion-dependent (major) varieties; the symptomless carrier states (minor) varieties; and a group of conditions of intermediate severity that fall under the loose heading "thalassemia intermedia". This classification is retained because it has implications for both diagnosis and management.

Thalassemias can also be classified at the genetic level into the α , β , $\delta\beta$ or $\epsilon\gamma\delta\beta$ thalassemias, according to which globin chain is produced in reduced amounts (Table 13.1). In some thalassemias, no globin chain is synthesized at all, and hence they are called α^0 or β^0 thalassemias, whereas in others

some globin chain is produced but at a reduced rate; these are designated α^+ or β^+ thalassemias. The $\delta\beta$ thalassemias, in which there is defective δ and β chain synthesis, can be subdivided in the same way, i.e., into $(\delta\beta)^+$ and $(\delta\beta)^0$ varieties.

Because the thalassemias occur in populations in which structural hemoglobin variants are also common, it is not unusual to inherit a thalassemia gene from one parent and a gene for a structural variant from the other. Furthermore, since both α and β thalassemia occur commonly in some countries, individuals may receive genes for both types. All these different interactions produce an extremely complex and clinically diverse family of genetic disorders, which range in severity from death *in utero* to extremely mild, symptomless, hypochromic anemias.

Despite their genetic complexity, most thalassemias are inherited in a mendelian recessive or codominant fashion. Heterozygotes are usually symptomless, while more severely affected patients are either homozygous for α or β thalassemia, or compound heterozygous for different molecular forms of the diseases.

Distribution

A world map of the distribution of the thalassemias is shown

in Figs 13.3 and 13.4. Several detailed accounts of their frequency and population genetics have been reported.^{1,7}

The α^0 thalassemias are found predominantly in Southeast Asia and in the Mediterranean islands. The α^+ thalassemias occur widely throughout Africa, the Mediterranean region, the Middle East, parts of the Indian subcontinent, and throughout Southeast Asia. They occur at remarkably high frequencies in some populations, achieving carrier rates of between 40 and 80%.

The β thalassemias have a distribution similar to that of the α thalassemias. With the exception of a few countries, the β thalassemias are less common in Africa, extremely frequent in some of the Mediterranean island populations, and occur at variable frequencies throughout the Middle East, the Indian subcontinent and parts of Southeast Asia. As we shall see later, the structural hemoglobin variant, HbE, is associated with the phenotype of a mild form of β thalassemia. This also reaches extremely high gene frequencies in eastern parts of India, Myanmar, and in many countries in Southeast Asia. Thus the interaction of HbE and β thalassemia, HbE thalassemia, is the most important form of the disease in these regions.

There is increasing evidence that these high gene frequencies for the different forms of thalassemia have been maintained by heterozygote advantage against severe forms

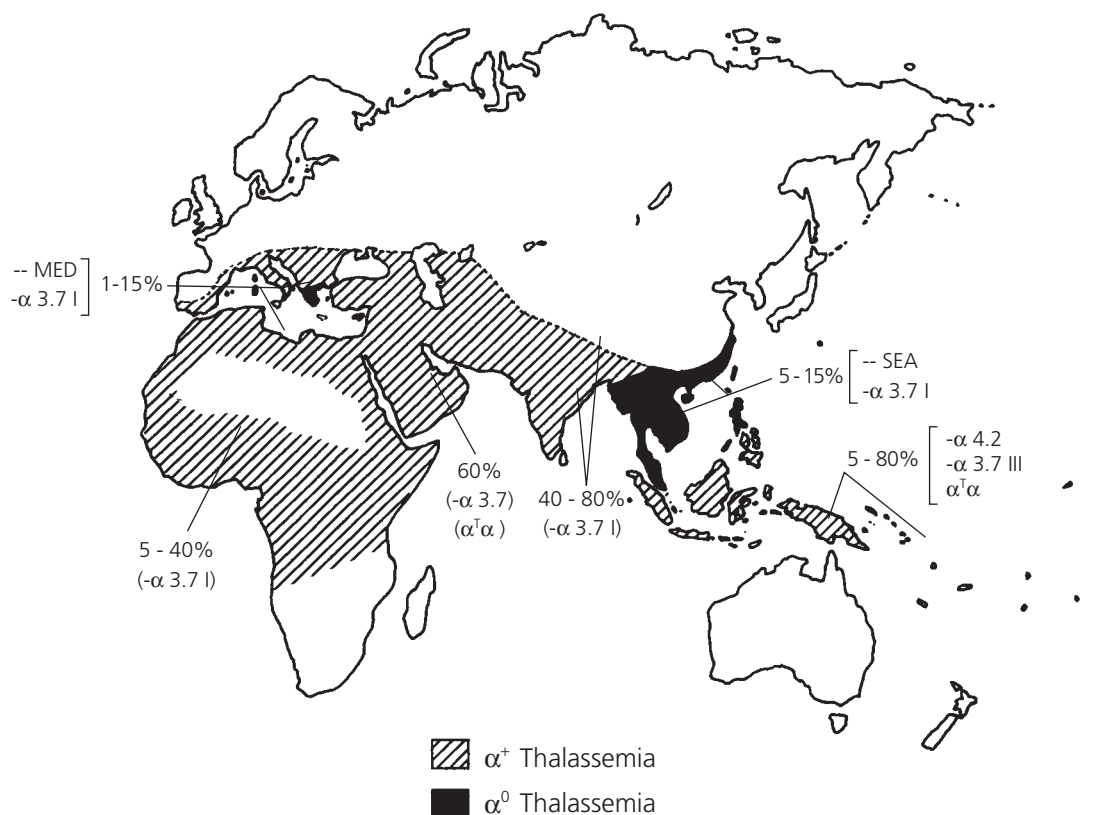

Fig. 13.4 World distribution of the different varieties of α thalassemia. The three different forms of α^+ thalassemia due to deletions of a single α -globin gene involving the loss of 3.7 kb of the α -gene cluster are represented as types I, II and III. The common deletional forms of α^0 thalassemia are designated MED (Mediterranean) and SEA (Southeast Asian). The percentages indicate the approximate frequency of these different genes.

of malaria, predominantly *Plasmodium falciparum*. One of the most remarkable features of the world distribution of these diseases is that in each high-frequency population there are different sets of mutations (Figs 13.3 and 13.4). This tells us that these diseases have arisen by new mutations and then been expanded very rapidly due to local selection by malaria. The fact that the mutations are so different among populations indicates that this selective force is, in evolutionary terms, quite recent, probably not more than a few thousand years.

Pathophysiology

To appreciate the pathophysiology of the thalassemias, it is necessary to understand both their molecular pathology and how globin chain imbalance causes the characteristic ineffective erythropoiesis and shortened red cell survival.

Molecular pathology

Although the basic principles are similar, the patterns of the mutations that cause α and β thalassemia are different. Because of their greater clinical importance, we consider the β thalassemias first.

Over 150 different mutations have been described in patients with β thalassemia (Fig. 13.5).^{8,9} Unlike the α thalassemias, major deletions causing β thalassemia are unusual. The bulk of β -thalassemia mutations are single base changes or small deletions or insertions of one or two bases at critical points along the genes. Remarkably, they occur in both introns and exons, and outside the coding regions of the genes.

Some substitutions, called nonsense mutations, result in a single base change in an exon that generates a stop codon in the coding region of the mRNA. This, of course, causes premature termination of globin chain synthesis and leads to the production of a shortened and nonviable β -globin chain. Other exon mutations cause frameshifts, which result in one or more bases being lost or inserted so that the reading frame of the genetic code is thrown out of phase or a new stop codon is produced. Mutations within introns or exons, or at their junctions, may interfere with the mechanism of splicing the exons together after the introns have been removed during processing of the mRNA precursor. For example, single substitutions at the invariant GT or AG sequences at the intron/exon junctions prevent splicing altogether and cause β^0 thalassemia. The sequences adjacent to the GT and AG sequences are highly conserved and are also involved in splicing; several β -thalassemia mutations involve this region

Fig. 13.5 Different classes of mutations of the β -globin gene involved in β thalassemia. FS, frameshift; NS, nonsense; SP, splicing; P, promoter; CL, polyA addition site mutations; IVS, intervening sequence.

and are associated with variable degrees of defective β -globin production. Mutations in sequences in exons that resemble consensus sequences at the intron/exon junctions may activate “cryptic” splice sites. For example, there is a sequence that resembles the IVS-1 consensus site and spans codons 24–27 of exon 1 of the β -globin gene; mutations at codons 19 (A→G), 26 (G→A), and 27 (G→T) result in both a reduced amount of mRNA due to abnormal splicing and an amino acid substitution encoded by the mRNA that is spliced normally and translated into protein. The abnormal hemoglobins produced are hemoglobins Malay, E and Knossos, each of which is associated with a mild β -thalassemia phenotype.

Single base substitutions are also found in the flanking regions of the β -globin genes. Those which involve the promoter elements downregulate β -globin gene transcription, and are usually associated with a mild form of β thalassemia. Other mutations involving the 3' end of the β -globin mRNA interfere with its processing and produce severe β -thalassemia phenotypes.

Because there are so many different β -thalassemia mutations, it follows that many patients who are apparently homozygous for the disease are, in fact, compound heterozygotes for two different molecular lesions. Rarely, patients are encountered with forms of β thalassemia in which the HbA₂ level, which is usually raised in carriers, is normal. Usually this results from the coinheritance of β and δ thalassemia.

The $\delta\beta$ thalassemias are also divided into the $(\delta\beta)^+$ and $(\delta\beta)^0$ forms. The $(\delta\beta)^+$ thalassemias result from misalignment of the δ and β globin genes during meiosis with the production of $\delta\beta$ fusion genes. These give rise to structural hemoglobin variants called the Lepore hemoglobins, after the family name of the first patient to be identified with this condition. Because the genes that direct the $\delta\beta$ fusion chains have δ -globin gene promoter regions that contain mutations which result in their ineffective transcription, the $\delta\beta$ chains are synthesized at a reduced rate and hence are associated with the phenotype of $\delta\beta$ thalassemia. The different forms of $(\delta\beta)^0$

thalassemia all result from long deletions of the β -globin gene cluster that remove the δ and β genes, and leave either one or both the γ -globin genes intact. Longer deletions that remove the β -globin LCR and all or most of the cluster completely inactivate the gene complex and result in $(\epsilon\gamma\delta\beta)^0$ thalassemia.^{9,10}

The molecular pathology and genetics of the α thalassemias are more complicated than that of β thalassemia, largely because there are two functional α -globin genes on each pair of chromosomes.^{9,11,12} The normal α -globin genotype can be written $\alpha\alpha/\alpha\alpha$. The α^0 thalassemias result from a family of different-sized deletions that remove both α -globin genes; the homozygous and heterozygous states are designated $--/--$ and $--/\alpha\alpha$, respectively. Rarely, α^0 thalassemia may result from deletions involving a region similar to the β -globin LCR, 40 kb upstream from the α -globin gene cluster, or from short truncations of the end of the short arm of chromosome 16.

The molecular basis for the α^+ thalassemias is more complicated. In some cases they result from deletions that remove one of the linked pairs of α -globin genes, $-\alpha/\alpha\alpha$, leaving the other intact, while in others both α -globin genes are intact but one of them has a mutation that either partially or completely inactivates it, $\alpha^T\alpha/\alpha\alpha$.

The deletion forms of α^+ thalassemia are further classified into the particular size of the underlying deletion. There are two common varieties, involving loss of either 3.7 or 4.2 kb of DNA; they are designated $-\alpha^{3.7}$ and $-\alpha^{4.2}$ respectively. It turns out that the former is quite heterogeneous, depending on the site of the abnormal genetic cross-over event that underlies the deletion. These deletions are thought to be due to misalignment and reciprocal cross-over between the α -globin gene segments at meiosis; this mechanism results in one chromosome with a single ($-\alpha$) α gene and the opposite of the pair with a triplicated ($\alpha\alpha\alpha$) α -gene arrangement.

Nondeletional forms of α thalassemia, in which the α -globin genes are intact, are caused by mutations that are very similar to those that cause β thalassemia. Some result from

initiation or splice mutations, or the production of a highly unstable α globin that is incapable of producing a viable tetramer. Another particularly common form, found in Southeast Asia, results from a single base change in the termination codon UAA, which changes to CAA. The latter is the code for the amino acid glutamine. Hence, when the ribosomes reach this point, instead of the chain terminating, mRNA which is not normally transcribed is read through until another stop codon is reached. Thus, an elongated α -globin chain is produced that is synthesized at a reduced rate; the resulting variant is called Hb Constant Spring after the name of the town in Jamaica where it was first discovered. It occurs in about 2–5% of the population of Thailand and other regions of Southeast Asia. Because the termination codon can change to yield several different codons, this variant is only one of a family of chain-termination mutants. Another common form of nondeletional α thalassemia, which is found in the Middle East, results from a single base change in the highly conserved sequence of the 3' coding region of the α -globin gene, AATAAA, which is changed to AATAAG. This is the signal site for polyadenylation of globin mRNA, a process that appears to stabilize its passage into the cytoplasm. This mutation results in marked reduction in α -globin chain production from the affected locus.

In addition to these common forms of α thalassemia, there is a syndrome characterized by mild α thalassemia and mental retardation (ATR) that is being recognized increasingly in many different populations. By combining clinical and molecular studies, it has been possible to subclassify this condition into two main syndromes, one encoded on chromosome 16 (ATR-16) and another on the X chromosome (ATR-X). ATR-16 is associated with relatively mild mental retardation and results from a variety of long deletions that remove the end of the short arm of chromosome 16. These may occur alone or as part of a chromosomal translocation.¹⁰ ATR-X, which is characterized by a more severe form of mental retardation with a severe dysmorphic picture, results from mutations of a gene on the X chromosome identified as *ATRX*.¹¹ The gene product is a DNA helicase that appears to be one of a family of *trans*-acting proteins involved with gene regulation through the remodeling of chromatin.¹² There is also a form of α thalassemia associated with myelodysplasia, particularly in elderly patients.¹³ Recently it has been found that this condition, like ATR, is also associated with acquired somatic mutations in *ATRX*.¹⁴

Cellular pathology

Although the basic defect, imbalanced globin chain synthesis, is similar in all types of thalassemia, the consequences of excess α or β chain production in the β and α thalassemias are quite different.¹ Excess α chains that are produced in β thalassemia are unable to form a hemoglobin tetramer and precipitate in the red cell precursors. On the other hand, the

excess of γ and β chains produced at different developmental stages in the α thalassemias are able to form homotetramers which, although unstable, are viable and form soluble hemoglobin molecules called Hb Barts (γ_4) and HbH (β_4). It is these fundamental differences in the behavior of the excess chains in the two common classes of thalassemia that are responsible for the major differences in their cellular pathology.

The β -thalassemias

The excess of α chains produced in β thalassemia is highly unstable, and rapidly precipitates and becomes associated with the membrane of red cell precursors and red cells. This phenomenon leads to extensive intramedullary destruction of red cell precursors, probably through a variety of complex mechanisms including interference with cell division and oxidative damage to the precursor membranes.^{15–18} Because they contain large inclusion bodies, such red cells as do reach the peripheral blood are damaged in their passage through the spleen and their membranes also suffer severe oxidative injury due to the action of heme liberated from denatured hemoglobin and the excess of iron that accumulates in the thalassemic red cell. Thus the anemia of β thalassemia reflects a combination of ineffective erythropoiesis combined with reduced red cell survival.

Small populations of red cell precursors retain the capacity for producing γ chains of HbF in extrauterine life. In β thalassemics these cells come under intense selection; the excess of α chains is smaller because some of them combine with γ chains to produce HbF. Thus, the baseline level of fetal hemoglobin is elevated in β thalassemia. Cell selection occurs throughout the lifespan of the HbF-rich population;¹ it is also apparent that there are a number of genetic factors that modify the ability to make HbF in response to severe anemia.¹⁹ These factors combine to produce increased levels of HbF in all forms of severe β thalassemia. Since δ -chain synthesis is unaffected in β thalassemia, heterozygotes usually have an elevated level of HbA₂, another important diagnostic feature.

The profound anemia of β thalassemia, and the production of red cell populations rich in HbF and a high oxygen affinity, combine to cause severe hypoxia and stimulate erythropoietin production. This, in turn, leads to extensive expansion of the ineffective erythroid mass with consequent bone changes, increased iron absorption, a high metabolic rate, and many of the other clinical features of severe β thalassemia. The bombardment of the spleen with abnormal red cells causes increasing splenomegaly; hence the disease may be complicated by trapping of part of the circulating red cell mass in the spleen which, together with sequestration of white cells and platelets, may produce the classical picture of severe hypersplenism.

Many of these features can be reversed by suppressing ineffective erythropoiesis by transfusion, which leads in turn to increased iron overload. The resulting pathology can

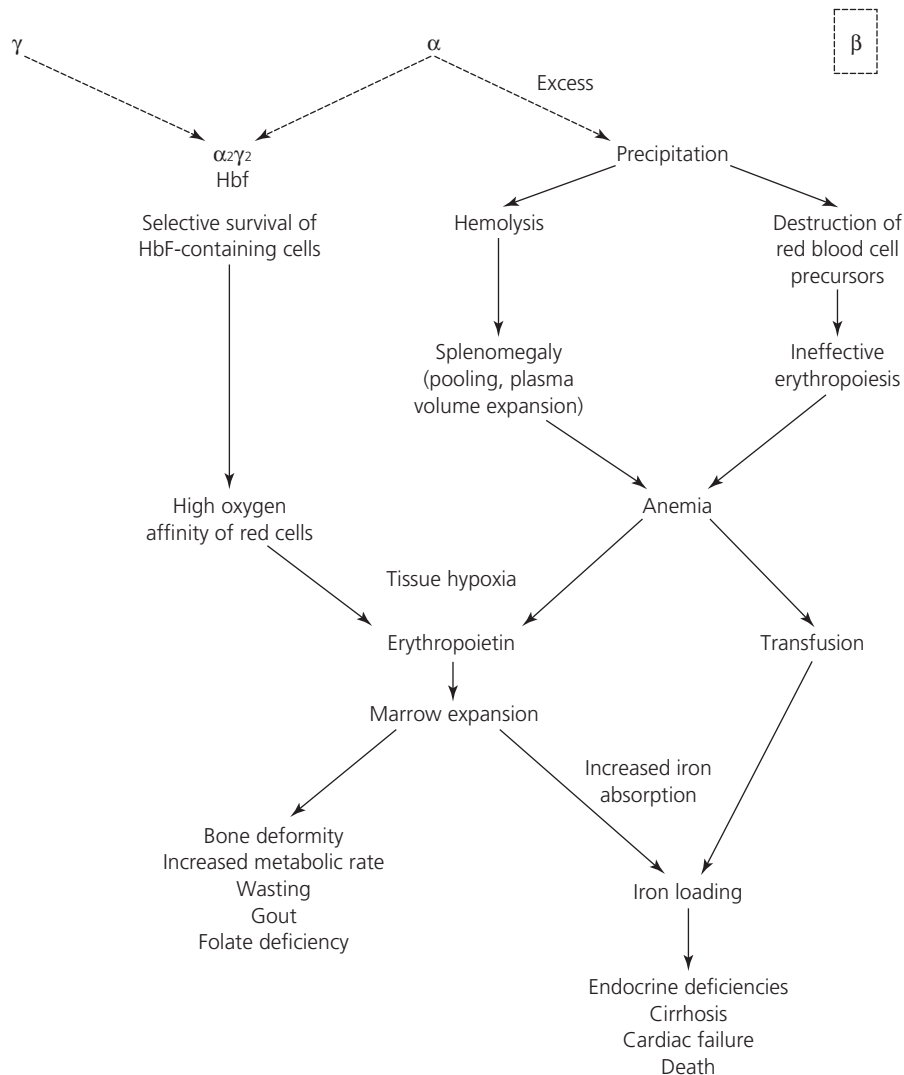

Fig. 13.6 Pathophysiology of β thalassemia.

be best appreciated against the background of normal iron metabolism.²⁰ In normal individuals, tight binding of plasma iron to the transport protein transferrin prevents the catalytic activity of iron in free-radical production.²¹ In heavily iron-loaded patients, transferrin becomes fully saturated and a nontransferrin-bound fraction of iron becomes detectable in plasma. This may accelerate the formation of free hydroxyl radicals and results in accelerated iron loading in tissues, with consequent organ damage and dysfunction. In patients with iron overload, excess iron is deposited in both reticulo-endothelial cells (where it is relatively harmless) and parenchymal tissue, primarily myocytes and hepatocytes (where it may cause significant damage). The toxicity of iron is mediated, in part, by its catalysis of reactions that generate free hydroxyl radicals, propagators of oxygen-related damage.²¹

Clearly, therefore, it is possible to relate most of the clinical features of severe β thalassemia to the consequences of defective β-globin production, the deleterious results of excess α-

globin chain synthesis on erythroid maturation and survival, and the effects of iron loading resulting from increased absorption and blood transfusion (Fig. 13.6). If these principles are appreciated, it is easy to understand why some forms of β thalassemia are associated with a much milder phenotype. Indeed, all the known factors that modify the phenotype of this disease act by reducing the amount of globin chain imbalance. They include the coinheritance of α thalassemia, the presence of a mild β-thalassemia allele, or the cosegregation of a gene that results in a higher than usual output of fetal hemoglobin.¹⁹

The α-thalassemias

The cellular pathology of α thalassemia, because of the properties of HbH and Hb Barts, is different in many ways to that of β thalassemia.^{1,11,18} As the result of the generation of these soluble tetramers there is less ineffective erythropoiesis. Particularly in the case of HbH, the tetramer tends to pre-

capitate as cells age, with the production of inclusion bodies, and hence a major hemolytic component is a feature of the disorder. The clinical effects of the anemia are exacerbated by the fact that both HbH and Hb Barts are homotetramers and therefore cannot undergo the allosteric changes required for normal oxygen delivery. They behave, in effect, like myoglobin and are unable to give up oxygen at physiologic tensions. Hence, high levels of Hb Barts or HbH are associated with severe hypoxia.

The pathophysiology of the α thalassemias can be best understood in terms of simple gene dosage effects.¹¹ In the homozygous state for α^0 thalassemia ($-/-$) no α chains are produced. Affected infants have very high levels of Hb Barts with some embryonic hemoglobin. Although their hemoglobin concentration might be compatible with intrauterine life if the structure of their hemoglobin were normal, the fact that it is nearly all Hb Barts renders them seriously hypoxic. Most affected infants are stillborn with all the signs of gross intrauterine hypoxia. The compound heterozygous state for α^0 and α^+ thalassemia ($-/\alpha^-$) results in less chain imbalance and is compatible with survival, a condition called HbH disease. This disorder is characterized by a variable hemolytic anemia; adaptation to the level of anemia is often unsatisfactory because HbH, like Hb Barts, is unable to function as an oxygen carrier.

The heterozygous state for α^0 thalassemia ($-/\alpha\alpha$) and the homozygous state for the deletion form of α^+ thalassemia ($-\alpha/-\alpha$) are associated with a mild hypochromic anemia, very similar to β -thalassemia trait. Although a few red cells contain HbH inclusions in α^0 -thalassemia trait, they are not observed in α^+ -thalassemia trait, suggesting that there must be a critical level of excess β chains required to form viable β_4 tetramers. Interestingly, the homozygous states for the nondeletion forms of α thalassemia ($\alpha^T\alpha/\alpha^T\alpha$) are associated with a more severe deficiency of α chains and the clinical phenotype of HbH disease.

Clinical features

The β thalassemias

Most children with the severe forms of homozygous or compound heterozygous β thalassemia present within the first year of life, with failure to thrive, poor feeding, intermittent bouts of infection, and general malaise. These infants are pale and, in many cases, splenomegaly is already present. At this stage there are no other specific clinical signs and the diagnosis rests on the hematologic changes, outlined later. If the infant receives regular red cell transfusions, subsequent development is usually normal and further symptoms do not occur until puberty, when, if they have not received adequate chelation therapy, the signs of iron loading start to appear. If, on the other hand, the infant is not adequately transfused,

the typical clinical picture of thalassemia major develops. It follows therefore that clinical manifestations of the severe forms of β thalassemia can be described in two contexts: in the well-transfused child, and in the child with chronic anemia throughout early childhood.^{1,22}

In the adequately transfused child, early growth and development are normal and splenomegaly is minimal or absent. If chelation therapy is effective, these children may enter normal puberty and continue to grow and develop normally into early adult life.^{23,24}

On the other hand, if chelation therapy is inadequate, there is a gradual accumulation of iron, the effects of which start to become manifest by the end of the first decade. The normal adolescent growth spurt fails to occur and the hepatic, endocrine and cardiac complications of iron overloading give rise to a variety of symptoms, including diabetes, hyperthyroidism, hypoparathyroidism and progressive liver failure. Secondary sexual development is delayed or absent.

The commonest cause of death in iron-loaded children, which usually occurs toward the end of the second decade or early in the third decade, is iron-induced cardiac dysfunction; these patients die either in protracted cardiac failure or suddenly due to an acute arrhythmia, often precipitated by infection.

The clinical picture in inadequately transfused patients is quite different.¹ The rates of growth and development are retarded and progressive splenomegaly may cause a worsening of the anemia, and is sometimes associated with thrombocytopenia. There may be extensive bone marrow expansion leading to deformities of the skull, with marked bossing and overgrowth of the zygomata giving rise to the classical "mongoloid" appearance. These bone changes are associated with a characteristic radiologic picture that includes a lacy trabecular pattern of the long bones and phalanges, and a characteristic "hair on end" appearance of the skull. These children are prone to infection, which may cause a catastrophic drop in the hemoglobin level. Because of the massive expansion of the ineffective erythroid mass, they are hypermetabolic, run intermittent fevers, and fail to thrive. They have increased requirements for folic acid; deficiency is often associated with worsening of anemia. Because of the increased turnover of red cell precursors, hyperuricemia and secondary gout occur occasionally. There is also a bleeding tendency, which, although partly explained on the basis of thrombocytopenia, may also be exacerbated by liver damage associated with iron loading, viral hepatitis, or extramedullary hemopoiesis. If these children survive to puberty, they often develop the same complications of iron loading as well-transfused patients; in this case some of the iron accumulation results from an increased rate of gastrointestinal absorption.

The prognosis for inadequately transfused thalassemic children is poor. If they receive no transfusions, they may die within the first 2 years; if maintained at a low hemoglobin

level throughout childhood, they usually die of infection or other intercurrent illness in early childhood. If they survive to reach puberty, they succumb to the effects of iron accumulation in the same way as the adequately transfused but poorly chelated child.

It should be emphasized that poor growth in children with β thalassemia is not restricted to those who are inadequately transfused or iron chelated. This problem is also observed in well-managed patients for reasons that are not entirely understood, and may include iron-induced selective central hypogonadism, impaired growth hormone responses to growth hormone-releasing hormone, delay in pubertal development, zinc deficiency, and over-intensive deferoxamine administration.

On presentation, hemoglobin values in the thalassemic child range from 2 to 8 g/dL. The red cells show marked hypochromia and variation in shape and size; there are many hypochromic macrocytes and misshapen microcytes, some of which are mere fragments of cells. There is moderate basophilic stippling and nucleated red cells are always present in the peripheral blood. After splenectomy these may appear in large numbers. The reticulocyte count is only moderately elevated. The white cell and platelet counts are normal unless hypersplenism is present. The bone marrow shows marked erythroid hyperplasia and many of the red cell precursors contain ragged inclusions, best demonstrated by staining with methyl violet, that represent α -globin precipitates.

The HbF level is always elevated and it is heterogeneously distributed among the red cells. In β^0 thalassemia there is no HbA; the hemoglobin consists of F and A₂ only. In β^+ thalassemia the level of HbF ranges from 20 to over 90%. The HbA₂ value is usually normal and of no diagnostic value. *In vitro* globin synthesis studies, involving the labeling of the globin chains with radioactive amino acids, reveals a marked degree of globin chain imbalance with an excess of α over non- α chain production.

β -Thalassemia trait

This is almost invariably asymptomatic and is characterized by mild anemia; splenomegaly is unusual. There is a slightly reduced hemoglobin level and a marked reduction in mean cell hemoglobin (MCH) and mean cell volume (MCV). The blood film shows hypochromia, microcytosis and variable basophilic stippling. In the majority of cases the HbA₂ level is elevated to about twice normal (i.e., in the 4–6% range), while there is a slight elevation of HbF in about 50% of cases. In some populations, notably those of the Mediterranean, β -thalassemia trait may be associated with a normal HbA₂ level. By far the commonest cause is the coinheritance of a gene for δ thalassemia. For genetic counseling (see later), it is vital to distinguish this condition from the different forms of α -thalassemia trait.

Intermediate forms of β thalassemia

Not all forms of homozygous or compound heterozygous β thalassemia are transfusion dependent from early life. The term “ β thalassemia intermedia” is used to describe a wide spectrum of conditions, ranging from those that are almost as severe as β thalassemia, with marked anemia and growth retardation, to those which are almost as mild as β -thalassemia trait and which may only be discovered on routine hematologic examination.¹⁹ In the more severe varieties there is obvious growth retardation, bone deformity and failure to thrive from early life and, except for a later presentation, the condition differs little from the transfusion-dependent forms of the illness. For its management this type of thalassemia intermedia should be considered to be in the same category as the severe transfusion-dependent form. On the other hand, many varieties are associated with good early growth and development, a satisfactory steady-state hemoglobin level, and mild to moderate splenomegaly. Even in these patients, several important complications may develop as these patients grow older, including increasing bone deformity, progressive osteoporosis with spontaneous fractures, leg ulcers, folate deficiency, hypersplenism, progressive anemia, and the effects of systemic iron overload due to increased intestinal absorption.

β Thalassemia associated with β -globin structural variants

Although β thalassemia has been found in association with many different β -globin chain variants, the only common disorders of this type are due to the coinheritance of HbS, HbC, or HbE.^{1,3}

HbS β thalassemia

HbS β thalassemia varies considerably in its clinical manifestations, depending mainly on the nature of the associated β -thalassemia gene. HbS β^0 thalassemia, in which no HbA is produced, is often indistinguishable from sickle cell anemia. Similarly, HbS β^+ thalassemia in which the thalassemia gene results in a very low output of normal β chains, and hence a level of HbA in the 5–10% range, often runs a severe course. On the other hand, HbS β^+ thalassemia in which the β -thalassemia allele is of the mild variety, particularly those forms seen in Black populations and in which levels of HbA are in the 30–40% range, may be extremely mild and are often asymptomatic. The clinical manifestations of the sickling disorders are described in Chapter 10.

HbC β thalassemia

HbC β thalassemia occurs in West Africa and in the Mediterranean population and is characterized by a mild to moderate form of thalassemia intermedia with the typical hematologic changes of thalassemia associated with the presence of nearly 100% of target cells in the peripheral blood.

Fig. 13.7 Child with HbE β thalassemia showing the typical facial appearance of the more severe forms of the disease. This child had undergone splenectomy for worsening anemia.

HbE β thalassemia

HbE β thalassemia is a condition of major importance in eastern parts of India, Bangladesh, Myanmar, and throughout Southeast Asia. Since HbE behaves like a mild β -thalassemia allele, it is not surprising that this condition can behave like homozygous β thalassemia. However, what is difficult to explain is the remarkable clinical variability in its course. The clinical picture and complications may range from those of transfusion-dependent homozygous β thalassemia (Fig. 13.7) through the milder forms of thalassemia intermedia, as described above. The pattern of complications of the more severe forms of HbE β thalassemia are similar to those described earlier for β thalassemia major; the milder forms behave like β -thalassemia intermedia. The hemoglobin pattern depends on the nature of the associated β -thalassemia gene; in HbE β^0 thalassemia the globin is made up of F and E, whereas in HbE β^+ thalassemia there are variable amounts of HbA.

$\delta\beta$ Thalassemia

The common forms of $(\delta\beta)^+$ thalassemia are the Hb Lepore disorders.^{1,19} The homozygous state is usually characterized by a clinical disorder that is indistinguishable from β

thalassemia major, although some cases run a milder course. The hemoglobin consists mainly of HbF, with up to 20% Hb Lepore. Heterozygotes for the different Hb Lepore disorders have the hematologic findings of thalassemia trait, with a hemoglobin pattern that consists of approximately 5–15% Hb Lepore and low or normal levels of HbA₂.

There are many different molecular varieties of $(\delta\beta)^0$ thalassemia. The homozygous states are characterized by a mild to moderate form of thalassemia intermedia with typical thalassemic red cell changes and a hemoglobin pattern characterized by 100% HbF. Heterozygotes have mild thalassemic red cell changes, with levels of HbF in the 10–20% range and low-normal levels of HbA₂.

$(\epsilon\gamma\delta\beta)^0$ Thalassemia

This condition has not been observed in the homozygous state, presumably because it would be incompatible with fetal survival. Heterozygotes may be quite severely anemic at birth, with the clinical picture of hemolytic disease of the newborn²⁵ associated with hypochromic red cells and globin chain imbalance typical of β -thalassemia trait. For reasons that are not understood, anemia improves with age, hemoglobin level increasing during childhood; in adult life a blood picture typical of β -thalassemia trait but with a normal HbA₂ level is observed.

The α thalassemias

Homozygous α^0 thalassemia

This condition, Hb Barts hydrops syndrome, is usually characterized by death *in utero*.^{1,12} These babies are either stillborn near term or, if liveborn, untreated usually only survive for a short period. The clinical picture is typical of hydrops fetalis, with marked edema and hepatosplenomegaly. The blood picture shows a hemoglobin level in the 6–8 g/dL range and the red cells are hypochromic with numerous nucleated forms. The hemoglobin consists of approximately 80% Hb Barts, with the remainder the embryonic Hb Portland. This syndrome is associated with a high frequency of toxemia of pregnancy, with postpartum bleeding, and other problems due to massive hypertrophy of the placenta. Autopsy studies show an increased frequency of fetal abnormalities, although these are not always present; in a few babies that have been rescued by exchange transfusion and maintained on regular red cell transfusions, growth and development has not always been normal.

α^0/α^+ Thalassemia: HbH disease

This condition is characterized by a moderate degree of anemia and splenomegaly. It has a remarkably variable clinical course: while some patients become transfusion dependent,

the majority are able to grow and develop normally without transfusion. The blood picture shows typical thalassemic red cell changes and the hemoglobin pattern is characterized by variable amounts of HbH, small amounts of Hb Barts, and a low-normal level of HbA₂. HbH may be demonstrated by incubating the red cells with a redox agent like brilliant cresyl blue, which causes it to precipitate with the formation of inclusion bodies. After splenectomy, large preformed inclusion bodies are present in many of the red cells.

α -Thalassemia trait

The clinical picture of α -thalassemia trait may result from the heterozygous state for α^0 thalassemia ($-/-\alpha\alpha$) or the homozygous state for α^+ thalassemia ($-\alpha/-\alpha$) as described above. These conditions are asymptomatic and the hematologic findings are characterized by a mild hypochromic anemia with a marked reduction in MCH and MCV. The hemoglobin pattern is normal and these conditions can only be diagnosed with certainty by DNA analyses. In the newborn period there are increased levels of Hb Barts, in the 5–10% range, but HbH is not demonstrable in adult life; occasional inclusions may be seen in the red cells in α^0 -thalassemia carriers.

“Silent” α -thalassemia carriers

The heterozygous state for α^+ thalassemia ($-\alpha/\alpha\alpha$) is associated with no hematologic abnormalities and a normal hemoglobin pattern in adult life. At birth approximately 50% of cases have slightly elevated levels of Hb Barts in the 1–3% range, but its absence does not rule out the diagnosis.

α Thalassemia mental retardation syndromes

The ATR-16 syndrome is characterized by moderate mental retardation and a very mild form of HbH disease or a blood picture resembling α -thalassemia trait. Patients with this disorder should undergo detailed cytogenetic analysis; in some cases chromosomal translocations may be found that are of importance for genetic counseling for future pregnancies. The ATR-X syndrome is characterized by severe mental retardation, seizures, an unusual facial appearance with flattening of the nose, urogenital abnormalities, and other dysmorphic features.²⁶ The blood picture shows a mild form of HbH disease or α -thalassemia trait, and HbH inclusions can usually be demonstrated. The mothers of these children usually have small populations of red cells that contain HbH inclusions.

Screening and prevention

There are two major approaches to the avoidance of the thalassemias. Since the carrier states for β thalassemia can

be easily recognized, it is possible to screen populations and provide genetic counseling about the choice of marriage partners. If two β -thalassemia heterozygotes marry, one in four of their children will have the severe compound heterozygous or homozygous disorder. Alternatively, when heterozygous mothers are identified prenatally, the husbands may be tested; if they are also carriers, the couple may be counseled and offered the possibility of prenatal diagnosis and termination of pregnancies carrying a fetus with a severe form of β thalassemia.

Screening

If populations wish to offer marital choice, it is essential to develop premarital screening programs, best carried out in schoolchildren. It is vital to have a very well organized genetic counseling program in place and to provide both verbal advice and written information about the results of screening. The alternative approach is to screen every woman of an appropriate racial background in early pregnancy.

Probably the most cost-effective way of screening for thalassemia is through red cell indices.²⁷ If MCV and MCH values are found to be in the range associated with the carrier states for thalassemia, a HbA₂ estimation should be carried out.⁵ This will be elevated in the majority of cases of β thalassemia. If the HbA₂ level is normal, it is essential to refer the patient to a center that can analyze the α -globin genes. It is important to distinguish between the homozygous state for α^+ thalassemia ($-\alpha/-\alpha$) and the heterozygous state for α^0 thalassemia ($-/-\alpha\alpha$); in the former case the patient is not at risk for having a baby homozygous for α^0 thalassemia with its attendant obstetric risks. In those rare cases in which the blood picture resembles heterozygous β thalassemia but the HbA₂ level is normal and the α -globin genes are intact, the differential diagnosis lies between a nondeletional form of α thalassemia and a normal-HbA₂ form of β thalassemia. These conditions have to be distinguished by globin chain synthesis analysis and further DNA studies.²⁸ It is important, of course, to carry out routine hemoglobin electrophoresis in all these cases to exclude a coexisting structural hemoglobin variant.

Prenatal diagnosis

Prenatal diagnosis of different forms of thalassemia can be carried out in several ways.²⁸ It can be made by studies of globin chain synthesis in fetal blood samples obtained by fetoscopy at 18–20 weeks' gestation, although this approach has now been largely replaced by fetal DNA analysis. DNA is usually obtained by chorionic villous sampling (CVS) between weeks 9 and 12 of gestation. There is a small risk of fetal loss and of the production of fetal abnormalities following this approach.²⁷

The diagnostic techniques used for DNA analysis after CVS have changed rapidly over recent years.²⁸ The first

diagnoses were carried out by Southern blotting of fetal DNA, using either restriction fragment length polymorphisms (RFLPs) combined with linkage analysis, or direct detection of mutations. More recently, following the development of the polymerase chain reaction (PCR), the identification of thalassemia mutations in fetal DNA has been greatly facilitated. For example, it can be used for the rapid detection of mutations that alter restriction enzyme cutting sites. The particular fragment of the β -globin gene is amplified, after which the DNA fragments are digested with an appropriate enzyme and separated by electrophoresis; these fragments can be detected by either ethidium bromide or silver staining of DNA bands on gels, and radioactive probes are not required.

Now that the mutations have been identified in many forms of α and β thalassemia, it is possible to detect them directly as the first-line approach to fetal DNA analysis. The development of PCR, combined with the availability of oligonucleotide probes to detect individual mutations, has opened up a variety of new approaches for improving the speed and accuracy of carrier detection and prenatal diagnosis. For example, a diagnosis can be made using hybridization of specific ^{32}P -end-labeled oligonucleotides to an amplified region of the β -globin genes dotted onto nylon membranes. Since the β -globin gene sequence of interest can be amplified more than a million-fold, thus increasing the efficiencies of probe annealing, hybridization times can be limited to 1 hour, and the entire procedure can be carried out in 2 hours.

There are many variations on the PCR approach to prenatal diagnosis. For example, in a technique called ARMS (amplification refractory mutation system), which is based on the observation that, in many cases, oligonucleotides for the 3' mismatched residue will, under appropriate conditions, not function as primers in the PCR, it is possible to construct two specific primers.²⁹ The normal primer is refractory to PCR on a mutant template DNA, while the mutant sequence is refractory to PCR on normal DNA. Other modifications of PCR involve the use of nonradioactively labeled probes.

The error rate using these different approaches in most laboratories is now well below 1%.³⁰ Potential sources of error include maternal contamination of fetal DNA, nonpaternity and, if RFLP linkage analysis is used, genetic recombination.

More recently, other approaches have been developed for prenatal detection of the thalassemias, including the isolation of fetal cells from maternal blood and preimplantation diagnosis.¹ Although there have been a few reported successes of the prenatal diagnosis of β thalassemia and Hb Lepore thalassemia by the analysis of fetal cells isolated from the maternal circulation, this technique is still under development and is only applicable to certain forms of β thalassemia. Several laboratories have reported success with preimplantation diagnosis but this remains technically difficult; this seems to be a promising area for future development in this field.

Clinical management

Over recent years there have been major improvements in the clinical management of the severe forms of β thalassemia.²² The development of better blood transfusion regimens, combined with effective iron-chelating therapy, has transformed the outlook for children with this disease, at least those for whom, in richer countries, this treatment is available.

Red cell transfusions

Regular red cell transfusions eliminate the complications of anemia and ineffective erythropoiesis, permit normal growth and development throughout childhood, and extend survival in thalassemia major.^{20,22} The decision to initiate regular transfusions is generally based on the observation of a hemoglobin concentration less than 6 g/dL over three consecutive months, a finding usually associated with poor growth, splenic enlargement and some degree of marrow expansion. Determination of the molecular basis for severe β thalassemia is only occasionally of value in predicting a requirement for regular transfusions.^{1,19} Prior to the first transfusion, iron and folate status should be assessed, a hepatitis B vaccine series should be initiated, and a complete red cell phenotype obtained so that subsequent alloimmunization may be detected.

It is important that the pretransfusion hemoglobin concentration does not generally exceed 9.5 g/dL.³¹ The pretransfusion hemoglobin concentration, the volume of red cells administered, the weight of the patient, and the size of the spleen should be recorded at each visit in order to detect the development of hypersplenism.

Type of red cell concentrates

All patients should receive leukocyte-reduced red cell preparations.³² Early clinical experience with neocytes, young red blood cells separated from older cells by density centrifugation, suggested that their use is associated with modest extensions of transfusion intervals and reduction in annual transfusional iron load.³³ However, because these potential benefits are offset by major increases in preparation expenses and donor exposure,³⁴ neocytes have had a minor impact on the long-term management of patients with thalassemia.

Alloimmunization

Red cell alloimmunization may be higher in patients in whom blood transfusion was begun after the age of 1 year,³² and lower in Mediterranean patients (3–10%) compared with Asian individuals (~21%), because of differences in antigenic distribution.³⁵ If possible, patients with thalassemia should receive blood matched for ABO, CcDdEe, and Kell antigens.

Splenectomy

In the past, an increase in transfusion requirements due to hypersplenism was frequently observed at the age of approximately 10 years. When annual transfusion requirements exceed 200–250 mL packed cells per kilogram body weight, splenectomy significantly reduces these requirements.³⁶ In the modern era, with improved transfusion practices, hypersplenism is reduced and many patients do not require splenectomy.²² Concerns that splenectomy may be associated with acceleration of iron loading in other organs remain unproven; the spleen does not appear to be a significant repository of transfused iron.³⁷ The biliary tract should be carefully assessed at surgery, but in the absence of disease there seems little place for prophylactic cholecystectomy. Because of the risk of postsplenectomy infection, splenectomy should usually be delayed until the age of 5 years.²² At least 3 weeks prior to splenectomy, patients should be vaccinated with the pneumococcal and *Haemophilus influenzae* type B vaccines, and after surgery daily prophylactic penicillin should be administered at least during childhood and probably indefinitely. Erythromycin should be substituted for those who are allergic to penicillin.

Infectious complications

Hepatitis B and hepatitis C virus, HIV, human T-cell leukemia virus and cytomegalovirus may cause significant morbidity and mortality in humans.³² Iron-induced hepatic damage may be influenced by infection with hepatitis C virus, the most frequent cause of hepatitis in thalassemic children. The clinical and pathologic responses to interferon- α in thalassemia patients with hepatitis C may be inversely related to body iron burden.³⁸ A 70% response rate in interferon-naïve patients treated for 12 months with interferon α and ribavirin has been reported.³⁹ Infection with *Yersinia enterocolitica*, which poses a risk because of its growth enhancement in iron-rich environments,⁴⁰ should be suspected in patients with iron overload who present with high fever and no obvious focus of infection. Even in the absence of a positive blood culture for *Yersinia* in this clinical setting, therapy with intravenous gentamicin and oral trimethoprim-sulfamethoxazole should be promptly instituted, and continued for at least 7 days. Transfusion-transmitted malaria remains a major hazard in many developing countries.

Iron overload and iron-chelating therapy

Iron overload is the most important consequence of life-saving transfusions in thalassemia.²⁰ The only chelating agent approved for first-line therapy is deferoxamine. The standard method of deferoxamine administration today is prolonged parenteral infusion using portable ambulatory pumps (reviewed in ref. 20). Even suboptimal doses of defer-

oxamine prevent a rise in body iron during transfusion.⁴¹ Early reports of the beneficial effects of deferoxamine therapy on survival^{42,43} were confirmed by two studies from four North American centers with follow-up periods of 10–15 years.^{23,24} Patients in whom most serum ferritin concentrations were maintained at less than 2500 $\mu\text{g/L}$ over 15 years had an estimated cardiac disease-free survival of 91%. Similarly, patients with hepatic storage iron less than 15 mg/g liver dry weight were protected from cardiac disease, impaired glucose tolerance and diabetes mellitus. Survival in recent studies in compliant patients is reported as 95–100% at 30 years of age.^{44–49}

Liver disease

The beneficial effects of deferoxamine on liver disease, the second leading cause of death in thalassemia,⁴² include reduction in iron concentration and improvement in liver function even in patients with massively elevated hepatic iron concentrations.⁴¹

Endocrine function

Long-term deferoxamine appears to have a beneficial effect on growth, sexual maturation and other endocrine complications (reviewed in ref. 20). Normal pubertal development has been reported in approximately 50–70% of younger patients,⁴² although the development of secondary amenorrhea may develop eventually in about 20% of women. Adequate deferoxamine therapy also reduces the likelihood of the development of diabetes mellitus and hypothyroidism.^{24,44} A striking increase in fertility in both men and women, as well as many successful pregnancies, has been reported over the last decade.⁴⁵

Growth

In well-transfused but inadequately chelated patients, the first evidence of iron-mediated damage to the hypothalamic-pituitary axis may be amelioration of the pubertal growth spurt, associated with delayed sexual maturation. In some patients overintensive deferoxamine administration may be a cause of poor growth.⁴⁶

Optimal body iron in patients with thalassemia major

The magnitude of the body iron burden is the principal determinant of clinical outcome.^{23,24} A balance must be struck between the risk of complications from iron overload and the toxicity of deferoxamine, which is increased in the presence of a relatively reduced body iron burden.⁴⁷ A conservative goal for iron-chelating therapy in thalassemia is maintenance

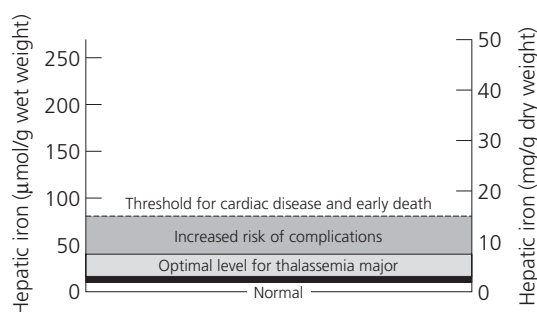

Fig. 13.8 Thresholds of hepatic iron concentration in thalassemia (see text).

of hepatic storage iron between 3.2 and 7 mg/g liver dry weight (Fig. 13.8).^{20,48}

Management of iron-chelating therapy

One practical problem associated with long-term chelating therapy is the assessment of body iron. While plasma or serum ferritin concentration is the most commonly used indirect estimate of body iron stores, a concentration exceeding 4000 μg/L, the result of ferritin release from damaged cells, may not reflect body iron stores.⁴⁹ Changes above this level of serum ferritin may have limited clinical relevance. Inter-

pretation of the serum ferritin may be complicated by a variety of conditions that alter concentrations independently of changes in body iron, including ascorbate deficiency, acute and chronic infection and inflammation, hepatic disease, and ineffective erythropoiesis.²⁰ Because of this, in thalassemia major, variations in body iron account for only 57% of the variation in serum ferritin.⁵⁰

In contrast, measurement of hepatic iron concentration is a quantitative, specific and sensitive method of assessing body iron burden in thalassemia (Table 13.2).^{51,52} Liver biopsy represents the best means of evaluating the pattern of iron accumulation, and the inflammatory activity and histology of the liver. Liver biopsy under ultrasound guidance has a low complication rate in children,⁵³ and should be performed at important crossroads in the management of the child with thalassemia.

Imaging techniques including computed tomography and magnetic resonance imaging (MRI) have been used to evaluate tissue iron stores *in vitro* and *in vivo*.⁵¹ Although MRI potentially provides the best available technique for examining the distribution of excess iron, further research is needed to develop means of making these measurements quantitative.⁵¹ To date, MRI has been more useful as a screening technique for the detection of marked iron overload than as a means for quantitative measurement.⁵¹ A calibration curve relating liver MRI signal to hepatic iron concentration has

Table 13.2 Assessment of body iron burden in thalassemia.

Test	Comments
<i>Indirect (most tests widely available)</i>	
Serum/plasma ferritin concentration	Noninvasive Lacks sensitivity and specificity Poorly correlated with hepatic iron concentration in individual patients
Serum transferrin saturation	Lacks sensitivity
Tests of 24-hour deferoxamine-induced urinary iron excretion	Less than half of outpatient aliquots collected correctly Ratio of stool to urine iron variable; poorly correlated with hepatic iron concentration
<i>Imaging of tissue iron</i>	
Computed tomography: liver	Variable correlation with hepatic iron concentration reported
Magnetic resonance	
Liver	Variable correlations with hepatic iron concentration reported Treatment-induced changes confirmed by liver biopsy
Heart	Only modality available to image cardiac iron stores; changes observed during chelating therapy consistent with reduction in cardiac iron
Anterior pituitary	Only modality available to image pituitary iron; signal moderately well correlated with pituitary reserve
Evaluation of organ function	Most tests lack sensitivity and specificity; may identify established organ dysfunction
<i>Direct (most tests not widely available)</i>	
Cardiac iron quantitation: biopsy	Imprecise due to inhomogeneous distribution of cardiac iron
Hepatic iron quantitation: biopsy	Reference method; provides direct assessment of body iron burden, severity of fibrosis and inflammation Safe when performed under ultrasound guidance
Superconducting susceptometry (SQUID)	Noninvasive; excellent correlation with biopsy-determined hepatic iron

Table 13.3 Monitoring of deferoxamine-related toxicity.

Toxicity	Investigations	Frequency	Alteration in therapy
High-frequency sensorineural hearing loss	Audiogram	Yearly; if patient symptomatic, immediate reassessment	Interrupt DFO immediately Directly assess body iron burden Discontinue DFO \times 6 months if HIC 3.2–7 mg/g dry wt liver tissue Repeat audiogram every 3 months until normal or stable Adjust DFO to HIC (see Table 15.2)
Retinal abnormalities	Retinal examination	Yearly; if patient symptomatic, immediate reassessment	Interrupt DFO immediately Directly assess body iron burden Discontinue DFO \times 6 months if HIC 3.2–7 mg/g dry wt liver tissue Review every 3 months until normal or stable Adjust DFO to HIC (see Table 15.2)
Metaphyseal and spinal abnormalities	Radiography of wrists, knees, thoraco-lumbar-sacral spine Bone age of wrist	Yearly	Reduce DFO to 25 mg/kg daily \times 4/week Directly assess body iron burden Discontinue DFO \times 6 months if HIC \leq 3 mg/g dry weight liver tissue Reassess HIC after 6 months Adjust DFO to HIC (see Table 15.2)
Decline in height velocity and/or sitting height	Determination of sitting and standing heights	Twice yearly	As for metaphyseal and spinal abnormalities Regular (6-monthly) assessment by pediatric endocrinologist

DFO, deferoxamine; HIC, hepatic iron concentration.

been deduced over a clinically relevant range of hepatic iron concentrations, with a coefficient of variation of 2.1%.⁵⁴ Biomagnetic susceptometry (SQUID)⁵⁵ provides the only noninvasive measurement of tissue iron stores validated for use in clinical studies, but it is available in only a few centers worldwide.⁵¹ Recently, attempts to assess cardiac iron using different MRI techniques have included a much-promoted “T2*” technique,^{56,57} the validity and prognostic significance of which requires clarification by long-term, prospective studies.⁵⁸ The most comprehensive and valid assessment of cardiac function is still the combined information obtained from the patient’s transfusion record, knowledge of adherence to a chelation regimen, and serial hepatic iron concentrations.⁵⁹

Initiation and management of chelating therapy

Few guidelines exist with respect to the start of iron-chelating therapy. In practice, the usual approach is to begin a regimen of nightly subcutaneous deferoxamine based on the serum ferritin concentration after a period of regular transfusions, but initiation (and titration) of deferoxamine therapy is ideally based on hepatic iron concentration, determined after 1 year of regular transfusions. If a liver biopsy is not obtained, treatment with subcutaneous deferoxamine not exceeding 25–35 mg/kg body weight per 24 hours should be initiated after approximately 1 year of regular transfusions.

Balance between effectiveness and toxicity of deferoxamine (Table 13.3)

Virtually all toxicities are *dose related*, occurring only when excessive doses, or regular doses in patients with modest body iron burdens, are administered. Guidelines for safe dosage include restricting daily doses to 50 mg/kg body weight or less and twice-yearly calculation of a “toxicity” index, calculated as mean daily dose of deferoxamine (mg/kg) divided by serum ferritin concentration ($\mu\text{g/L}$), which should not exceed 0.025.^{47,60,61}

Alternatives to subcutaneous infusion of deferoxamine

The most common difficulty associated with long-term therapy is erratic compliance, especially in adolescents. Regimens of intravenous ambulatory deferoxamine, in which drug is administered through implantable venous access ports,⁶² circumvents tissue irritation and are associated with rapid reduction of body iron burden and good patient compliance. Such regimens have been shown to reverse cardiac dysfunction.⁶³

Orally active iron-chelating agents

The expense and inconvenience of deferoxamine has led to a long-time search for an orally active iron chelator. The agent most extensively evaluated to date is deferiprone. Clinical

trials that were intended to support an application for the licensing of deferiprone were terminated prematurely by their corporate sponsor in 1996 after concerns were raised by the investigators about inadequate control of body iron in many patients.⁶⁴ Because serum ferritin showed a less clear relationship to hepatic iron concentration⁶⁵ than in patients treated with deferoxamine, it may be problematic to interpret changes in serum ferritin as evidence of the effectiveness of deferiprone. In studies which determined hepatic storage iron, this exceeded 15 mg/g dry weight in 18–65% of patients treated over 2–8 years,⁶⁶ raising concerns that deferiprone may not be sufficiently effective to protect all patients from iron-induced cardiac disease.

Claims that deferiprone is a more effective cardioprotective agent than deferoxamine are not yet supported by prospective clinical data.^{58,67} Continued cardiac mortality in patients receiving deferiprone has been reported,^{65,68} including deaths after years of treatment, during which period an improvement in cardiac disease is regularly observed with deferoxamine.

Since 1999, deferiprone has been licensed for patients in Europe “unable to use” deferoxamine. An application submitted to North American regulators in 2002 has been unsuccessful in obtaining marketing approval to date. Reassuringly, only 16 patients truly “unable to use” deferoxamine are reported in the literature over 20 years;⁶⁹ all have been capable of being desensitized and of resuming deferoxamine safely. Non-compliance remains a serious problem however.

Deferiprone has also been administered “in combination” with deferoxamine (although this combination is not formally permitted under European licensing). Most of these are short-term studies, with periods of administration less than 2 years, report poor control of iron in most of the 39 patients. No long-term efficacy or safety data are available for combination therapy.^{69a}

Toxicity of deferiprone

Reports of arthropathy in deferiprone-treated patients are somewhat confusing. Most reviews claim that this complication, “varies between ethnic groups;” subtotal destruction with an incidence of 2–10%, is reversible on stopping the drug. However, recent data suggest that both the incidence and severity of this complication varies between ethnic groups; subtotal destruction of the knee joints has now been observed in some patients. In India,^{70,71} Sri Lanka,^{72,73} and Lebanon,^{74,75} arthropathy is reported as developing in up to 50% of patients. A lower incidence (0–18%) has been reported from other centers.^{68,76–80}

Accelerated progression of hepatic fibrosis has been observed at proportions of 29%,⁷⁸ 36%,⁸¹ 37%,⁷⁹ and 0%⁸² (of all patients who underwent baseline and follow-up biopsies). In some^{79,82} but not all⁸¹ studies, liver function worsened in

deferiprone-treated patients, regardless of hepatitis C virus status, while remaining unchanged in deferoxamine-treated patients. More worrisome is the evidence of hepatocellular damage in deferiprone-treated patients emerging after many years of treatment,^{68,83} consistent with the observation that the time to onset of accelerated hepatic damage might exceed 3 years.⁸¹ The one study to report no accelerated liver damage⁸² was undermined by a failure to report striking increases (32–85% over baseline) in hepatocellular iron, although this finding was reported in an earlier publication.⁸⁴ Other toxicities of deferiprone include nausea, agranulocytosis and neutropenia. In summary, it is generally accepted that deferiprone is less effective than deferoxamine in maintaining iron balance. Its potential for cardioprotection requires further prospective study.⁸⁵

Other orally active iron chelators

The iron chelator ICL670A (Exjade; Novartis) has undergone early evaluation in a randomized, double-blind, placebo-controlled, dose-escalation study that established its short-term tolerability.⁸⁶ This was followed by Phase II and Phase III studies to examine short-term efficacy and safety,^{87–89} in which hepatic iron was assessed at baseline and after 1 year of treatment. The long-term effectiveness and safety of this drug await further study.

Bone marrow transplantation

Allogeneic bone marrow transplantation offers an accepted alternative to standard clinical management. Three pretransplant characteristics are significantly associated with survival and event-free survival: (i) hepatomegaly greater than 2 cm below the costal margin; (ii) the presence of portal fibrosis on liver biopsy; and (iii) the effectiveness of therapy with deferoxamine prior to transplantation.⁹⁰ In patients in whom none of these factors were present prior to transplantation (identified as “class 1” patients), event-free survival exceeded 90%; in contrast, in those with all three (“class 3” patients), event-free survival was only 56%. In over 1000 consecutive transplants in patients aged 1–35 years, overall survival was 68%.⁹¹ In class 1 patients, thalassemia-free survival was 90% and survival was 93%. Umbilical cord blood has been used as a source of stem cells for class 1 and 2 children.⁹²

Less than 30% of patients have an available HLA-identical family donor. In a study of unrelated donors matched by high-resolution molecular HLA methods (“extended haplotypes”), 69% of patients were alive and well after 7–109 months.⁹³ This approach, and the use of related partially mismatched donors, is considered experimental in thalassemia.⁹⁴

Successful transplantation liberates patients from chronic transfusions, but does not eliminate the necessity for iron-chelating therapy in all cases. Iron overload and hepatitis

C virus are independent and synergistic risk factors for progression of hepatic fibrosis and the development of cirrhosis in the “ex-thalassemic”. Removal of iron by phlebotomy and deferoxamine is safe and effective in the reduction of tissue iron and the arrest of fibrosis and early cirrhosis.⁹⁵

Many parents may be confronted with the choice between standard medical (transfusion and chelation) therapy and bone marrow transplantation. The excellent results from Italy suggest that marrow transplantation should be offered to any patient with a compatible donor. On the other hand, the choice between these therapeutic approaches may be a difficult one, since extended cardiac disease-free survival in patients regularly compliant with deferoxamine exceeds 90%, comparable to that achieved with transplantation in class 1 patients. However, while the long-term outcomes of transplantation are not fully known, and mortality is always a risk, this cost-saving procedure renders patients not merely cardiac disease-free but also thalassemia-free. Furthermore, if compliance with regular deferoxamine falters or ineffective treatments are embarked upon, survival in “medically treated” patients may be considerably less than 90%.

Experimental approaches

Augmentation of fetal hemoglobin synthesis may reduce globin chain imbalance and ameliorate the severity of the disease.⁹⁶ Several cell cycle-specific chemotherapeutic agents, and nonchemotherapeutic drugs including hematopoietic growth factors and short-chain fatty acids, stimulate HbF production *in vitro* and in animal models. Clinical trials in thalassemia have included short- and long-term administration of 5-azacytidine, hydroxycarbamide, recombinant human erythropoietin, butyric acid compounds, and combinations of these agents.⁹⁶

5-Azacytidine successfully increased HbF levels in early studies of patients with β thalassemia but predictably causes bone marrow suppression, limiting drug administration in some patients. Consideration of its potential adverse effects shifted interest to the use of alternate therapies.^{96,97}

Clinical responses associated with administration of hydroxycarbamide have been disappointing, given the recent observation that patients with certain polymorphisms and specific mutations, notably Gy-158 (c \rightarrow T) and Hb Lepore, may demonstrate durable responses to hydroxycarbamide, with some patients achieving transfusion-independence.⁹⁷ Further trials may be of interest.

In patients treated with recombinant human erythropoietin therapy, total hemoglobin increased in a few, usually without observed effects on HbF synthesis.^{96,97} This expensive regimen has not shown great promise in thalassemia.

Butyric acid compounds, derivatives of natural short-chain fatty acids, have offered potential therapy for the

hemoglobinopathies following the observation that elevated plasma concentrations of α -amino-*n*-butyric acid in infants of diabetic mothers delayed the switch from β to γ globin around the time of birth.⁹⁸ Hematologic responses to arginine butyrate and sodium phenylbutyrate have been reported in thalassemia,⁹⁷ the most striking, for reasons that remain undefined,⁹⁹ in two siblings with homozygous Hb Lepore.

Management of other forms of thalassemia

Thalassemia intermedia

Thalassemia intermedia, a descriptive title with no clear-cut genetic meaning, is used to refer to patients with a hemoglobin level persistently below 9 g/dL who can be maintained without transfusions. The diagnosis should be made only after a considerable period of observation, and often requires revision.

At diagnosis, folate supplementation should be initiated and the hemoglobin should be determined twice monthly. A substantial decline should prompt investigations for secondary causes, including infection, folate deficiency, or hypersplenism. In patients over 4 years of age, splenectomy may be indicated prior to initiation of a program of regular transfusions. Some patients may become less tolerant of anemia with advancing age, or may develop transfusion dependency in adolescence or early adulthood. Abnormal growth, pathologic fractures, or signs of intolerance of anemia should prompt consideration of a program of regular transfusions. Spinal or nerve compression should be treated by red cell transfusion or local irradiation followed by transfusions.¹⁰⁰

Iron loading is less accelerated than in thalassemia major. Daily gastrointestinal iron loading may be in the order of 3–9 mg, or about 2–5 g/year.¹⁰¹ In contrast, in regularly transfused patients iron accumulation is in the range of 6–7 g/year. The coinheritance of hereditary hemochromatosis may adversely increase iron loading in thalassemia intermedia.¹⁰² In patients with elevated serum ferritin concentrations, assessment of liver iron is indicated; if this exceeds 6 mg/g liver dry weight, deferoxamine should be initiated.

HbE β thalassemia

This is the commonest form of severe thalassemia in many Asian countries and is being seen increasingly in North America and Europe. Relatively little is known about its natural history, the reasons for its clinical diversity, or how it should be managed and it may not be possible to define its severity without a long period of observation. Until more is known about this important disease, approaches to its management should follow those recommended above for thalassemia intermedia.

The α thalassemias

All children with Hb Barts hydrops fetalis syndrome require regular blood transfusion and chelation therapy. Many patients with HbH disease can be managed conservatively with regular folate supplementation and avoidance of oxidant drugs, which tend to exacerbate their anemia. Occasionally, the hemoglobin level is such that a regular transfusion regimen, similar to that employed for severe cases of β thalassemia, may be required. Overall, the results of splenectomy are disappointing, and in a few cases it has been followed by severe thrombotic complications. Older patients may accumulate considerable amounts of iron through increased gastrointestinal absorption. Coexistence with the common form of hereditary hemochromatosis may explain more severe iron overload in occasional patients.

4 Granulocyte Disorders

14

Disorders of granulopoiesis and granulocyte function

Arian Laurence, Pratima Chowdary and Philip Ancliff

Introduction

Granulocytes by definition include leukocytes with granules, that is, neutrophils, eosinophils and basophils. Physiologically monocytes and neutrophils act sequentially and concurrently, constituting a vital component of innate immunity. A decrease in neutrophil numbers and/or impairment of neutrophil function may result in life-threatening infections. Neutropenia is not uncommon and is usually transient with little significance. Persistent neutropenia is uncommon and can be life-threatening, but an early diagnosis and appropriate interventions can have profound impact on the life of the patient.

A disorder of phagocyte function should be considered in a child with a normal or raised neutrophil count that has a history of repeated bacterial and fungal infections. Many of the diseases discussed are either very rare or common with uncertain clinical significance. Children being investigated for these disorders should have a history of unusually severe infections involving peculiar organisms (*Serratia*, *Aspergillus*) in peculiar places (brain, liver) or the presence of severe childhood periodontal disease.

For the purpose of this chapter the disorders have been separated as disorders of function and disorders of numbers. Where appropriate, an attempt has been made to give a brief overview of the normal physiology of a process to explain the clinical manifestations of altered physiologic states.

Innate immunity

The immune system is an organization of various specialized cells and molecules with several key functions that aim to prevent invasion by parasitic microbes. The three lines of defense that human pathogens need to breach to cause disease are *physical barriers*, *innate immunity* and *adaptive immunity*. A brief overview of the physical barriers and

innate immunity is presented to provide a basis for clinical consequences, secondary to disorders of granulocytes. Adaptive immunity and its disorders are presented elsewhere.

Physical barriers and antimicrobial peptides

Mechanical

Intact epithelial cells lining the respiratory, gastrointestinal and urogenital tracts and the skin prevent intrusion by their tight junctions and local physical adaptations, for instance, the mucociliary escalator in the respiratory system.

Microbiologic

Normal flora on the external surfaces prevent colonization by pathogenic and resistant strains.

Chemical defense

Proteins, peptides and other substances act by inactivating potential pathogens; examples are lysozyme in salivary secretions and azurocidin in human neutrophils, fatty acids in skin, and the acid pH of the stomach.

Antimicrobial peptides

The two major classes of antimicrobial peptides (AMPs) described in humans are defensins and cathelicidins. They protect mucosal and dry epithelial surfaces of all multicellular organisms. The protection is immediate due to rapid inactivation of potential pathogens, and the defense is as powerful as that provided by any of the body's circulating cells.¹ AMPs are produced not only by neutrophils and macrophages, but also by the epithelial cell lining of the gastrointestinal and genitourinary tracts, the tracheobronchial tree and keratinocytes. Some are produced constitutively, whereas others are induced by proinflammatory cytokines and exogenous microbial products. They act on selected molecular targets, for example phospholipid membrane peptidoglycans, resulting in disruption of cell membranes.

AMPs have a broad spectrum of activity against bacteria, fungi, viruses and frequently transformed cells. Most organisms synthesize several different types of AMP within their epithelial surfaces, creating a synergistic broad-spectrum antimicrobial cocktail. It is difficult for a microbe to change the phospholipid organization of its membrane, therefore resistance to the peptides occurs at levels that are orders of magnitude lower than those observed for conventional antibiotics.² Increasingly it is being recognized that AMPs are chemotactic for phagocytes, T cells and immature dendritic cells, providing evidence for their participation in alerting, mobilizing and amplifying innate and adaptive antimicrobial immunity of the host.³

Innate immunity

Innate immunity represents the second line of defense and is triggered rapidly without the need for prior exposure. It is immediate and stereotyped with the potential for being completely effective. Innate immunity does not have the specificity of adaptive immunity, but is capable of distinguishing self from nonself.

Immune recognition is mediated by probably hundreds of germline-encoded receptors with predetermined specificity that have evolved by natural selection. These pattern-recognition receptors identify highly conserved structures in microorganisms: pathogen-associated molecular patterns (PAMPs).² The best-known examples of PAMPs are bacterial lipopolysaccharide (LPS), peptidoglycan, lipoteichoic acids, mannans, bacterial DNA, double-stranded RNA and glucans. These patterns are unique to microbial pathogens, are usually essential for the survival or pathogenicity of microorganisms, and often are invariant structures shared by entire classes of pathogens; for instance, all Gram-negative bacteria have LPS. The pattern-recognition receptors are expressed on many effector cells of the immune system, most importantly on macrophages, dendritic cells and B cells.

Functionally, pattern-recognition receptors can be divided into three classes: secreted, endocytic and signaling. Secreted pattern-recognition receptors function as opsonins by binding to microbial cell walls and flagging them for recognition by the complement system and phagocytes. For example, mannan-binding lectin, on binding to microbial carbohydrates initiates the lectin pathway of complement activation. Endocytic pattern-recognition receptors occur on the surface of phagocytes; for example, macrophage mannose receptor recognizes mannose repeating sequences on microbial cell walls and mediates the uptake and delivery of the pathogen to the lysosome. Signaling receptors recognize PAMPs and activate signal-transduction pathways that induce the expression of a variety of immune-response genes. The Toll-like receptors (TLRs) are found on macrophages, dendritic cells and epithelial cells and are a well-defined family of at least ten evolutionarily conserved transmembrane receptors that

appear to function exclusively as signaling receptors; for example, TLR4 recognizes bacterial lipopolysaccharide.

The effector branch has three major components. First is the release and, at times, activation of a variety of extra-cellular humoral mediators such as complement, cytokines, chemokines and AMPs including defensins and cathelicidin. Second is the recruitment and activation of phagocytic granulocytes, monocytes/macrophages, and in some instances natural killer cells to sites of microbial invasion. Third, there is surface expression of antigen-presenting cell-derived costimulatory molecules, necessary for efficient antigen presentation, leading to T-cell activation and induction of adaptive immunity. The T-helper cells in turn promote antigenic activation of B cells, and CD4 and CD8 effector T cells that produce cytokines capable of activating phagocytes to eliminate pathogens more effectively. A deficiency of innate immunity typically results in recurrent bacterial and fungal infections.

Recruitment of leukocytes to sites of inflammation

Granulocytic phagocytes represent the foot soldiers of the immune system. For a granulocyte to function, it must be able to extravasate from the bloodstream into affected tissues, adhering to inflamed endothelial cells of the venules. It must efficiently phagocytose microbes and kill them. The first half of the chapter is subdivided to consider these discrete abilities and the diseases that stem from their disruption.

Excluding tissue macrophages, most professional phagocytes of the immune system are found within the bone marrow or bloodstream. These cells must be recruited to sites of infection by a complex series of chemotactic stimuli, which not only attract the cells to infection sites but also sustain their survival and promote any necessary maturation. Cells within inflamed tissues are able to secrete a number of agents that are capable of attracting granulocytes, for example inflammatory proteins including fragments of complement (C3a, C5a), the inflammatory eicosanoid lipids (leukotrienes B₄ and C₄), and the chemokines.

Chemokines are a family of 40 small, structurally related proteins that are potent inducers of chemotaxis and maturation.⁴ Chemokines are subdivided into two principal groups based on the spacing between two cysteine residues. The CC chemokines have the cysteine residues juxtaposed. An individual CC chemokine will often bind to multiple CC receptors expressed on multiple cell types. The CXC chemokines in contrast tend to bind to unique CXC receptors. A single chemokine may attract a certain cell type and induce its maturation so that the affected cell in turn recognizes a different repertoire of chemokines and moves in a different direction. In this manner a number of chemokines can regulate complex movement of cells. Table 14.1 lists a number of common chemokines and the cells they are able to recruit.

Table 14.1 An abridged list of some common chemokines.

Modern name	Original name	Receptor	Cells affected
<i>CXC chemokines</i>			
CXCL7	NAP-2	CXCR2	Endothelial cells, granulocytes
CXCL8	IL-8	CXCR1, CXCR2	Endothelial cells, neutrophils
CXCL10	IP-10	CXCR3	Endothelial cells, T lymphocytes
CXCL12	SDF-1	CXCR4	Endothelial cells, lymphocytes, myeloid stem cells
<i>CC chemokines</i>			
CCL2	MCP-1	CCR2	Endothelial cells, monocytes, T lymphocytes
CCL3	MIP-1a	CCR1, CCR5	Monocytes, T lymphocytes
CCL4	MIP-1b	CCR5	Monocytes, T lymphocytes
CCL5	RANTES	CCR1, CCR3, CCR5	Eosinophils, basophils, monocytes, T lymphocytes
NAP-2	Neutrophil Activating Protein-2		
IL-8	Interleukin-8		
IP-10	gamma interferon Induced Protein-10		
SDF-1	Stromal cell-Derived Factor-1		
MCP-1	Monocyte Chemoattractant Protein-1		
MIP-1 α	Monocyte Inflammatory Protein-1 α		
MIP-1 β	Monocyte Inflammatory Protein-1 β		
RANTES	Regulated upon Activation, Normal T-cell Expressed and Secreted		

Table 14.2 A summary of ligands involved in leukocyte endothelial adhesion.

	Leukocyte surface	Endothelial surface	Associated disorder
Leukocyte rolling	L-selectin Carbohydrate residues	Carbohydrate residues E-selectin, P-selectin	LAD2
Leukocyte sticking, diapedesis	Integrins: LFA-1, Mac-1 (CR3)	Immunoglobulin family adhesion molecules: ICAM-1, ICAM-2	LAD1

To reach most sites of infection granulocytes must adhere to the inflamed endothelium of blood vessels and extravasate to the site of inflammation; this requires the expression of a number of adhesion molecules both on the attracted granulocyte and the target endothelial lining. Most extravasation typically occurs in the postcapillary venules. Chemokines secreted at sites of inflammation are carried across the vessel wall and coat the luminal surface of the endothelium.

Quiescent endothelial cells and neutrophils weakly express a number of selectins: E and P selectins on the endothelial cells; L selectin on the neutrophil. These proteins bind to carbohydrate residues on neighbouring cells. These weak interactions between neutrophil and endothelial cell result in a proportion of neutrophils rolling along the surface of the endothelium.

At sites of inflammation, chemokines induce the further expression of E, P and L selectins, resulting in an increased proportion of the blood neutrophils rolling along the endothelial surface.⁴ Rolling leukocytes are then fixed by the binding of endothelial intercellular adhesion molecules

(ICAMs) to integrin proteins on the leukocyte surface. Integrins are expressed constitutively on both the leukocyte and endothelium; after chemokine stimulation the avidity of the integrins is increased by a mechanism of “inside out” signaling involving the small G protein Rap1.^{5,6} With tight adhesion to the endothelial cell wall the leukocyte extravasates toward the chemokine signal within the inflamed tissues. Phagocytes exposed to pathogens within the inflamed tissue in turn secrete more chemokines. This mechanism is common to all granulocytes and any failure of adhesion will prevent multiple cell types from reaching sites of infection. The proteins involved are summarized in Table 14.2 and Fig. 14.1.

Diseases of phagocyte adhesion and chemotaxis

Disorders of adhesion tend to result in dry and necrotic infections associated with raised white cell counts as neutrophils are unable to leave the bloodstream and form pus.

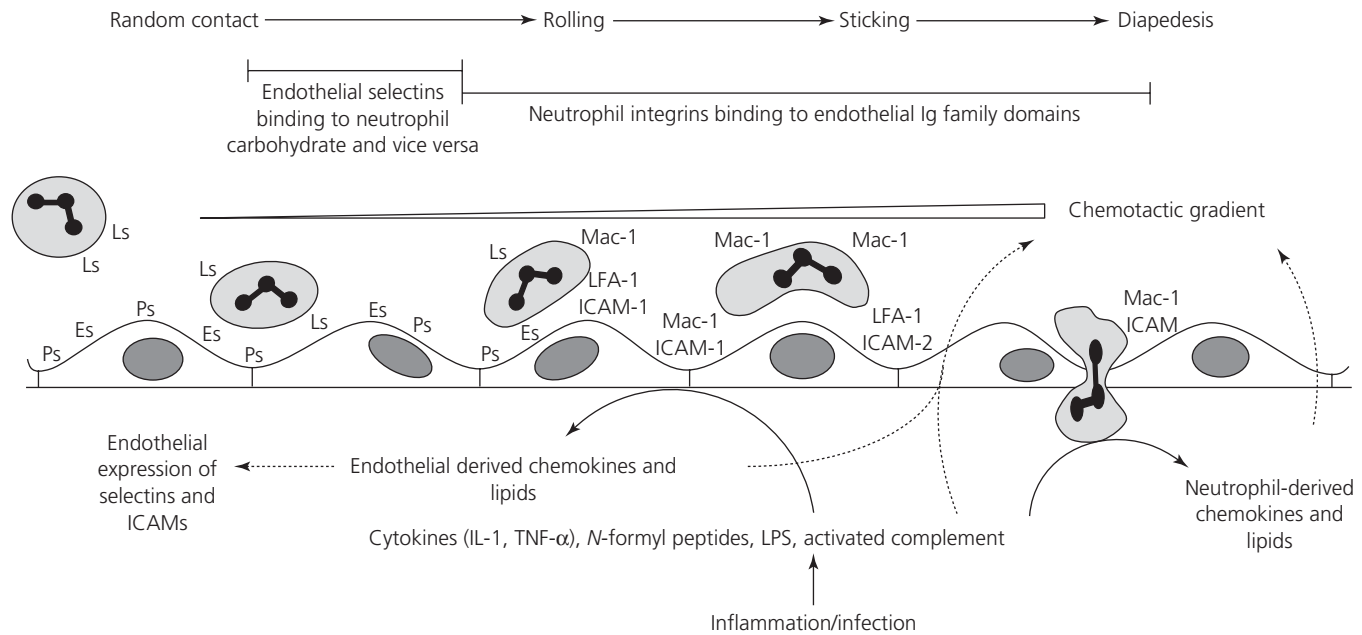

Fig. 14.1 Granulocyte chemotaxis and extravasation across the endothelium to a site of acute inflammation. Random contact and rolling is mediated by the binding of lectin receptors: Ps, P-selectin; Ls, L-selectin; Es, E-selectin to carbohydrates (not shown). Movement arrest and extravasation is mediated by the binding of immunoglobulin superfamily receptors, intercellular adhesion molecules 1 and 2 (ICAM-1 and -2), to the integrins Mac-1 (the C3bi receptor) and LFA-1 (leukocyte fixation antigen 1).

Leukocyte adhesion deficiency type 1

Leukocyte adhesion deficiency (LAD) is a rare autosomal recessive disorder of neutrophil adhesion, chemotaxis and opsonization. Approximately 100 cases have been reported. Patients express either a structurally abnormal or reduced amounts of β_2 integrin (CD18b).⁷ CD18b is an essential component of the integrins LFA-1 and Mac-1 (the C3bi receptor). Absence of LFA-1 prevents neutrophils from binding tightly to inflamed vascular endothelium, a prerequisite for their migration into the interstitial tissues. Absence of C3bi receptor prevents granulocytes and monocytes from binding C3bi opsonized particles.

Affected children present with recurrent severe bacterial infections. Infections tend to involve the skin and gut. The failure to adhere to endothelium results in both a raised peripheral blood neutrophil count and infections that are dry, necrotic and lacking pus. Responsible bacteria include pneumococci and *Pseudomonas* species. Lack of monocyte function renders these children susceptible to fungal infections, typically *Aspergillus* and *Candida albicans*. Patients typically present with a delayed umbilical cord separation and associated infection of the stump. There is some variability in the severity of the disorder, with different mutations leading to a variable degree of clinical severity.⁸ Children with severe disease typically die by the age of 2 years.^{9,10}

The diagnosis is made by flow cytometry. Surface CD18b levels of > 11% are associated with no phenotype; 2.5–11% represents a mild phenotype; 0.3–2.5% is a moderate pheno-

type; and < 0.3% is a severe phenotype. Neutrophil function tests identifying the inability to opsonize C3bi-coated particles confirm the diagnosis. Both these investigations can be performed on cord blood allowing a prenatal diagnosis to be made.¹¹

Management of mild to moderate disease requires prophylactic oral antibiotics and antifungals with parenteral antibiotic therapy for breakthrough infections. Patients with a severe phenotype should be assessed for bone marrow transplantation.

Leukocyte adhesion deficiency type 2

Four Arabic children and a Turkish child have been reported to have a variant LAD, now called LAD type 2.¹² This vanishingly rare autosomal recessive disorder is due to an inability to form sialyl Lewis X structures that form the Lewis and ABO blood group antigens and are the targets of endothelial E and P selectin binding on the neutrophil surface. LAD2 is a multisystem disorder; affected individuals have mental retardation and distinctive facies. The lack of ABO and Lewis antigens gives them a Bombay (hh) red cell phenotype. Generally the immune features of the disease are as for mild LAD1.

Leukocyte adhesion deficiency type 3

Two groups have reported children with a LAD1 picture associated with mucosal bleeding and platelet function

abnormalities. These children express both β_1 and β_2 integrins but are unable to increase the avidity of their receptors in response to cell stimulation.¹³ Recently, Kinashi *et al.*¹⁴ have implicated a defect of the small G protein Rap1 as a cause of this disorder in one of the children studied. The children reported all required antibiotic prophylaxis together with management for their thrombasthenia.

Hyperimmunoglobulin E syndrome

Hyperimmunoglobulin E syndrome (HIES) is a rare heterogeneous multisystem disorder of unknown etiology. It is classically a triad of susceptibility to bacterial and fungal infections, atopy associated with a grossly raised IgE, and a connective tissue disorder.^{15,16} Most cases are sporadic but a few follow an autosomal dominant (classic phenotype) or recessive (variant phenotype) inheritance pattern. Linkage analysis has identified a region involving the proximal region of 4q. area of chromosome 4.¹⁷ T cells from HIES patients show a decreased response to candidal antigens. Although the mechanism is uncertain, some groups have implicated a reduction in interferon (IFN)- γ secretion suggesting that there is a shift from a type 1 (cellular) to a type 2 (humoral) response.^{18,19} This would explain the elevated IgE and atopy that is a hallmark of the disorder; however, reduced IFN- γ secretion is not a consistent finding. Recently, Martinez *et al.* have noted that HIES T cells have a reduction in ICAM-1 expression.²⁰ They go on to show that this is associated with a reduction in T-cell responses and an increase in B-cell production of IgE. Any defect in ICAM-1 expression could explain the poor *in vivo* neutrophil chemotaxis.

The clinical features are characterized by recurrent skin and chest infections beginning in infancy and typically involving staphylococci, *Haemophilus influenzae* and fungi. Skin infections manifest as cold staphylococcal abscesses involving the head and neck regions. Pulmonary infections are typically cystic, leading to bronchiectasis,²¹ and cysts may become colonized by fungal balls. Fungal nail infections are common. Skin and pulmonary infections may be precipitated and exacerbated by the associated atopic complications of eczema and asthma. Features of the connective tissue disorder include hyperextensible joints, scoliosis, delayed shedding of primary teeth and coarse facies. Osteopenia and long-bone fractures are common.¹⁵

On investigation there is a marked elevation of IgE (>2 kIU/mL) together with an eosinophilia.²² The other immunoglobulin subtypes are often reduced. Neutrophil function tests including chemotaxis tests are usually normal suggesting an indirect effect. The differential diagnosis is that of Wiskott–Aldrich and DiGeorge syndromes together with severe simple atopy where attacks of asthma and eczema can be associated with comparable IgE levels.

Management of HIES is threefold:

- minimizing the atopic symptoms to avoid breakage of the skin;
- use of prophylactic antistaphylococcal antibiotics and anti-fungal agents;
- use of surgery to drain abscesses and remove lung cysts before they become colonized with fungus.²³

A number of other therapies have been considered although none has been proven to be of benefit.^{21,24} The hypo-IgG gammaglobulinemia would suggest that intravenous immunoglobulin (IVIG) may be of benefit, and this has been reported in a few cases.²⁵ There is a debate about the role of IgE in the disorder, and some groups have considered plasmapheresis in patients that fail to respond to antibiotics²¹ (although of note, plasma from HIES patients has no inhibitory action on neutrophils from healthy donors). Finally, the reduced secretion of IFN- γ in HIES T cells has led some groups to use IFN- γ as a therapy.²⁶ However, this agent is unproven and has been reported to precipitate autoimmune disease in a patient with HIES.²⁷

Localized juvenile periodontitis

Localized juvenile periodontitis is a rare heterogeneous group of familial disorders that present in puberty with severe alveolar bone loss around the first molars and incisors. The underlying mechanism is unclear although it should be noted that most neutrophil disorders predispose to severe periodontal disease.²⁸

Localized juvenile periodontitis neutrophils have been shown to have defects in chemotaxis in response to formyl peptides, C5a and leukotrienes although none of these defects is universal.^{29,30} More recently, Shibata and colleagues have identified a defect in calcium signaling.³¹ The underlying defect may be exacerbated by both inhibitory and inflammatory agents secreted by bacteria known to colonize the oral cavity.^{28,32} Good oral hygiene is critical to minimize tooth loss in this disorder.

Wiskott–Aldrich syndrome

Wiskott–Aldrich syndrome (WAS) is an X-linked disorder associated with mutations of the WAS protein (WASp). Children present with a spectrum of disease ranging from a mild thrombocytopenia to a severe immunodeficiency with failure to clear bacterial and viral infections leading to multiple chest infections and Epstein–Barr virus-driven lymphomas. WASp is involved in regulation of the actin cytoskeleton.^{33,34} When activated, WASp is activated by the Rho family GTPases Cdc42 and Rac, in turn leading to activation of the cytoskeletal organising complex Arp 2/3. This protein complex regulates the polymerization of actin monomers to form structural filaments. WASp-deficient lymphocytes activated by the presence of antigen-presenting cells are unable to form a stable immunologic synapse

Table 14.3 A summary of the signs and symptoms of Wiskott–Aldrich syndrome.

<i>Neonatal onset</i>
Thrombocytopenia possibly exacerbated by increased platelet consumption
<i>Early childhood onset</i>
Eczema, colitis, susceptibility to pyogenic (bacterial) and opportunistic (viral, PCP) infections
Lymphopenia, abnormal B-cell function with reduced IgM and elevated IgA and IgE
<i>Late childhood/adolescent onset</i>
Virally precipitated B-cell lymphomas

PCP, *Pneumocystis carinii* pneumonia.

leading to inadequate stimulation and deficiencies in both cell-mediated and humoral adaptive immunity.³⁵ An inability to organize the cytoskeleton leads to deficiencies of phagocyte chemotaxis³⁶ and neutrophil phagocytosis, the latter requiring the formation of an actin cup.³⁷

Patients usually present at birth with a thrombocytopenia, the platelet count typically being in the range $10\text{--}20 \times 10^9/\text{L}$ together with small platelets. The other manifestations of the disease appear with age and are summarized in Table 14.3. The disorder may be diagnosed by flow cytometry looking for the lack of WASp.

Management of WAS involves supportive care for deficiencies of both acquired and innate immunity. Splenectomy has been successful in limiting the thrombocytopenia and is still a recommended therapy in those without a suitable bone marrow donor.^{38,39} Bone marrow transplantation using a sibling or matched unrelated donor remains the gold standard cure but is not available to all.⁴⁰ Gene therapy to replace the nonfunctioning gene is under investigation and has been successful in mouse models.^{41,42}

Mutations of Rac2

Rac is a Rho family small G protein involved in regulation of the actin cytoskeleton. Whereas Rac1 is ubiquitously expressed, Rac2 is found only within the hematopoietic lineage. Mouse neutrophils lacking Rac2 are unable to translocate across epithelia.⁴³ A couple of cases of children with inactivated Rac2 have been described. Clinically they presented with a LAD1-like picture.⁴⁴ The diagnosis is made by Western blotting of neutrophil lysate for Rac2.

Acquired disorders of adherence and chemotaxis

Prematurity

Neonates are at increased risk of group B streptococcal infection with defects of chemotaxis, adherence, and phagocytosis

all reported.⁴⁵ Chemotaxis and adherence defects may be due to a defect in signaling in response to chemokines. These defects are more pronounced in preterm infants. To compound this, bone marrow reserves of neutrophils are smaller resulting in a greater propensity to become neutropenic. It is unclear whether reduced antibody-mediated opsonization is an important factor.

Drugs

Corticosteroids and epinephrine (adrenaline) are associated with a decrease in neutrophil adhesion, the former by inhibiting eicosanoid metabolism.^{46,47} This is usually of little significance except to note that a reduction in adhesion liberates endothelial neutrophils and artefactually raises the blood neutrophil count. In contrast agents that increase neutrophil adhesion such as amphotericin and granulocyte colony-stimulating factor (G-CSF) are associated with a neutrophil lung syndrome where neutrophil aggregates precipitate in the lung, causing respiratory insufficiency.^{48,49}

A neutrophil lung syndrome may be precipitated by complement activation secondary to bacterial sepsis, thermal injury, tissue necrosis or manipulation of blood or blood products such as hemofiltration or leukopheresis. Rarely, neutrophils may be activated by the infusion of anti-neutrophil antibodies present in blood products inducing a transfusion-related lung injury (TRALI).

Hematologic disease

Children with myelodysplasia often have a predisposition to bacterial infections even in the presence of near normal neutrophil counts. Many reports have shown qualitative abnormalities in neutrophil adhesion and migration;⁵⁰ this is noted particularly in myelodysplasia with a monosomy 7.

Functional *in vitro* abnormalities of granulocytes are a common feature of chronic myeloid leukemia (CML) in chronic phase with abnormal adhesion and reduced migration common. However, this may be of limited clinical significance as patients in chronic phase are not usually susceptible to bacterial infections.

Neutrophils of donor origin in patients who have recently undergone bone marrow transplantation (BMT) may show reduced chemotaxis particularly when associated with graft-versus-host disease.⁵¹

Nonhematologic disease

Diabetes mellitus is commonly associated with pyogenic infections, particularly when glycemia is poorly controlled. Chemotactic and adhesion defects have both been identified in this situation.⁵² Depressed neutrophil activity, mainly chemotaxis, has been reported in liver disease, burns and premature neonates.⁵³ Defects of chemotaxis and adhesion have

been described in splenectomized patients,⁵⁴ a group known to be at risk of infections with encapsulated bacteria.

Several viral infections have been shown to inhibit monocyte chemotaxis including herpes simplex, influenza and human immunodeficiency virus (HIV).⁵⁵ Several other diseases, including α -mannosidase deficiency, myotonic dystrophy, α_1 -antitrypsin deficiency, cirrhosis and sarcoidosis are also associated with diminished chemotaxis.⁵⁵

Disorders of phagocyte opsonization and ingestion

For a target to be phagocytosed it must either contain compounds that innately bind to receptors on the phagocyte surface, such as lipopolysaccharide, or be opsonized by bound immunoglobulin or complement. Consequent disorders can be divided into those that are due to a lack of proteins that opsonize targets, such as immunoglobulin or complement proteins, or those that lack the receptors to bind opsonized targets.

Humoral disorders of opsonization

Hypogammaglobulinemias

Typically B-cell disorders may be subclass specific or affect all antibody production. Those affecting IgG are most likely to be associated with pyogenic encapsulated bacteria (*Haemophilus influenzae*, pneumococci, *Staphylococcus aureus*).

Complement disorders

Deficiencies of the classical pathway (C1, C2, C4) cause only minor infectious problems as the alternate pathway remains intact. Deficiency of C3 renders patients susceptible to encapsulated organisms (pneumococci, etc.). Deficiencies of these factors are associated with a lupus-like disorder as immune complexes are not efficiently cleared.⁵⁶ Deficiencies of C5–9 result in a lupus-like disease and susceptibility to *Neisseria* infections.⁵⁶ Patients at risk should be vaccinated for pneumococcus, *Haemophilus influenzae* and meningococcus.

Mannose-binding protein deficiency

Mannose-binding protein (MBP) binds free mannose on bacteria and triggers the complement cascade (Fig. 14.2). Five percent of the population have low MBP levels but this is of uncertain significance.⁵⁷ MBP may be important in the first year of life to bridge the gap between maternal and infant immunoglobulin. MBP deficiency may coexist with other defects of innate immunity making a mild disorder severe. A rare autosomal dominant condition that disturbs the ability

of MBP to trigger complement is associated with herpetic and *Klebsiella* infections in adults.⁵⁸

Cellular disorders of ingestion

Targets of neutrophil phagocytosis are often opsonized with either bound antibody or fragments of complement. Neutrophils adhere to these bound proteins via specific receptors. There are a number of rare familial disorders, summarized in Table 14.4, where neutrophils lack one or more of these receptors. Excluding CR3 deficiency (LAD1), individual receptor defects confer a minor susceptibility to infection although multiple deficiencies can occur with more severe symptoms. As with MBD deficiency, these disorders may coexist with other defects of innate immunity making an otherwise mild disease severe.

Acquired disorders of opsonization and ingestion

Neutrophils of patients with myelodysplasia have been reported to have qualitative defects of phagocytosis that may contribute to the predisposition to infection seen in patients with this disorder.⁵⁰ A defect in opsonization has been noted in splenectomized patients although the mechanism is unclear.⁵⁴

Disorders of granule contents and integrity

Once phagocytosed, microorganisms are held within the phagosome. This then fuses with various lysosomal granules containing potent digestive enzymes necessary for killing. Early myeloid cells express primary or azurophilic granules containing inflammatory proteins, digestive enzymes and bactericidal proteins. Later myelocytes develop secondary or specific granules, which contain further enzymes for cell killing including the NADPH oxidase, followed by tertiary or secretory granules that contain plasma proteins. Regulation of granule formation is performed by transcription factors. Knockout mouse studies have identified the factor C/EBP α as crucial for the formation of primary granules and C/EBP ϵ as crucial for the formation of secondary granules. A summary of the different types of neutrophil granule contents is given in Table 14.5.

Disorders of granulation include a lack of these lysosomal granules or a failure to regulate their fusion with other granules resulting in uncontrolled mixing and inactivation of their contents.

Chédiak–Higashi syndrome (Fig. 14.3)

This is an autosomal recessive multiorgan disorder of lysosomal trafficking that presents with a tetrad of neurologic,

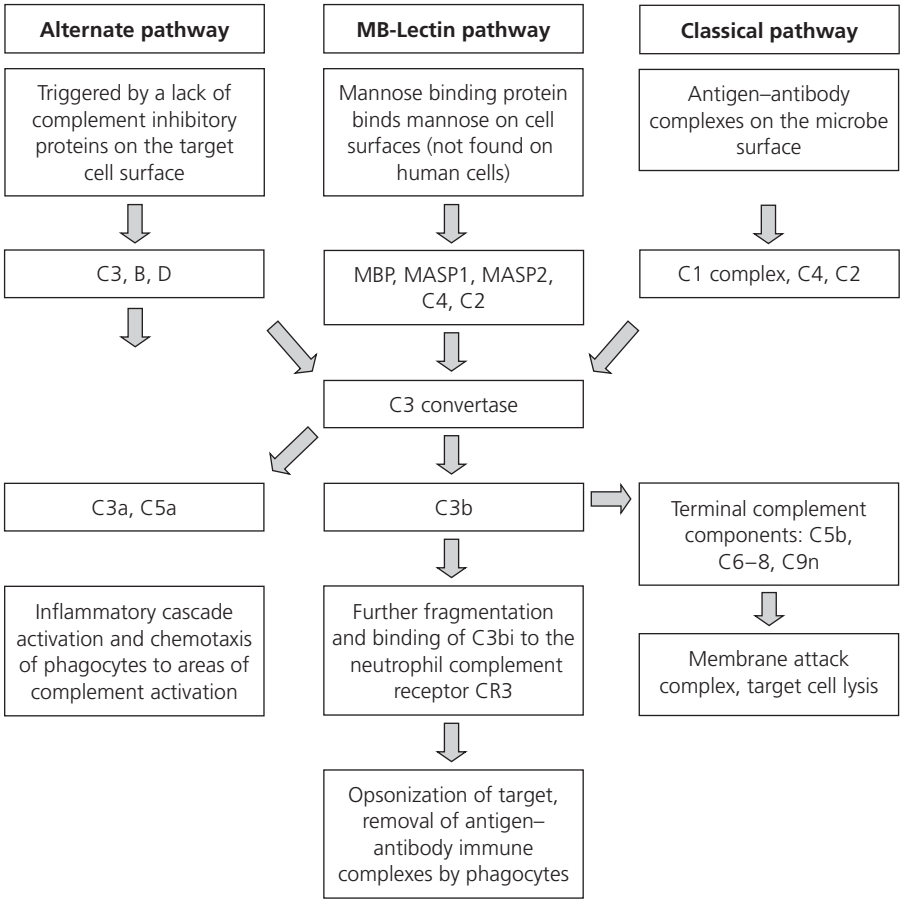

Fig. 14.2 The complement cascade.

Table 14.4 Granulocyte receptors of phagocytosis.

Receptor	Clinical association	Reference
CR3/C3bi receptor		See LAD type 1
FcγRIIIb receptor	Deficiency is common (1 in 800). GPI-linked receptor, absent in paroxysmal nocturnal hemoglobinuria. Isolated deficiency is of uncertain significance	59,60
FcγRIIIa receptor	Deficiency may confer susceptibility to encapsulated bacteria, may be potentiated by FcγRIIIb deficiency	61

Table 14.5 Granule contents of mature neutrophils.

	Granule		
	Primary (azurophil)	Secondary (specific)	Tertiary (secretory)
Membrane proteins	CD63, CD68	CD11b, f-Met receptor, NADPH oxidase	CD11b, CD14, CD16, f-Met receptor, alkaline phosphatase
Granule contents	β-Glucuronidase, defensins, elastase, myeloperoxidase, lysozyme	Collagenase, gelatinase, lactoferrin, lysozyme	Albumin, B ₁₂ -binding protein and other plasma proteins

Fig. 14.3 Giant neutrophil inclusions seen in the Chédiak-Higashi syndrome. A myelocyte in the picture also shows abnormal giant granules.

Table 14.6 Clinical features of the stable phase of Chédiak-Higashi syndrome.

Organ	Signs and symptoms
Skin	Patchy oculocutaneous albinism
Central nervous system	Photophobia, nystagmus, ataxia
Peripheral nervous system	Peripheral sensorimotor neuropathy, cranial nerve lesions
Clotting	Minor bleeding problems typically presenting with easy bruising and epistaxis
Innate immunity	Multiple life-threatening bacterial (commonly <i>Staphylococcus aureus</i>) and fungal infections of the mouth, skin and lungs

coagulation, immunologic and skin pigmentation defects. The underlying defect is due to mutations in the *CHS1* or *LYST* gene.^{62,63} Lack of this protein leads to fusion of heterogeneous lysosomes and the formation of giant particles with mixed contents. In neutrophils azurophilic and secondary granules fuse leading to perturbation of their contents with a reduced cathepsin G noted.⁶⁴ Similarly, cells in other affected organs show giant granules including platelets (bleeding disorder), Schwann cells (peripheral neuropathy), hepatocytes (hepatomegaly) and melanocytes (partial or patchy oculocutaneous albinism). The exact mechanism of the immune disorder is complex; neutrophils have a defect in the contents of their giant granules but also have defects of degranulation and chemotaxis. Other cells of the immune system are affected with giant granules seen in lymphocytes and monocytes. The underlying defect may also affect the plasma membrane and associated cytoskeleton as cytoskeletal and membrane fluidity defects have been reported in natural killer (NK) cells and fibroblasts.^{65,66}

The clinical features and course of the disease is complex. Patients typically present early in the first decade of life with a stable phase, features of which are summarized in Table 14.6.

Children in the stable phase typically have a reduction in peripheral neutrophils due to ineffective myelopoiesis; neutrophils show the classical giant azurophilic granules. Neutrophil function tests are perturbed, with delayed degranulation and impaired chemotaxis. Platelet function tests demonstrate a storage pool defect.⁶⁷ There are diffuse abnormalities on electroencephalography, and visual evoked potentials highlight the defects of the optic chiasm. Patients commonly have a raised intracranial pressure.⁵⁵

Patients that survive into their second decade of life develop an accelerated phase of the disease that is thought to be mediated by Epstein-Barr virus infection.⁶⁸⁻⁷⁰ The accelerated phase is characterized by pyrexia together with pancytopenia and a diffuse polyclonal multiorgan lymphohistiocytic infiltration classically involving the liver, spleen and bone marrow.

The management of stable-phase patients includes prophylactic oral antibiotics and antifungals. Ascorbic acid has been used to try to prevent fused neutrophil granule contents from redox breakdown but its use is controversial.⁷¹ Once a hemophagocytic syndrome has developed, chemotherapy using vincristine, corticosteroids and antithymocyte globulin has been used but with little success.⁷² In the UK patients are typically started on a standard hemophagocytic lymphohistiocytosis protocol such as HLH-94, which uses a mixture of corticosteroid, etoposide and ciclosporin. The only proven curative therapy for this condition is BMT.⁷³

Specific granule deficiency

This very rare neutrophil disorder is characterized by a lack of specific, or secondary, granules together with morphologic abnormalities including bilobed neutrophils. Secondary granules are lined with components of the oxidase system, vital for bacterial killing.⁵³ The absence of secondary granules is reflected in lactoferrin and vitamin B₁₂-binding protein levels at 3–10% of normal.⁷⁴ Similarly the neutrophil alkaline phosphatase (NAP) score is low. Primary granules are present but have abnormal morphology and an altered content with increased myeloperoxidase and decreased defensins. In many patients the gene encoding the C/EBPε transcription factor is mutated.⁷⁵ Secondary granules are also required for expression of β₂ integrins and consequently the affected neutrophils show defects in chemotaxis.

Clinically the disorder presents with recurrent and often indolent pyogenic infections of the epithelia typically presenting in infancy.⁷⁶ Therapy involves prompt use of antibiotics and antifungals together with surgical drainage of any chronic abscesses. The prognosis is relatively good, with most patients surviving to adulthood. Cytogenetic investigation and neutrophil function tests help differentiate this disorder from myelodysplasia as the latter includes defects of chemotaxis and respiratory burst together with a failure of neutrophil disaggregation following stimulation.⁷⁴

Acquired granule disorders

Rarely an acquired loss of neutrophil granule contents can be seen in neutrophils from patients with myelodysplasia and acute myeloid leukemia.⁷⁷ This may contribute to bacterial infections seen with these disorders. In contrast, loss of some granule enzymes including alkaline phosphatase is common in myeloproliferative disorders; however, this is of uncertain significance as recurrent infections are not a significant problem in patients with chronic phase CML.

Disorders of oxidative metabolism

Granulocytes and other professional phagocytosing cells of the immune system require a potent mechanism of cell killing to combat the many microorganisms that they ingest; central to this is their ability to secrete chemically highly active reactive oxygen species (ROS). Most ROS stem from the production of free radical forms of oxygen. A free radical is a compound that contains an unpaired electron, which drives it to covalently bind to neighbouring compounds, forming adducts that often maintain the unpaired electron and trigger a cascade of chemical reactions that disrupt complex biological macromolecules. A typical cascade is summarized below, where the unpaired electron is denoted by a dot and R1, R2 represent biological macromolecules:

Granulocyte free radical ROS include superoxide (O_2^-) and the hydroxyl radical ($\cdot\text{OH}$), the dot denoting the unpaired electron. The superoxide radical serves as the starting point for the production of a large assortment of other radical and nonradical ROS including oxidized halogens (OCl^- , ClO_2^-), oxides of nitrogen ($\text{NO}\cdot$), singlet oxygen (O^-) and, in turn, ozone (O_3).⁷⁸

The NADPH oxidases provide granulocyte superoxide and are similar in structure to the mitochondrial redox transport chain, with membrane-associated proteins oxidizing NADPH at one end and the reducing potential passing via the cytochrome b_{558} complex to oxygen. The reaction can be summarized as follows:

In contrast to the mitochondrial redox transport chain the reaction is not linked to the generation of ATP and so this energetically favorable reaction must be tightly regulated. Recently, this mechanism has been elucidated.^{79–81} Cytochrome b_{558} exists as a heterodimer of two proteins, the glycoprotein gp91^{PHOX}, which contains the NADPH binding site, and a p22^{PHOX}, which passes the electron to oxygen

to form superoxide. In order for the reaction to proceed, the oxidase must be held in place by three adaptor proteins: p40^{PHOX}, p47^{PHOX} and p67^{PHOX}. The binding of bacterial lipopolysaccharide, chemokines or opsonized particles to their specific receptors on the granulocyte surface activates downstream signaling pathways leading to the formation of phosphatidylinositol 3-phosphate (PI 3-P) and the active form of the small G protein Rac1 (Rac^{GTP}). The presence of membrane PI 3-P and Rac^{GTP} recruits p40^{PHOX} and p47^{PHOX} to the inner surface of the lysosomal membrane where the latter is serine phosphorylated. This leads to the assembly of the active NADPH oxidase.⁸² The assembled oxidase induces a respiratory burst as granulocyte stores of NADPH are rapidly oxidized to NADP^+ and oxygen is converted into ROS (Fig. 14.4).

Superoxide is formed on the luminal surface of the lysosomal membrane and reacts with biologic material within the lysosomal contents. Much of this superoxide is metabolized by superoxide dismutase (SOD) into hydrogen peroxide (H_2O_2). H_2O_2 is a weak oxidant but in the presence of free metal ions or ozone can dissociate to form the potent hydroxyl radical. The presence of myeloperoxidase within lysosomes converts H_2O_2 into the potent oxidant HOCl:

Eosinophils contain their own peroxidase enzyme, which can form other potent oxidizing agents including HOBr and HOSCN.^{83,84}

All the ROS discussed will damage both neutrophil and bacterial proteins indiscriminately, and the NADPH oxidase can be inactivated by its own product. Granulocytes and monocytes must have a potent array of antioxidant enzymes to maintain their integrity.⁸⁵ Excess H_2O_2 that leaks back into the granulocyte cytosol is inactivated either by catalase or by the oxidation of glutathione. Glutathione is in turn restored via the oxidation of NADPH by glutathione reductase. It is of note that NADPH is important both for the formation of oxygen radicals and their removal.

Chronic granulomatous disease

Chronic granulomatous disease (CGD) (Fig. 14.5) is the product of a heterogeneous collection of inherited defects of the phagocyte respiratory burst. The overall incidence is 1 in 250 000, with autosomal recessive and X-linked inheritance being described (Table 14.7). Mutations affecting the gp91^{PHOX} protein account for the majority of patients. Mutations involving the cytosolic adaptor proteins tend to carry a milder phenotype as the intact flavocytochrome leaks a small amount of superoxide in the nonstimulated state.⁸⁶

Patients suffer recurrent and chronic infections with catalase-positive organisms. They present from the first year of life with infections of the epithelia and associated draining lymph nodes. Catalase is a ubiquitous enzyme that inactivates hydrogen peroxide, converting it to oxygen and water.

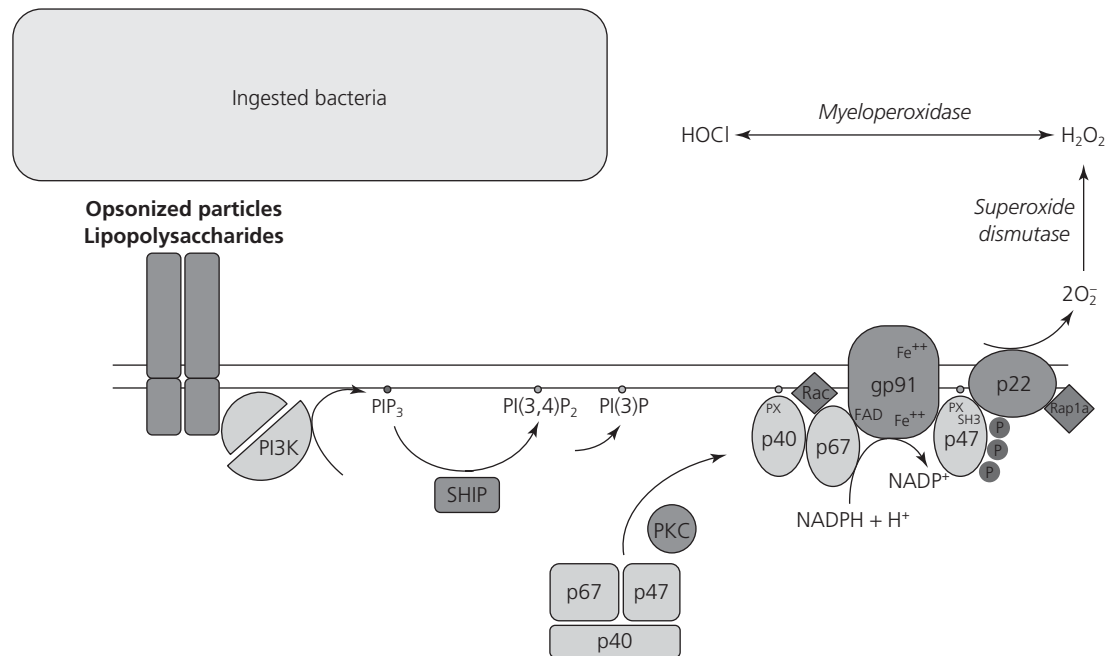

Fig. 14.4 Assembly of the lysosomal NADPH oxidase and formation of hypochlorite. On phagocytosis, lipopolysaccharide (LPS), complement and antibody receptors activate neutrophil phosphoinositol 3-kinase (PI3K), protein kinase C (PKC) and the small G proteins Rac and Rap1. The products of PI3K, phosphoinositol 3-phosphate (PIP₃) and phosphoinositol 3,4-bisphosphate (PI(3,4)P₂), recruit the adaptor proteins p40 and p47 respectively via binding to their PX domains. The adaptor proteins in turn assemble the components of the oxidase: gp91 and p22. Upon localization at the membrane, p47 is phosphorylated and activated by PKC. The activated complex secretes superoxide into the lumen of the lysosome, where it is further metabolized to hydrogen peroxide and hypochlorite.

Fig. 14.5 Chronic granulomatous disease. Persisting submandibular soft tissue infection with incipient skin breakdown and chronic discharge.

Ingested catalase-negative organisms are killed by the small amount of oxygen radicals that accumulate within the phagosome. Staphylococci are responsible for half of the infections seen, *Aspergillus* is the next most common at 10–20%, and Gram-negative enteric organisms make up the remainder.⁸⁶ Neutrophils and monocytes are recruited to sites of infection but are unable to kill ingested pathogens leading to the formation of chronic granulomas. Infectious abscesses are typically found in the skin and subcutaneous tissues, the facial sinuses, liver and urethral tract. Chronic granuloma formation may lead to noninfectious complications such as hepatosplenomegaly, lymphadenopathy, hypergammaglobulinemia and a chronic diarrhea associated with an inflammatory bowel-like disease that may require immuno-

Table 14.7 Chronic granulomatous disease and mutations of NADPH oxidase.

Affected protein	Coding gene	Gene locus	Inheritance	Location and protein function	Frequency (% of cases)
gp91 ^{PHOX}	CYBB	Xp21.1	X	Membrane flavocytochrome <i>b</i>	64
p22 ^{PHOX}	CYBA	16p24	AR	Membrane flavocytochrome <i>b</i>	7
p47 ^{PHOX}	NCF1	7q11.23	AR	Cytosolic adaptor protein	23
p67 ^{PHOX}	NCF2	1q25	AR	Cytosolic adaptor protein	6

X, X-linked; AR, autosomal recessive.

suppression.^{87,88} Granulomas can obstruct certain organs, such as the gastric pylorus, colon and ureters. Patients become chronically ill and their ability to withstand frequent infections gradually decreases. Death is often the result of fungal sepsis, mainly caused by *Aspergillus* species.⁸⁹

The diagnosis is made by demonstrating an absolute lack of superoxide production in activated phagocytes; those that are able to generate 1–10% of normal superoxide are regarded as having a variant disease (vCGD). In the Nitroblue Tetrazolium test, phorbol ester-stimulated neutrophils oxidize the yellow water-soluble dye to form a blue precipitate. In the absence of an X-linked history a Western immunoblot of neutrophil protein lysate is required to identify the affected protein. Identification of the genetic defect now makes it possible to provide earlier and accurate prenatal diagnosis of CGD using fetal DNA from chorionic villi or amniocytes.

Improvements in the management of CGD are reflected in an increase in life expectancy of children with this disorder.⁹⁰ A review of the American registry estimated a 2% chance of death per year.⁸⁶ Current and future treatment strategies are listed below.

- *Prophylactic antibacterial and antifungal drugs.* The widespread use of co-trimoxazole (Septrin) has led to an improvement in life expectancy for patients with CGD.⁹¹ Recently, co-trimoxazole has been superseded by azithromycin as this agent is better tolerated and need only be given in short courses fortnightly. The use of antibacterials has led to an increased proportion of fungal infections and hence the use of prophylactic antifungals such as itraconazole⁹² or more recently voriconazole.

- *Early aggressive treatment of breakthrough infections.* The identification of breakthrough infections can be difficult as patients can remain asymptomatic. Any pyrexia or rising inflammatory markers (C-reactive protein, erythrocyte sedimentation rate) should be thoroughly investigated and intravenous antimicrobials considered. Surgical drainage or excision of granulomas may be necessary. In severe infections granulocyte transfusions offer an alternative. Granulocytes can be derived either from buffy coat collected by national blood transfusion services or ideally can be leukapheresed from donors, often friends and relatives, who have taken a single dose of granulocyte colony-stimulating factor (G-CSF) together with a corticosteroid to increase the yield.⁹³

- *The use of IFN- γ .* The use of IFN- γ has been shown to reduce the frequency and severity of infection in patients with CGD.⁹⁴ The mechanism is unclear; approximately 14–28 days after a subcutaneous injection of IFN- γ there is an increase in macrophage gp91^{PHOX} mRNA levels;⁹⁵ in keeping with this, IFN- γ treatment is most effective in those with the X-linked variant form of CGD. However, in a phase III trial of IFN- γ , despite showing a clinical improvement, none of the patients showed an increase in neutrophil O₂⁻ production.⁹⁶ This suggests that in patients where gp91^{PHOX} levels are absent or

unaffected, IFN- γ therapy may still be of value by inducing nonoxidative bacterial killing by phagocytes.

- *The use of immunosuppressives.* It seems counterintuitive to treat a disorder blighted by multiple infections with immunosuppressives, and this strategy should be used with caution. However, corticosteroids have been successfully used to disperse granulomas causing obstruction to vital organs.⁹⁷ Corticosteroids, with or without ciclosporin, have been used to treat the inflammatory bowel disease associated with CGD.

- *Bone marrow transplantation.* Bone marrow transplantation offers a potential cure for the disease but its role is controversial as patients often receive therapy with multiple unresolved infections, and the transplant-related mortality rates are high in comparison with the long-term survival benefits achieved with antimicrobial prophylaxis. With the introduction of low-intensity, nonmyeloablative regimens, transplantation may have a role in severe disease.⁹⁸

- *Gene therapy.* CGD, along with other inherited disorders of granulocyte function, is a candidate for gene therapy as it is possible to stably infect intact genes into bone marrow stem cells using retroviral vectors. However, in contrast with the successful trials in patients with common gamma chain and adenosine deaminase deficiencies, the infected cells in CGD do not have a survival advantage over unaffected cells and are thus not able to dominate the marrow.⁹⁹

Glucose-6-phosphate dehydrogenase deficiency

The oxidation of NADPH to NADP⁺ provides the electron source for the formation of superoxide (O₂⁻). Much of granulocyte NADP⁺ is reduced back to NADPH by the action of glucose-6-phosphate dehydrogenase (G6PD) (Fig. 14.6). G6PD deficiency is one of the world's commonest inherited diseases and results in a hemolytic anemia. Despite erythroid and neutrophil G6PD being coded by the same gene and the ubiquity of G6PD deficiency, only a very rare subgroup of patients with the hemolytic anemia have a neutrophil dysfunction.¹⁰⁰ G6PD levels do not decay during the short lifespan of the neutrophil and there are shunt enzymes to transfer reducing potential between NADH and NADPH. However, if erythrocyte/neutrophil G6PD levels are less than 3% there is not enough NADPH to feed the redox enzyme chain to generate superoxide.

In the few cases reported, patients are male or homozygous females with the severe Mediterranean variant of the deficiency. The critically low erythrocyte G6PD levels (typically < 1% of normal) result in a chronic hemolytic anemia that does not require precipitation by an oxidative stress as in classical G6PD deficiency. This differentiates the disorder from CGD. The neutrophil defect is similar to variant CGD, and neutrophil function tests typically show 5–30% normal oxidative activity with an initially normal respiratory burst that is cut short.

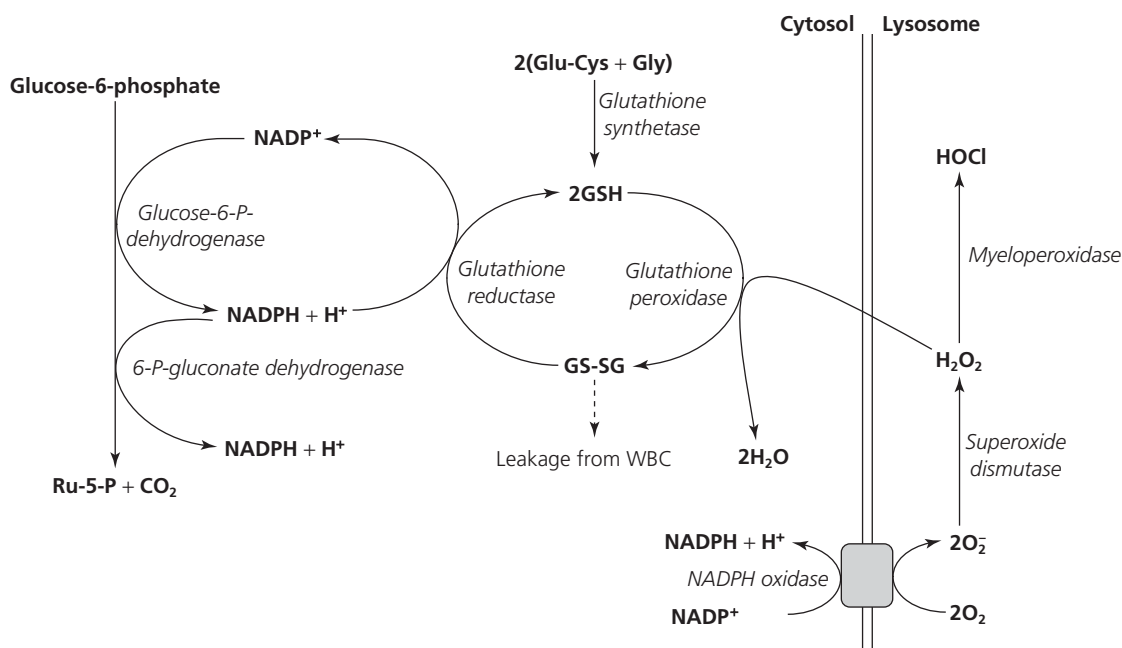

Fig. 14.6 Reduction of NADP^+ by glucose-6-phosphate dehydrogenase and glutathione metabolism. NADPH is required for both the production and removal of reactive oxygen species (ROS). Most NADPH is made via the shunt pathway of glucose metabolism using the enzyme glucose-6-phosphate dehydrogenase. NADPH is used to reconstitute glutathione (GSH), which in turn is oxidized into dimers (GS-SG) by the presence of hydrogen peroxide leaking back across the lysosomal membrane into the neutrophil cytosol.

Treatment is as for CGD together with supportive therapy for the chronic hemolysis and strict avoidance of oxidative stimuli that may trigger an acute life-threatening crisis. $\text{IFN-}\gamma$ is of little benefit in these patients.

Myeloperoxidase deficiency

Myeloperoxidase (MPO) deficiency is the commonest inherited disorder of neutrophil function. Inherited in an autosomal recessive fashion, partial deficiencies are seen in 1 in 2000 individuals, and complete deficiency in 1 in 4000 individuals.¹⁰¹ Monocytes and macrophages are affected, but not eosinophils as their peroxidase is encoded by a different gene. MPO is required for the generation of HOCl from H_2O_2 ; the hypochlorite in turn reacts with amine groups to form potent microbicidal radicals. This is important for *in vitro* killing of fungi. Rarely an acquired MPO deficiency can be seen in acute myeloid leukemia (AML) M2, M3, M4. In contrast, up to 25% of sufferers of CML and myelodysplasia with excess blasts acquire an MPO deficiency.^{102–104}

The disorder is surprisingly asymptomatic in both inherited and acquired forms, and prophylactic antibiotics are not indicated. This may be due to a compensatory increase in oxidative burst as HOCl destroys the neutrophil NADPH oxidase, limiting its production of superoxide.¹⁰⁵ Only in diabetics is MPO deficiency of concern, where it predisposes to severe *Candida* infections.

The disorder is diagnosed by demonstrating the absence of cytochemically stainable enzyme and can be identified by flow cytometry. Furthermore, some cell counters that identify neutrophils by virtue of a peroxide stain may erroneously diagnose the patients as neutropenic.¹⁰⁶ Neutrophil function tests are unnecessary as MPO-deficient neutrophils show normal chemotaxis, adherence, phagocytosis and degranulation. MPO-deficient neutrophils have an increased respiratory burst producing augmented amounts of H_2O_2 . Affected neutrophils can kill bacteria although this may be delayed.

Disorders of oxidant scavenging

Loss of granulocyte antioxidant enzymes can potentially reduce their lifespan and potency as oxidant enzymes are destroyed by their own product. However, in contrast with their effects on red cells these disorders show little evidence of a clinically significant reduction in neutrophil lifespan or ability to clear infection. These disorders can be subdivided into two groups.

Disorders of glutathione metabolism

Glutathione (GSH) is a tripeptide containing a central cysteine. The cysteine's $-\text{SH}$ group can be oxidized to form glutathione dimers (GSSG). The tripeptide is synthesized from

Table 14.8 A summary of disorders of glutathione metabolism.

Enzyme	Physiologic role	Clinical significance	Other features	References
Glutathione synthetase	Synthesis of glutathione (GSH)	Abnormal neutrophil phagocytosis in severe cases. May be relieved with vitamin E	Chronic hemolysis and acidosis due to an inability to reduce oxyproline	107, 108
Glutathione reductase	Recovery of glutathione dimers (GSSG) back to GSH	Reduced respiratory burst of uncertain significance	G6PD-like intermittent hemolytic anemia precipitated by oxidative stress	109, 110
Glutathione peroxidase	Reduction of H ₂ O ₂ to water, oxidizing GSH	CGD-like disorder, but the role of enzyme deficiency is unclear		111–114

glutamyl, cysteine and glycine by glutathione synthetase. Toxic ROS are reduced by the action of glutathione peroxidase, which in turn oxidizes GSH into GSSG. Free GSSG is able to diffuse out of the cell; to prevent its loss it is rapidly reduced back to GSH by glutathione reductase, a reaction that requires oxidation of NADPH. Thus the presence of NADPH is required both for the formation and inactivation of neutrophil ROS. Disorders of glutathione metabolism are summarized in Table 14.8.

Catalase deficiency

Catalase inactivates excess hydrogen peroxide to form oxygen and water. Roos *et al.*¹¹⁵ have reported two patients with reduced levels of both erythrocyte (<2% activity) and neutrophil (10–20%) catalase activity. Neither patient had a significant problem with pyogenic infections.

Investigation of the child with a suspected disorder of phagocyte function

Phagocytes are only one component of the normal defense mechanisms against infection, and many different phagocytic defects may present in a similar clinical fashion. A good history is important to differentiate the diseases listed. It is important to note that many children develop bacterial infections and that the incidence of most of the diseases discussed is rare; it follows that most children investigated for disorders of granulocyte function are entirely normal. Prior to embarking on an extensive program of investigations the following points should be considered.

- *Nature and timing of infections.* An early presentation suggests a severe disorder with a poor prognosis. A lack of pus together with a high neutrophil count suggests a defect of adhesion. The presence of granulomas suggests CGD. The milder phagocyte disorders may reveal themselves in the second decade of life with dental disease.
- *Type of infectious organisms.* CGD is associated with infections from staphylococci and other catalase producers.

Infections with *Pneumocystis* and viruses suggest a lymphocyte immunodeficiency in addition to a phagocyte disorder as in hyperimmunoglobulin E syndrome. All of the severe diseases listed are associated with fungal infections.

- *Noninfectious symptoms.* A history of atopy is associated with hyper-IgE, whereas the granulomas of CGD cause obstruction and an inflammatory bowel disease-like picture. Disorders of glutathione metabolism and G6PD present with a hemolytic anemia. A peripheral neuropathy and minor bleeding history is associated with Chédiak–Higashi.

Figure 14.7 represents a typical algorithm for the investigation of a phagocyte disorder.

Neutrophil function tests

Examination of a peripheral blood smear should precede any attempt at investigating neutrophil function. This can identify large abnormal granules in Chédiak–Higashi disease, or bilobed nuclei with a distorted nuclear membrane in neutrophil-specific granule deficiency. The Pelger–Huët anomaly may be seen in various marrow stem cell disorders such as myelodysplasia, Döhle-body-like inclusions in the May–Hegglin anomaly, and hypersegmented neutrophils in megaloblastic anemia. Neutrophil function tests are complex, unreliable and should only be performed in a specialist center.

- A Boyden chamber consists of two chambers linked by a thin flat channel. Phagocytes are placed in one chamber and a chemoattractant is placed in the second chamber. The proportion of motile cells is then measured after a defined period of time. The test can be performed in the presence of the patient's own or control plasma.
- Rebuck skin window measures the migration of neutrophils on to a glass cover slip applied to a superficial skin abrasion. An unreliable test that has been superseded by *in vitro* tests.
- Neutrophil adhesion can be determined *in vitro* by the adherence of the cells to nylon wool; this can be done in the presence of the patient's or control plasma.
- The respiratory burst is evaluated using the nitroblue tetrazolium (NBT) reduction test. Neutrophils are activated

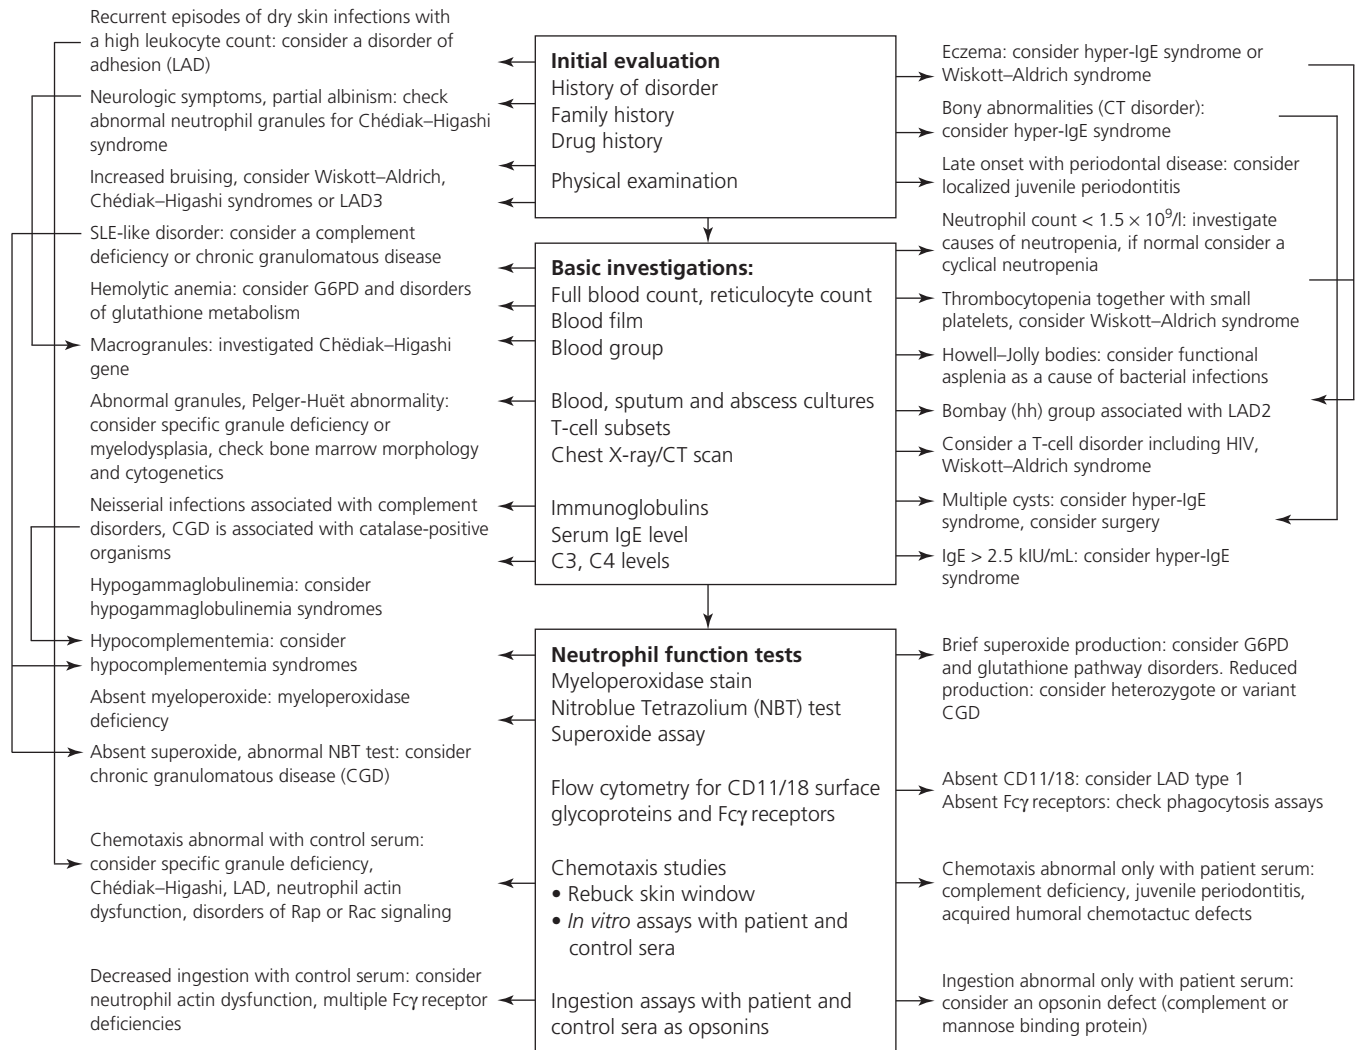

Fig. 14.7 Investigational algorithm for a neutrophil function defect.

in the presence of NBT, which produces a dark precipitate in cells producing superoxide (O_2^-). Respiratory burst activity can be measured directly as oxygen consumption, oxygen production (using cytochrome *c* reduction) or hydrogen peroxide production, and indirectly using neutrophil chemiluminescence.¹¹⁶ Such tests are now available in kit form (Phagoburst) using f-Met-Leu-Phe or LPS as stimulants. ORPEGEN Pharma Heidelberg, Germany.

- Cytochemical stains and flow cytometry can be used to detect deficiencies in the enzymes myeloperoxidase and alkaline phosphatase and the lack of β_2 integrins and antibody Fc receptors.
- Bacterial and fungal phagocytosis and killing can also be measured. These tests are now available in kit form (Phagotest) using opsonized microbes. ORPEGEN Pharma Heidelberg, Germany.
- Additional tests include measurement of neutrophil degranulation and can be used to differentiate between disorders of primary and secondary granules.

Disorders of phagocyte numbers

Normal neutrophil structure and development (Fig. 14.8)

Neutrophilic, eosinophilic and basophilic granulocytes are thought to follow similar patterns of proliferation, differentiation, maturation and storage in the bone marrow and delivery into the blood. For neutrophils the stages comprise myeloblast, promyelocyte, myelocyte, metamyelocyte, band form and mature neutrophil. The differentiation and maturation of polymorphonuclear neutrophils from a primitive stem cell involves sequential transcription of various genes and development of various organelles. Morphologically, using a light microscope, the various stages can be identified. The nuclei of immature cells with active gene transcription have open chromatin with promin-

Feature	Myeloblast	Promyelocyte	Myelocyte	Metamyelocyte	Band form	Mature neutrophil
Proliferation vs Maturation	The mitotic pool undergoes division and maturation. Currently it is believed that there are about five divisions, with possibly three at the level of the myelocyte and one each at the other levels			No evidence of cell division at these stages. There is maturation of the various components

Morphology						

Fig. 14.8 Neutrophil maturation.

ent nucleoli. Cytoplasmic basophilia (i.e., bluish coloration), is due to the presence of RNA and rough endoplasmic reticulum and represents active protein synthesis. Neutrophils have three types of granules with distinctive constituents, which arise chronologically. In general, cell maturation is accompanied by reduction in cell size, diminished cell volume, increased chromatin condensation of the nucleus, loss of nucleoli, appearance of cytoplasmic granules and a change in cytoplasmic basophilia. Further changes in the cell surface carbohydrates, glycoproteins, glycolipids, and HLA antigens and granule contents occur during the entire maturation.

Neutrophil kinetics

Neutrophil kinetics describes the process of neutrophil multiplication, maturation, storage and distribution to tissues and sites of infection and tissue damage. Various methods have been employed to study these processes, for example, neutrophil depletion to assess the size and rate of mobilization of reserves; radioactive tracers to study the production, distribution and survival times; mitotic indices of marrow granulocytic cells to assess proliferative capacity; and induction of inflammatory lesions to study cell movement into the tissues. Such studies are helpful in explaining the physiological variations in neutrophil counts

and potentially explaining the mechanisms of neutropenia and risk of infections in different neutropenic states.

The three major compartments are the marrow, blood and tissue (Table 14.9). The mechanisms controlling the release of neutrophils from the bone marrow are only partially understood. A variety of compounds induce neutrophil movement into the circulation, including endotoxin, glucocorticoids, chemoattractants such as C5a, and cytokines such as tumor necrosis factor (TNF)- α . From the blood, neutrophils migrate into the lung, oral cavity, gastrointestinal tract, liver and spleen. They may be lost from mucosal surfaces, die in tissues or be phagocytosed by macrophages. The survival time in tissues is not known exactly, but is believed to be short. On average it takes 10 days for a neutrophil to mature and be released into the blood.

Neutropenia: definition

Neutropenia refers to an absolute blood neutrophil count (ANC) that is less than two standard deviations below the normal mean of the population. The neutrophil count in the peripheral blood is influenced by age, activity, and genetic and environmental factors. In infants the threshold is $1.0 \times 10^9/\text{L}$, and after the age of 1 year, the usual value is $1.5 \times 10^9/\text{L}$ up to the age of 10 years, with an adult threshold of $1.8 \times 10^9/\text{L}$ being applied thereafter.¹¹⁹ The

Table 14.9 Neutrophil kinetics^{117,118}

Compartment	Transit time (h)	Size of cell compartment ($\times 10^9/\text{kg}$)
Stem cells	Not known	Not known
<i>Marrow: mitotic compartment</i>		
Myeloblasts	23	0.14
Promyelocytes	26–78	0.51
Myelocytes	17–126	1.95
<i>Marrow: maturation and storage compartment</i>		
Metamyelocytes	8–108	2.7
Band forms	12–96	3.6
PMN	0–120	2.5
<i>Blood</i>		
Circulating neutrophil pool	Half-life in blood is 6.7 h	0.31
Marginating neutrophil pool		0.39
Total blood neutrophil pool		0.70
Tissues	Not known	Neutrophil turnover rate is $0.3\text{--}1.3 \times 10^9/\text{kg}$ per day

white blood cell (WBC) and neutrophil counts are lower in black people than Caucasians, and lower in Africans than in West Indians or black people in the USA. Yermite Jews also have lower counts than Caucasians.¹²⁰ A recent population-based study in Uganda showed a median absolute neutrophil count $\approx 2 \times 10^9/\text{L}$, and 90% reference ranges were quoted for different age groups: < 1 year ($0.9\text{--}4.4 \times 10^9/\text{L}$), 1–5 years ($1.0\text{--}3.9 \times 10^9/\text{L}$), 6–12 years ($0.9\text{--}3.6 \times 10^9/\text{L}$).¹²¹ In most Afro-Caribbean adults an ANC above $1 \times 10^9/\text{L}$ is considered normal, but in infants the total neutrophil count may be less than $1.0 \times 10^9/\text{L}$ in as many as 20%.¹²²

The severity of neutropenia can be classified as:

- mild: below the lower limit of normal but $> 1.0 \times 10^9/\text{L}$;
- moderate: $0.5\text{--}1.0 \times 10^9/\text{L}$;
- severe: $< 0.5 \times 10^9/\text{L}$;
- very severe: $< 0.2 \times 10^9/\text{L}$.

The lower limits are useful because the risk of severe infections does not increase until the neutrophil count falls below $0.5 \times 10^9/\text{L}$. The term agranulocytosis means complete absence of neutrophils and is often used to refer to severe neutropenia.

Pathophysiologic mechanisms of neutropenia

Neutropenic conditions can be distinguished according to the neutrophil pool that is predominantly affected, and are listed as follows.

- Decreased proliferation of progenitor cells, e.g., decreased number of stem cells in aplastic anemia, hostile micro-

environment with decreased proliferating cells in leukemia and other infiltrative disorders, chemotherapy- or infection-induced inhibition of progenitor cells.

- Ineffective granulopoiesis/accelerated apoptosis, e.g., inherited defects of stem cells and progenitors in congenital neutropenia, acquired defect in B_{12} /folate deficiency.

- Reduced survival, e.g., increased peripheral consumption/accelerated destruction, in tissues during infections, by spleen in immune neutropenias, complement-mediated lysis in dialysis.

- Redistribution of the intravascular pool of neutrophils, e.g., endotoxin-induced margination of neutrophils.

It is of note that for a given ANC, the risk of infection is higher when the neutropenia is due to decreased production compared with increased destruction.

Severe chronic neutropenia

Severe chronic neutropenia is an inclusive term for hematologic diseases that cause severe neutropenia, that is a blood neutrophil count of $< 0.5 \times 10^9/\text{L}$ for months or years. It is not a disease but a group of conditions with common clinical manifestations and both congenital and acquired causes.¹²³ Currently in the literature the terms “severe congenital neutropenia (SCN)” and “Kostmann syndrome” are used synonymously by some authors although others solely apply the eponymous name to those conditions believed to be of autosomal recessive inheritance as in Kostmann’s original description.

The patients usually suffer infections with endogenous flora of the oropharynx, gastrointestinal tract and skin. Susceptibility to bacterial infections is variable even in patients with severe neutropenia. In SCN there is a very selective defect in the host defense mechanism with decreased neutrophils. The remaining components of innate immunity and adaptive immunity are intact and, indeed, compensatory monocytosis is not uncommon. This contrasts with chemotherapy-induced neutropenia, where innate immunity and adaptive immunity are also impaired, leading to a relatively higher incidence of infection. SCN patients present with recurrent oral ulcerations, gingivitis, recurrent upper respiratory tract infections, perirectal inflammation or minor skin infections and cellulitis. Frequent aphthous stomatitis and gingival hyperplasia lead to early loss of permanent teeth. Consequent to the sparing of the monocyte lineage, fungal infections are uncommon except as a possible complication of antibiotic therapy.¹²⁴

Congenital neutropenias

Classification

Congenital neutropenias are a group of disorders characterized by a genetic defect that is known or postulated, con-

Table 14.10 Classification of congenital neutropenias.*Isolated congenital neutropenias*

Kostmann syndrome and severe congenital neutropenia

Cyclic neutropenia

*Neutropenia as part of congenital bone marrow failure syndromes, e.g.,**Fanconi anemia, dyskeratosis congenita**Congenital neutropenia as part of multisystem disorder*

Severe combined immune deficiency (SCID) and reticular dysgenesis

X-linked hypogammaglobulinemia

Hyper-IgM

WHIM syndrome and myelokathexis

tributing to defective myelopoiesis (Table 14.10). The genetic defect might affect either the myeloid progenitors or stem cells or alter the microenvironment. Perhaps surprisingly, the neutropenia is not always present at birth. Although the age of onset is variable, symptoms can usually be traced back to the first year of life.

Common features

The congenital neutropenias have a number of common features, as summarized below.

- These are rare disorders. All modes of inheritance have been described. Patients with severe neutropenia are at risk of overwhelming infections. Clinical suspicion with early diagnosis and management can have a profound impact on the morbidity and mortality.
- Recombinant human G-CSF, cloned in 1986,¹²⁵ has revolutionized the management of these disorders. In 1987 it was shown that filgrastim selectively stimulated neutrophil production.¹²⁶ Four phase I/II trials and one phase III trial documented the safety and efficacy of G-CSF in the management of severe congenital, cyclic and idiopathic neutropenia. G-CSF elevated the neutrophil counts, and decreased or eliminated recurrent infections. More than 90% of patients respond to G-CSF.^{125–128}
- The use of G-CSF and antibiotics has allowed survival into adulthood even in severely affected children.
- Genetic mutations have been identified in a proportion of the congenital neutropenias. The exact pathogenetic mechanisms, i.e., the translation of gene to disease, remain largely unclear.
- Some of the congenital neutropenias are preleukemic conditions. Currently it is not possible, at least at an early stage, to identify patients who are at high risk of transformation.

With increasing genotype and phenotype analysis, an individualized risk assessment is both possible and desirable.

Severe congenital neutropenia and Kostmann syndrome

R. Kostmann was among the first to describe severe congenital neutropenia in a Swedish family, with an apparent autosomal recessive inheritance, maturation arrest at promyelocyte/myelocyte stage, and early onset of bacterial infections with high mortality.¹²⁹ Severe congenital neutropenia is genetically heterogeneous, and inheritance patterns now recognized include sporadic, autosomal dominant, autosomal recessive and X-linked forms.^{130,131} Constitutional heterozygous *ELA2* mutations are present in the majority of patients with sporadic and autosomal dominant disease, but not in the others. There is no association with other congenital abnormalities.

Clinical presentation

The disease usually presents in the first year of life with severe neutropenia, often $< 0.2 \times 10^9/L$, and recurrent infections. The infections are mostly bacterial and can present as an omphalitis immediately after birth. Fatal infections were common in the past, and in the pre-cytokine era 42% of the published cases died in the first two years of life usually from sepsis and pneumonia.¹³² Bone marrow aspirate shows a maturation arrest at the promyelocyte/myelocyte stage. Promyelocytes may show dysplastic features, including atypical nuclei, vacuolization of the cytoplasm and occasional abnormal granulation. The remaining hematopoietic system is essentially normal with mild anemia of chronic disease, reactive thrombocytosis and presumably a compensatory monocytosis and eosinophilia. Immune response to vaccination is normal. IgG levels are often elevated.

Treatment of neutropenia

The neutropenia of SCN responds to G-CSF in more than 90% of the patients. Most patients respond to a dose of 3–10 $\mu g/kg$ daily. Registry data suggest that 92% of patients respond to a dose of $< 30 \mu g/kg$ daily with an increase in mean neutrophil count of $> 1.5 \times 10^9/L$.^{132,133} Recommendations include a starting dose of 5 $\mu g/kg$ daily, and incrementing by 10 $\mu g/kg$ per day every 14 days, aiming for a neutrophil count of $1\text{--}5 \times 10^9/L$. Nonresponders are defined as not responding to 120 $\mu g/kg$ daily, although rarely is anything achieved beyond 30 $\mu g/kg$ daily. Partial responders are patients who increase their neutrophil counts to between 0.5 and $1 \times 10^9/L$. A good initial rise usually predicts good long-term improvement; loss of response with time through marrow exhaustion has not been observed with long-term therapy.

Other clinical features

Other clinical features associated with severe congenital neutropenia¹³⁴ are summarized below.

- Musculoskeletal pains and headache are commonly seen at the beginning of treatment with G-CSF, and respond well to a nocturnal dosing schedule and simple analgesics.
- Mild splenomegaly is seen in less than a fifth of patients before starting G-CSF, but the incidence increases with treatment.
- Thrombocytopenia is uncommon and should raise concerns about possible transformation to myelodysplastic syndrome (MDS)/AML, although sometimes it is associated with excessive G-CSF dosage.
- Osteopenia and osteoporosis have been documented either by dual energy X ray absorptiometry (DEXA) scan or symptomatic fractures in a small group of patients, but the true incidence and relation to G-CSF are unknown.
- Vasculitis, typically cutaneous or renal, has a 3% incidence, and is temporally related to an increase in ANC; biopsy shows leukocytoclastic vasculitis. Patients with recurrent vasculitis or organ involvement often have other autoimmune disorders, worsened by G-CSF.
- Growth and longitudinal development can be impaired, although this may merely be a manifestation of chronic illness in older cases series.

Transformation to myelodysplastic syndrome and acute myeloid leukemia

There is an excess incidence of MDS and AML in patients with severe chronic neutropenia and Shwachman–Diamond syndrome (SDS). This predisposition to hematologic malignancy is confined to SCN and SDS and has not been observed in other chronic neutropenias including cyclic and idiopathic variants. The transformation is often associated with the development of cytogenetic abnormalities (frequently partial or complete loss of chromosome 7, abnormalities of chromosome 21) and point mutations in the *ras* and G-CSF receptor genes.¹³⁵ There has been concern regarding the use of G-CSF and the excess risk of transformation in children with SCN. Epidemiologic data do not reveal an association between G-CSF dose or duration of treatment and transformation risk.¹³⁶ The current consensus is that G-CSF merely allows the most severely affected children to live long enough for the full disease phenotype to manifest rather than accelerating the progression *per se*.

The cumulative risk of development for AML/MDS by the end of year 8 of G-CSF was about 13%, based on 94 patients who had received a minimum of 8 years of G-CSF.¹³³ Leukemic events appear to be randomly distributed with reference to duration of observational exposure to G-CSF.

Chemotherapy alone offers no long-term survival once transformation has occurred. Although the data are largely

unpublished, bone marrow transplantation (without significant AML-like chemotherapy) can achieve a surprisingly good “cure” rate, even at this stage of the disease. Transplant-related mortality was historically very high but has been reduced dramatically with antifungal prophylaxis.

Follow-up

Clinical examination and blood count are recommended every 3 months for patients on long-term therapy. Cytogenetic changes may precede overt leukemia, therefore yearly bone marrow aspirates and cytogenetic studies are recommended.

Cyclic neutropenia

Cyclic neutropenia is a rare hematologic disorder, classically described as an autosomal dominant cyclical oscillation in the neutrophil count (and to a lesser extent other cell lineages) with a regular periodicity of 21 days. A few sporadic cases have also been documented. Mutations in *ELA2* (discussed later) are seen in almost all patients with the classic 21-day periodicity. During the nadir the neutrophil count is usually $< 0.2 \times 10^9/L$ for about 3–5 days, and during the normal periods the counts are typically around the lower limit of normal.¹³⁷ The role of *ELA2* mutations is described later.

Clinical presentation

The age of onset is variable, but most patients have symptoms in infancy. During the neutropenic phase patients present with fever, malaise, aphthous stomatitis, and cervical adenopathy. Cellulitis can develop at sites of injury and in the perianal region. Fatalities secondary to spontaneous peritonitis, segmental bowel necrosis and septicemia are recorded, possibly secondary to colonic ulcers.^{138,139} A wide spectrum of symptom severity, ranging from asymptomatic to life-threatening illness, can be observed even within families. Thrice weekly blood counts for 6 weeks are recommended by the Severe Chronic Neutropenia International Registry (SCNIR) to enable diagnosis, although this is difficult in children. Serial bone marrow examination shows maturation arrest at varying stages, with only early myeloid precursors being seen during the neutropenic phase.

Treatment

Cyclic neutropenia responds extremely well to G-CSF, often within 1–2 weeks of initiation of treatment. G-CSF shortens the duration of the neutropenic phase and increases the peak neutrophil count. More than 90% of patients respond and they require a smaller dose than SCN patients. The median daily dose is 2 µg/kg with a maximum of 10 µg/kg daily. There is no evidence of transformation to MDS/AML.^{133,134}

***ELA2* mutations in the pathophysiology of cyclic neutropenia and severe congenital neutropenia**

Heterozygous mutations of the *ELA2* gene are detected in nearly all families with cyclical neutropenia and the majority of patients with sporadic and autosomal dominant severe congenital neutropenia but not in those with autosomal recessive variants.^{130,131,140} Biallelic mutation of *ELA2* is unknown, and these mutations therefore do not explain the syndrome first reported by Kostmann.

ELA2 codes for neutrophil elastase (NE), the synthesis of which is confined to promyelocytes and promonocytes. NE is packaged into the azurophilic granules and appears to have an important role in both host response to infection and the inflammatory response. Pathophysiologically extracellular release of NE at sites of inflammation appears to have an important role in a variety of conditions including emphysema, cystic fibrosis and rheumatoid arthritis.

There is now plentiful genetic data supporting the role of *ELA2* mutations in the pathogenesis of cyclic neutropenia and some forms of SCN. Two major observations that strongly support an etiological role for *ELA2* mutations are firstly that they occur almost invariably in cyclic neutropenia and commonly in SCN, and none of the described mutations has been reported in a normal individual. Secondly, germline mosaic individuals who have fathered children with SCN demonstrate *ELA2* mutations in myeloid progenitors, but not neutrophils, indicating that the mutation alone is sufficient to prevent the maturation of stem cells into neutrophils.¹⁴¹

The severe neutropenia of these disorders is characteristically associated with a maturation arrest at the promyelocyte/myelocyte stage. There is no well-defined explanation for this arrest. Several hypotheses have been proposed to explain the role of abnormal NE in the development of SCN.^{142,143} Protein modeling suggests that a feature common to all mutations of NE is that they can lead to destabilization of the mature protein. This destabilization may result in a gain of function or abnormal function. A recent hypothesis suggests that there is abnormal trafficking of the neutrophil elastase with increased membrane expression. Although initial studies suggested that the mutations affect different areas of the protein in cyclic and congenital neutropenia, subsequent studies demonstrated considerable overlap in the mutations with some being reported repeatedly in both cyclical and congenital neutropenia. Furthermore, the excess risk of leukemia and MDS seen in SCN is not present in cyclic neutropenia, further adding to the difficulty of understanding the mechanism of disease. One genotype-phenotype study suggested that SCN patients whose disease is the result of *ELA2* mutations represent a subset with more severe disease, with lower neutrophil counts, higher requirements for G-CSF and a higher rate of neoplastic progres-

sion.¹⁴⁴ However, attempts to predict the risk of malignant transformation within the group that have *ELA2* mutations appear unlikely to be successful.

Shwachman–Diamond syndrome

SDS is a rare autosomal recessive multisystem disorder, and has already been described in Chapter 3. It is the second most common cause of pancreatic insufficiency after cystic fibrosis, and probably the third most common inherited bone marrow failure syndrome after Fanconi anemia and Diamond–Blackfan anemia. It has two main characteristics: pancreatic exocrine insufficiency and neutropenia/bone marrow failure.¹⁴⁵ SDS typically presents in infancy as failure to thrive due to a combination of pancreatic insufficiency, feeding difficulties and recurrent infections. In milder cases, the diagnosis can be delayed until the second decade of life.

Genetics and pathophysiology

SDS appears to be caused by mutations of the previously undescribed *SBDS* gene.¹⁴⁶ Most patients have compound heterozygous mutations. Homozygosity for the predicted null mutations has not been reported, these presumably being embryonically lethal and implying that some functional gene product is essential. This highly conserved gene is expressed in most human cell types and encodes a 250 amino acid protein whose function is unclear, although indirect genetic evidence suggests that it may be involved in RNA processing. Presumably, there is an effect on some aspect of RNA metabolism that is essential for development of the exocrine pancreas, hematopoiesis and chondrogenesis.¹⁴⁷

Hematologic abnormalities and MDS/AML

Ineffective hematopoiesis commonly presents as neutropenia. The neutropenia can be intermittent, although it is probably not truly cyclic as suggested in the past. Neutrophil dysfunction is present with impaired mobility, migration and chemotaxis. Anemia may be present at diagnosis but usually responds to the improved nutritional status associated with enzyme replacement and good gastrointestinal care. Intermittent mild thrombocytopenia is not unusual and pancytopenia develops in a significant proportion of patients. The marrow appearances include varying degrees of hypoplasia, left-shifted granulopoiesis with maturation arrest, and scattered trilineage dysplastic changes. SDS is a preleukemic stem cell disorder with a crude risk of leukemic transformation probably > 30% with prolonged (40-year) follow-up. Stable clonal cytogenetic abnormalities are not uncommon, with occasional spontaneous disappearance of large clones.¹⁴⁸ Cytogenetic abnormalities often involve chromosome 7; however, clones containing isochromosome 7q and del(20q) frequently wax and wane over many years in SDS and their exact prognostic value is

unknown. Although the neutropenia does respond to G-CSF, most patients manage well on prophylactic antibiotics alone.

Pancreatic dysfunction

Varying severity of pancreatic dysfunction due to acinar maldevelopment is a hallmark of SDS. There is extensive fatty replacement of pancreatic acinar tissue with relatively normal ductal architecture. Secretion of lipase, amylase and trypsinogen is decreased. Malabsorption and steatorrhea are present in around 90% of the patients at diagnosis. Surprisingly, with increasing age, up to half of SDS patients show improvement in enzyme production and can just become pancreatically sufficient although remaining clearly abnormal on more formal testing.

Other abnormalities

Skeletal dysostosis produces thoracic cage and gait abnormalities. The latter can be severe and require surgical correction. Dental dysplasia (not solely related to neutropenia) and behavioral and intellectual problems are also frequent.

Pearson syndrome

This syndrome is caused by deletions in mitochondrial DNA.¹⁴⁹ It presents with macrocytic anemia, variable degrees of neutropenia, thrombocytopenia and exocrine pancreatic failure. The bone marrow is characteristic, with hemosiderosis, ring sideroblasts and remarkable vacuolization of erythroid and myeloid precursors, all of which point to the diagnosis and largely exclude the diagnosis of SDS, with which there can be confusion clinically.¹⁵⁰

Barth syndrome

Barth syndrome is an inherited disorder, often fatal in childhood, characterized by cardiac and skeletal myopathy, short stature, neutropenia and 3-methylglutaconic aciduria.¹⁵¹ The disease is caused by mutations in the X-linked G4.5 gene, which encodes for a protein involved in cardiolipin biosynthesis.¹⁵² The mechanism of neutropenia is unknown. The neutropenia responds well to G-CSF. Early diagnosis and initiation of G-CSF is important as neutropenia and cardiomyopathy are a potentially lethal combination. There does not appear to be a risk of malignant transformation.

Glycogen storage disease type Ib

Glycogen storage disease type Ib (GSDIb) results from deficiency of the glucose 6-phosphate translocase enzyme, which transports glucose 6-phosphate into the endoplasmic reticulum for conversion to glucose. Absence of the enzyme leads to an inability to produce glucose by either gluconeogenesis or glycogenolysis, with the risk of fasting hypoglycemia and

lactic acidosis. These patients suffer from severe neutropenia, neutrophil function defects and recurrent infections.¹⁵³ The mechanism of the neutropenia is again uncertain. Surprisingly, an inflammatory bowel disease is associated with the neutropenia of GSDIb. G-CSF treatment reduces the number and severity of infections and the inflammatory bowel disease improves subjectively.¹⁵⁴ G-CSF can lead to splenomegaly, and some patients require dose reduction. There have been two case reports of AML in patients on long-term G-CSF; affected individuals therefore need monitoring similarly to the SCN children.¹⁵⁵

Neutropenia associated with primary immunodeficiency disorders

Neutropenia is a feature of congenital immunodeficiency states and a factor contributing to the increased risk of infection in many patients. The primary immunodeficiency diseases involve virtually every component of the immune system. Most of the immunodeficiency disorders are inherited as single gene defects. The disorders of primary immunodeficiency are discussed in detail in Chapter 19. A brief mention is made of disorders where neutropenia is severe or prominent.¹⁵⁶

Severe combined immunodeficiency disease and reticular dysgenesis

Reticular dysgenesis is a form of severe combined immunodeficiency disease (SCID), characterized by complete failure of development of both myeloid and lymphoid stem cells. The lack of adaptive immunity with absence of phagocytes leads to severe and often fatal infections in the first year of life. Bone marrow transplantation has been reported to be curative. In the other variants neutropenia is variable, and can respond to G-CSF.

X-linked agammaglobulinemia

Severe often intermittent neutropenia is seen in about one-quarter of patients. The *XLA* gene responsible for the disorder is expressed in cells of myeloid lineage, although the mechanism of neutropenia is ill defined.

Hyper-IgM syndrome

Intermittent or chronic neutropenia is prominent and affects over half of the patients. Although an autoimmune basis has been suggested, there is no evidence of antineutrophil antibodies. A defective interaction with the microenvironment due to deficiency of CD40 ligand would appear to alter the cytokine milieu necessary for myelopoiesis. Indeed, the marrow in these patients shows a maturation arrest with vacuolated promyelocytes, indistinguishable from that seen in SCN.

Common variable immunodeficiency

Neutropenia has been noted, probably on an autoimmune basis. There is an association with hemolytic anemia and thrombocytopenia. The neutropenia has been reported to be responsive to G-CSF, and G-CSF is indicated if the patient is symptomatic in spite of IVIG and antibiotics.

Cartilage-hair-hypoplasia syndrome

This rare autosomal recessive syndrome is characterized by short limb dwarfism with hyperextensible digits, fine hair, neutropenia, lymphopenia and recurrent infections. The syndrome is due to mutation in the *RMRP* gene, which encodes the mitochondrial RNA-processing endoribonuclease.¹⁵⁷

Chédiak–Higashi syndrome

The neutropenia is mild, and recurrent infections are due to the combination of neutropenia with defective microbicidal activity. It has been discussed in detail with disorders of function, above.

Myelokathexis and WHIM syndrome

Myelokathexis is a rare cause of severe leukopenia and neutropenia. It is a genetically heterogeneous disorder, and WHIM syndrome is one of the autosomally dominant inherited variants. The acronym WHIM was coined to describe an unusual form of congenital neutropenia characterized by warts, hypogammaglobulinemia, immunodeficiency and myelokathexis (the apparent retention of mature neutrophils in the bone marrow). The pathognomonic bone marrow findings are myeloid hypercellularity with morphologic abnormalities consistent with apoptosis, which are cytoplasmic vacuolation, hypersegmented and pyknotic nuclei, and long thin strands of chromatin separating the nuclear lobes. Affected individuals typically present with recurrent infections and leucopenia. The total leukocyte counts are often $< 1 \times 10^9/L$, and absolute neutrophil counts tend to be 0.0 to $0.5 \times 10^9/L$. The clinical course is relatively benign, and indeed a significant proportion of cases are diagnosed in adulthood. There is no excess of viral infections, except for a unique susceptibility to human papillomavirus, which can occur from infancy to adolescence. Hypogammaglobulinemia can range from moderate deficiency to essentially normal levels. T- and B-cell dysfunction fluctuate in the same individual over time. No neutrophil function defects have been reported in WHIM syndrome, although some of the isolated forms appear to show functional defects.

Truncating mutations in the cytoplasmic tail of the chemokine receptor 4 (CXCR4) are the cause of WHIM syndrome.^{158,159} The mutations result in prolonged activation, with enhanced chemotactic responsiveness of neutrophils

Table 14.11 Examples of acquired neutropenias.

<i>Neutropenia as the only or dominant cytopenia</i>
Infections: viral, bacterial, fungal, rickettsial and protozoal
Drugs
Immune
Neonatal alloimmune neutropenia
Primary autoimmune neutropenia of infancy and childhood
Secondary autoimmune neutropenia
Nutrition: anorexia nervosa, copper deficiency
Chronic idiopathic neutropenia
Neutropenia associated with complement activation
<i>Neutropenia as part of pancytopenia</i>
Acquired marrow failure due to decreased proliferation of progenitors in the bone marrow, e.g., aplastic anemia, marrow infiltration
Nutritional deficiency, e.g., vitamin B ₁₂ and folate deficiency
Splenic sequestration

to CXCL12, its natural ligand in the stroma. This results in impaired migration from bone marrow. The identification of mutations in CXCR4 in individuals with WHIM syndrome represents the first example of aberrant chemokine receptor function causing human disease, and suggests that the receptor may be important in cell-mediated immunity to human papillomavirus infection. Infection, epinephrine and steroids all cause release of neutrophils into the periphery and neutrophil survival in infections may be increased resulting from the surge of endogenous cytokines and growth factors, which would explain the relatively benign course of the disease.

Acquired neutropenias

Pathophysiologically, acquired neutropenias may be due to any of the mechanisms alluded to earlier, namely decreased proliferation of the myeloid precursors, ineffective granulopoiesis, increased peripheral destruction, or abnormal tissue distribution. Neutropenia is often the only cytopenia, but there may be a concurrent mild anemia and thrombocytopenia. In the following pages, disorders with dominant or isolated neutropenia are covered, and mention is made of disorders where neutropenia is an important component of pancytopenia (Table 14.11).

Infections

Viral infections

Viral infections are the most common cause of transient neutropenia in childhood. Viruses commonly associated with neutropenia include hepatitis A and B, herpes simplex virus, cytomegalovirus, Epstein–Barr virus (EBV), influenza A and B, measles, mumps, rubella and respiratory syncytial virus. Transient neutropenias develop in the initial 1–2 days of the illness in association with the peak viremic phase, and persist

for 3–7 days. The neutropenia can be severe, but rarely causes serious bacterial infection. The suggested mechanisms include: redistribution of neutrophils from the circulating to the marginating pool; aggregation and sequestration of neutrophils after activation by complement; and destruction of the neutrophils by circulating antibodies.¹⁶⁰ Prolonged neutropenia with or without other cytopenias is known to occur with hepatitis B, EBV, parvovirus B19, Kawasaki disease and HIV infection. Neutropenia is also seen with yellow fever, dengue fever, Colorado tick fever and sandfly fever.

Bacterial infections

Significant neutropenia and other cytopenias are seen in certain bacterial infections, where the bacteria tend to be intracellular pathogens. It is not uncommon with typhoid, paratyphoid, brucellosis and tularemia, which are all characterized by bacteria with a predilection for macrophages. Neutropenia and other cytopenias in tuberculosis are only seen in disseminated/miliary tuberculosis. Rickettsias, which are obligate intracellular Gram-negative organisms, are another important cause of neutropenia. In scrub typhus, epidemic typhus, rickettsial pox and severe cases of Rocky Mountain spotted fever, there is infection of the vascular endothelial cells of the lungs and brain, with secondary neutropenia and other cytopenias as part of a vasculitic process.

Sepsis is one of the most serious causes of neutropenia. The mechanism is due to increased destruction/utilization, impaired production and C5a-mediated sequestration in the pulmonary vasculature. This sequestration can result in the release of toxic mediators and subsequent tissue damage. Neonates are particularly susceptible to sepsis-induced neutropenia as their storage pool is small and the baseline production of granulocytes is often near maximal.

Protozoal infections

Visceral leishmaniasis is commonly associated with neutropenia and pancytopenia. Mechanisms include hypersplenism, antineutrophil antibodies and ineffective hematopoiesis.¹⁶¹ Malaria and trypanosomiasis have been associated with neutropenia. The neutropenia during febrile episodes in malaria is due to margination, although severe disease presents with neutrophilia. Hypersplenism is an important cause of neutropenia in tropical hyperactive malarial splenomegaly.

Drug-induced neutropenia

Drug-induced neutropenia is rare in children, with only 10% of the cases reported in children and young adults.¹⁶² The drugs most commonly implicated are antibiotics (beta-lactam and trimethoprim-sulfamethoxazole), antithyroid drugs, antiplatelet agents, neuroleptic and antiepileptic agents and nonsteroidal antiinflammatory agents.¹⁶³

Mechanisms of idiosyncratic drug reactions

Immune-mediated destruction of granulocytes or their precursors

Hapten- or T-cell-mediated allergic reactions can occur when drugs act as haptens. Most drugs are small molecules with a molecular mass less than 1000 Da, and are not capable of eliciting a direct immune response. They conjugate with another macromolecule or at times directly to MHC molecules. The end result is antibody formation, complement fixation and neutrophil destruction. The antineutrophil antibodies are often identified *in vitro* only in the presence of the drug. Examples of such drugs include penicillin, propylthiouracil, aminopyrine, antithyroid drugs and gold.¹⁶⁴

Drug-induced autoimmunity (e.g., with quinidine, alpha-methyl dopa) involves a drug inducing the formation of antineutrophil antibodies, which bind the neutrophils and cause premature destruction. Most often the antibodies disappear after the drug is withdrawn, but at times they can persist even when the drug is stopped.¹⁶⁵

Dose-dependent inhibition of granulocytic precursors

Dose-dependent inhibition of granulopoiesis has been documented with beta-lactam antibiotics, carbamazepine and valproic acid. Both valproic acid and carbamazepine cause dose-dependent inhibition of the granulocyte-macrophage colony-forming unit (CFU-GM), which is pronounced at high levels and variable at low levels. Valproate, in addition to neutropenia and Pelger-Huët abnormalities, causes a spectrum of hematologic abnormalities, including aplastic anemia, other cytopenias and acquired von Willebrand disease.^{166,167}

Direct toxic effect on marrow progenitors or mature cells

Clozapine accelerates apoptosis of neutrophils due to the generation of a reactive metabolite within the neutrophil. Sulfasalazine is toxic to promyelocytes at therapeutic levels in comparison with lymphocytes. With azathioprine, polymorphism of thiopurine methyltransferase increases the risk of hematologic toxicity.

Clinical presentation and management

Drug-induced neutropenia is associated with a high rate of infectious complications and is reported to have a mortality rate of approximately 10%. In drug-induced neutropenia, most studies have shown that G-CSF shortens the time to neutrophil recovery, although several authors have commented that evidence-based data are lacking to justify its use.^{163,168} Given the rarity and heterogeneity of drug-induced neutropenia, it seems unlikely that an evidence-based algorithm for G-CSF use will ever be validated. However, because drug-induced neutropenia is an acute, life-threatening complication of therapy, the demonstrated safety and apparent

Table 14.12 Human neutrophil antigen (HNA) nomenclature and disease associations.

Antigens	Previous nomenclature	Glycoprotein	Allele frequency (%) in Caucasians	Disease associations
HNA-1a	NA1	FcγIIIb (CD16)	58	NAIN, AIN, TRALI
HNA-1b	NA2	FcγIIIb (CD16)	88	NAIN, AIN, TRALI
HNA-1c	SH, NA3	FcγIIIb (CD16)	5	NAIN, AIN, TRALI
HNA-2a	NB1	CD177 (NB1gp)	97	NAIN, AIN, TRALI and drug-induced neu.
HNA-3a	5b	gp70–95	97	TRALI
HNA-4a	MART	CD11b (CR3)	99	NAIN (1 case)
HNA-5a	OND	CD11a (LFA-1)	96	Not known

CR3, C3bi receptor; LFA-1, leukocyte function antigen 1; gp, glycoprotein; NAIN, neonatal alloimmune neutropenia; AIN, (primary) autoimmune neutropenia; TRALI, transfusion-related acute lung injury.

Modified with permission from Refs 169 and 170.

effectiveness of G-CSF in hastening neutrophil recovery justifies its use in this setting.

Immune neutropenia

Immune neutropenia can be subdivided into neonatal alloimmune neutropenia (NAIN), primary autoimmune neutropenia (AIN) and secondary autoimmune neutropenias. The immune neutropenias are mostly due to accelerated destruction of mature neutrophils.

Granulocyte alloantigens and the human neutrophil antigen system

Antibodies directed against granulocyte membrane antigens cause NAIN and primary AIN. The implicated antigens are highly immunogenic membrane glycoproteins. Alloantibodies to these glycoproteins are responsible for alloimmune neonatal neutropenia, nonfebrile hemolytic transfusion reactions, refractoriness to granulocyte transfusions, post-bone-marrow-transplant immune neutropenia and TRALI. Autoantibodies to the same antigens are responsible for primary and some secondary autoimmune neutropenias, and drug-induced neutropenia.

Currently there are seven well-defined clinically relevant human neutrophil antigens (HNAs), which are assigned to five glycoproteins (Table 14.12).

Granulocyte alloantigens and polymorphisms

In a recent review on platelet and granulocyte glycoprotein polymorphisms, Lucas and Metcalfe have suggested that the granulocyte membrane antigens be divided into three types.¹⁷¹

- granulocyte-specific antigens;
- the “shared” antigens, which often have a limited distribution amongst other cell types, mostly white cells; and

- the “common” antigens, which have wider distribution on other tissue and blood cells, e.g., HLA class I molecules, I and P blood groups, etc.

Granulocyte-specific antigens

HNA-1, localized to FcγRIIIb (CD16), is the most common antigen against which antibodies are detected. The Fc receptors belong to the immunoglobulin superfamily and bind to the constant domain of the antibody molecule, which is specific for each class of immunoglobulin. The most important receptors for microbial opsonization are the Fcγ receptors, which recognize IgG. The Fcγ receptors are of three types, varying in their structure, function and the types of cells they are distributed across. FcγRIII exists in two non-allelic forms, a and b. FcγRIIIb is linked to the plasma membrane via a glycosylphosphatidylinositol (GPI) anchor, has low affinity for IgG and is exclusively expressed on neutrophils. The HNA-1a, -1b and -1c antigens are all located on FcγRIIIb. HNA-1a and -1b show five nucleotide differences at the DNA level; four of these substitutions result in amino acid changes and two of them result in additional glycosylations. The immunogenicity of this receptor may be related to the high concentration of the molecules on the surface of the neutrophil, with 100 000 to 300 000 copies per neutrophil.

HNA-2a antigen is located on the NB1 glycoprotein, which is a glycosyl-phosphatidylinositol-anchored glycoprotein (gp) found on neutrophil membranes and secondary granules. NB1 gp is unusual in that it is expressed on a subpopulation of neutrophils, representing 45–65% of the total. It is encoded by the CD177 gene which has another allele- PRV-1. CD177mRNA levels are increased in polycythemia vera, hence the labelling of the second allele.¹⁷²

Shared antigens

HNA-3a antigen is located on a 70–90-kDa neutrophil

glycoprotein, whose gene is not yet known. HNA-4a and 5a are located on neutrophil β_2 -integrin. It belongs to the integrin superfamily and consists of three members sharing a common β subunit with three different α subunits. HNA-4a is the result of a polymorphism in complement receptor 3 (CR3, CD11b) and HNA-5a is the result of a polymorphism in the leukocyte function antigen 1 (LFA-1, CD11a).

Detection of antineutrophil antibodies

Screening for neutrophil antibodies is technically challenging because of the need for intact neutrophils (which have a short lifespan) as a source of antigen. A panel of donor neutrophils of known phenotype is used, so as to detect all clinically relevant antibodies. The following tests can be done on patient sera.¹⁶⁹

- Granulocyte agglutination test: detects microscopic agglutination of neutrophils.
- Granulocyte immunofluorescence test (GIFT): antigen-antibody reactions are detected by fluorescence-conjugated secondary antibodies using a fluorescent microscope or flow cytometry.
- Monoclonal antibody immobilization of granulocyte antigens (MAIGA): allows detection of antibodies to specific neutrophil membrane glycoproteins, even in the presence of antibodies to HLA antigens.¹⁷³

There are methodologic limitations to the above tests, and often the tests need to be repeated on at least two occasions to increase detection rate and decrease false positivity. The following points should also be noted.

- A minimum of two techniques should be used to detect granulocyte-specific serum antibodies, including one of the two techniques recommended, i.e., the granulocyte agglutination test and the granulocyte immunofluorescence test. The chosen techniques must enable reliable detection of clinically significant alloantibodies, including anti-HNA-1a, -1b, -1c, -2a, and -3a and be able to detect both IgG and IgM isotypes.
- At least two techniques should be available to detect cytotoxic and noncytotoxic antilymphocyte antibodies and thereby aid the distinction between granulocyte-specific antibodies, HLA class I antibodies, granulocyte/lymphocyte/monocyte-reactive antibodies and antibody mixtures.
- Further techniques, usually glycoprotein-specific assays that can be used to detect and identify granulocyte-specific antibodies in the presence of HLA class I or lymphocyte-reactive antibodies, should also be available.

Neonatal alloimmune neutropenia

NAIN is analogous to alloimmune neonatal thrombocytopenia purpura of the newborn. During gestation there is maternal sensitization to paternally derived fetal neutrophil

antigens, resulting in IgG antibodies that cross the placenta and prime the fetal neutrophils for premature destruction.¹⁷⁴ Newborns develop transient neutropenia, the duration of which is related to the clearance of maternal IgG, on average 11 weeks (range 3–28 weeks).¹⁷⁵ Infectious complications include omphalitis, skin infections, pneumonia, urinary infections and septicemia. A few deaths have been reported in some case series. Treatment is supportive and G-CSF has been used with good effect.¹⁷⁶

Alloantibodies to most of the neutrophil antigens have been described in association with NAIN. Anti-HNA-1a and anti-HNA-1b are the most frequent. In a study of unselected pregnant women where HNA-1a and -1b genotypes were done, genotypic fetomaternal incompatibility was seen in 20% of cases. However, only 3% of the mothers with an incompatible child developed antibodies and none of the neonates developed NAIN.¹⁷⁷ These observations are similar to earlier serologic data.^{178,179} The exact incidence is unknown, but a rate of 1 in 6000 has been suggested based on unpublished data.

Primary autoimmune neutropenia

Primary AIN is predominantly a disorder of infancy and early childhood and is the most frequent cause of neutropenia in this age group. A study of 240 children with primary AIN has given a comprehensive picture of the clinical and laboratory features, infectious complications and natural history of the disorder.¹⁸⁰ The key features can be summarized as follows.

- Age: majority of children are under 3 years at diagnosis and two-thirds present between the ages of 5 and 15 months.
- Full blood count (FBC): severe neutropenia is present in two-thirds of cases, and a compensatory monocytosis in one-third.
- Bone marrow: a decreased number of mature neutrophils is the most common finding. Ten percent of the patients can show unusual features like hypocellularity, and maturation arrest at later stages of development. No cases were seen with maturation arrest at the promyelocyte stage.
- Serology: antibodies are often detected on the first occasion, but one-quarter of patients require multiple testing.
- Antibody specificity: IgG or IgM or a combination. The specificity is either HNA-1 or HNA-2 or none, with rarer cases associated with antibodies to CD11b (HNA-5a) or pan-FC γ RIIIb. This is in contrast to secondary AIN, where pan-FC γ RIIIb antibodies are frequently detected. Interestingly the same group in a later study showed the presence of panspecific antibodies earlier in the primary AIN, with specificity to a single antigen developing later on.^{181,182}
- Clinical presentation: mild skin and upper respiratory tract infections predominate. One-tenth of patients can present with severe infections such as pneumonia, meningitis or sepsis. A significant number are asymptomatic.

- In 80% of the patients observed, the neutropenia persisted for 7–24 months. Disappearance of antibodies preceded the normalization of the counts.
- Management: symptomatic treatment with antibiotics is sufficient in most patients. Patients with recurrent infections respond well to antibiotic prophylaxis. The most severe cases require the use of regular G-CSF therapy.

Secondary immune neutropenias

The mechanism of the immune neutropenia is variable. Targeted antigens are both membrane bound and intracellular. Antibody- and T-cell-mediated destruction are important mechanisms. There is evidence of neutrophil dysfunction in a few diseases. The various diseases associated with secondary immune neutropenia will be discussed briefly below.

Evans syndrome is characterized by autoimmune hemolytic anemia with immune thrombocytopenia. Immune neutropenia is not uncommon.¹⁸³

Neutropenia is found in about 50–60% of patients with active *systemic lupus erythematosus* (SLE), at some stage of the disease. The neutropenia is usually mild, and often acts as a marker of disease activity. Clinically, increased susceptibility to infections is a major cause of morbidity and mortality in patients with SLE. The increased risk of infections is, however, most probably related to potent immunosuppression. The pathogenesis can be multifactorial and may include both specific and nonspecific antineutrophil antibodies and direct bone marrow suppression. G-CSF can be useful for treating the neutropenia, but it has been associated with worsening of the underlying lupus.

Felty syndrome is classically described as a triad of rheumatoid arthritis, splenomegaly and neutropenia. Patients have high levels of rheumatoid factor, immune complexes, hypergammaglobulinemia and antinuclear antibodies. Recurrent pyogenic infections contribute to a significant disease mortality. There are two main mechanisms of neutropenia, antibody- and cell-mediated, the latter due to a secondary expansion of cytotoxic T cells not dissimilar to that seen in large granular lymphocytic leukemia.^{143,184} The treatment is that of the underlying disease. G-CSF is effective for the treatment of neutropenia, but should be used with caution as there is increased incidence of leukocytoclastic vasculitis at 6%.

Large granular lymphocytic (LGL) leukemia is a clonal proliferation of cytotoxic T lymphocytes, characterized by neutropenia, anemia and/or thrombocytopenia. It is generally an indolent disorder of the elderly, but has been described in all age groups, including children. Clinical presentation is often with recurrent infections, B symptoms or asymptomatic cytopenia. Splenomegaly is more common than hepatomegaly. Examination of blood films shows the large granular lymphocytes, but diagnosis is usually established by peripheral blood flow cytometry demonstrating the presence of pro-

liferation of T cells with the characteristic immunophenotype of CD3⁺CD4⁻CD8⁺CD16⁺CD57⁺. Clonality is demonstrated by polymerase chain reaction (PCR) for T-cell receptor gene rearrangement.¹⁴³

One-third of patients with LGL leukemia have rheumatoid arthritis and there is association with other autoimmune disorders. Indications for treatment include severe chronic neutropenia, recurrent infections or transfusion-dependent anemia. Effective medications include low-dose methotrexate, ciclosporin, prednisolone and cyclophosphamide. Interestingly, although immunosuppression ameliorates the cytopenias, cytotoxic T lymphocytes continue to be present in the peripheral blood.

Nutritional deficiencies

Neutropenia can be caused by certain nutritional deficiencies or disorders.

- Vitamin B₁₂ and folate deficiency cause anemia and pancytopenia, although isolated neutropenia is uncommon.
- Copper deficiency can present with isolated neutropenia, followed by anemia and occasionally pancytopenia.¹⁸⁵ It was first noted in the context of total parenteral nutrition prior to the introduction of trace element supplementation. Currently it is mainly seen in the context of protein-energy malnutrition.
- Anorexia nervosa is associated with leucopenia, neutropenia and anemia in various combinations. Gelatinous transformation of the bone marrow has been reported in severe cases.¹⁸⁶

Chronic idiopathic neutropenia

The term chronic idiopathic neutropenia (CIN) encompasses an ill-defined group of heterogeneous disorders characterized by persistent unexplained neutropenia. Patients rarely have serious infections. Some cases of CIN appear to be acquired, and certainly a significant proportion of CIN reported in the literature (in particular, benign neutropenia of infancy) most likely were immune in nature. CIN is also often used to describe milder probably inherited cases of neutropenia.

Neutropenia associated with complement activation

The exposure of blood to artificial membranes used in medical procedures, including dialysis, cardiopulmonary bypass, apheresis and extracorporeal membrane oxygenation may result in activation of the classical complement pathway with generation of C3a and C5a.¹⁸⁷ This results in increased neutrophil aggregation and adherence to endothelial surfaces, especially in the lung, with transient neutropenia and occasional cardiopulmonary symptoms.

Investigation of neutropenia

A detailed history and a few investigations tend to identify most common causes of neutropenia. The presence of other system abnormalities often necessitates investigations for rare disorders. The initial FBC will dictate further investigations by documenting either isolated neutropenia or pancytopenia. In relatively well children only a FBC, film and antineutrophil antibody screen are required at the first consultation. The following schema may be helpful.

History

- Detailed evaluation of the infection history; including the type, severity and frequency and duration of each episode.
- Age of onset of neutropenia.
- History of recent infections, medication use.
- Family history of infections.
- Any documented normal counts in the past.

Examination

- Stigmata of chronic neutropenia, in particular gingivitis.
- Congenital abnormalities.
- Hepatosplenomegaly.

Investigations

- Document severe chronic neutropenia, $ANC < 0.5 \times 10^9/L$, ideally tested at least thrice within 3 months.
- Antineutrophil antibodies to exclude primary AIN.
- If there is periodicity of infections, especially mouth, consider FBC over 6 weeks, thrice weekly, to attempt to define a 21-day oscillation (cyclic neutropenia).
- If there is a history of severe infections consider: bone marrow aspirate, serum immunoglobulins, basic lymphocyte panel; maturation arrest at the promyelocyte stage.
- History and physical examination to exclude other system involvement: no metabolic abnormalities indicates Kostmann syndrome; fatty stools, failure to thrive, abnormal pancreatic function indicate Shwachman–Diamond syndrome; hypoglycemia, hepatomegaly and glucose 6-phosphate translocase defect indicate GSDIb.

Neutrophilia

Neutrophilia is defined as an increase in the absolute neutrophil count to a level greater than two standard deviations above the mean value for normal individuals. Neutrophilia is most often secondary to an appropriate stimulus and may occur by several mechanisms.

- Demargination: a shift of neutrophils from the marginating pool to the circulating pool, which usually takes a few minutes.

- Mobilization: a shift from the marrow storage pool to the circulation, which takes a few hours.
- Increased proliferation: a maximum response can take up to a week.
- Increased survival.

The etiologic classification of neutrophilia is shown in Table 14.13.^{120,188}

Eosinophils

Structure

The eosinophil is recognized by characteristic intracytoplasmic granules, the secondary or specific granules, which appear bright red by light microscopy, due to their high affinity for eosin, a negatively charged dye. The mature eosinophil is slightly larger than the neutrophil, with a diameter of 12–17 μm , and the nucleus is characteristically bilobed. The specific granules contain the basic proteins (MBP, major basic protein; ECP, eosinophil cationic protein; EDN, eosinophil-derived neurotoxin; EPO, eosinophil peroxidase), which are potent cytotoxic proteins.

Function

The eosinophil contains a potent array of proinflammatory mediators with considerable potential to initiate and sustain an inflammatory response. Eosinophils are believed to have a pathologic or physiologic role in helminth infections, allergic inflammation and tissue repair.¹⁸⁹

Normal range, eosinopenia and eosinophilia

The normal eosinophil count varies with age, time of the day, exercise status, and environmental stimuli, particularly allergen exposure. The normal count is taken as $< 0.4 \times 10^9/L$, although a range of $0.015\text{--}0.65 \times 10^9/L$ has been suggested, based on a study in medical students. Division of eosinophil counts is arbitrary, but a mild eosinophilia is regarded as $< 1.5 \times 10^9/L$, a moderate elevation is $1.5\text{--}5.0 \times 10^9/L$, and severe eosinophilia is $> 5.0 \times 10^9/L$. Allergic diseases generally cause a mild to moderate eosinophilia, but infection with helminths can often result in very high eosinophil count.

Eosinopenia

The causes of isolated eosinopenia are limited. In a hospital-based study, when patients with abnormal white cell counts, hematologic disorders or requiring chemotherapy were excluded, isolated eosinopenia was uncommon at 0.1% and was associated with the use of corticosteroids or severe organic disease.¹⁹⁰

Table 14.13 Etiologic classification of neutrophilia.*Physiologic neutrophilia*

Mediated by epinephrine and other catecholamines; due to demargination
 Associated with monocytosis and lymphocytosis
 Acute physical stress, including vigorous exercise, convulsions, labor, surgery, anesthesia and blood loss
 Acute emotional stimuli, like panic, rage
 Acute hypoxia, acute hemorrhage

Glucocorticosteroids

Mechanism is via decreased egress into the tissues
 Over prolonged periods it is associated with lymphopenia and monocytopenia

Infections

Neutrophilia occurs with most acute bacterial infections, localized or systemic. It is seen less predictably with other infections, when neutrophilia is probably due to tissue damage caused either by the organism or a toxin produced by it
 Neutrophilia is common in Gram-positive infections, but in Gram-negative infections there may be an initial neutropenia caused by the endotoxin, followed by extreme neutrophilia due to the various cytokines, chemokines and complement components

Tissue damage (e.g., inflammation/infarction)

Burns, electric shock, trauma, surgery
 Hepatic necrosis, pancreatitis, myocardial infarction, pulmonary embolism
 Connective tissue disorders including rheumatoid arthritis, gout, vasculitis, antigen–antibody complexes, complement activation, Still disease
 Most acute inflammatory reactions, such as colitis, dermatitis, drug sensitivity reactions, Sweet syndrome

Drugs

Epinephrine
 Glucocorticosteroids
 Lithium

Tumors

Large tumor burden or secretion of colony-stimulating factors

Endocrine and metabolic emergencies

Eclampsia, diabetic ketoacidosis, Cushing syndrome, thyrotoxic crisis

Inherited neutrophilias

Familial cold urticaria, presents with fever, urticaria, and a rash characterized histologically by a neutrophil infiltrate, occurring 7 hours after exposure
 Leukocyte adhesion deficiencies

Hematologic disorders

Chronic hemolysis and bleeding
 Sickle cell crisis
 Asplenia

Myeloproliferative disorders

Clonal hematopoietic stem cell disorders characterized by proliferation in the bone marrow of one or more of the myeloid lineages
 Proliferation is associated with relatively normal maturation that is effective, resulting in increased numbers of granulocytes and/or red cells and platelets

Acute bacterial or viral infections characteristically produce eosinopenia persisting for the duration of the fever, with the exception of scarlet fever where eosinophilia is common. This can be helpful in the differential diagnosis of rashes where drug-induced rashes are often associated with eosinophilia, but not viral exanthemas.¹⁹¹

Eosinophilia

The various causes of peripheral blood eosinophilia are summarized in Table 14.14.

Basophils**Structure, development and function**

The normal mature basophil is 10–15 µm in diameter, has a central nucleus with two to three lobes and characteristic granules, which are large, coarse, purplish-black, usually filling the cytoplasm and often obscuring the nucleus. The primary granules are formed early in the development and contain large amounts of histamine and heparin, features that are responsible for the affinity of the granules for basic dyes.¹¹⁷ Both basophils are a key component of allergic inflammation polycythaemia vera, essential thrombocythosis, chronic idiopathic myelofibrosis.

Basopenia and basophilia¹⁹³

Basophils are so infrequent in normal blood that their reduction is not likely to be noticed on inspection of blood films. In theory basopenia can be detected by automated counters since their reference ranges for basophils are 0.02–0.12 × 10⁹/L. However, in practice, automated basophil counts are not very accurate and the observation of basopenia has not been found to be of great diagnostic significance.

Basophilia is commonly associated with type I hypersensitivity reactions mediated by IgE, for example drug, food and inhalant hypersensitivity, and urticaria. The inflammatory disorders ulcerative colitis and juvenile rheumatoid arthritis show an increase in basophil count in contrast to most other inflammatory disorders. Important causes of significant basophilia are clonal disorders of hematopoiesis, including CML. Basophilia is almost always present in CML and at times it can represent 20–90% of all white cells.

Monocytes**Structure, development and function**

The mononuclear phagocyte system is composed of bone marrow monoblasts and promonocytes, blood monocytes

Table 14.14 Causes of peripheral blood eosinophilia.*Allergic diseases*

Atopic disorders: eczema and allergic asthma show a variable eosinophilia and are the commonest causes in general pediatric practice

Drug-induced eosinophilia: drugs commonly involved are semisynthetic penicillins, nonsteroidal antiinflammatory agents and tetracyclines

Infectious disease

Helminth parasites, including nematodes, trematodes, and cestodes.

Outside the Western world, invasive parasitic infections are the commonest cause of eosinophilia. The degree of eosinophilia seen is related to the magnitude and extent of tissue invasion by the parasite, but lack of eosinophilia does not exclude helminth infection. Helminths commonly involved in developed countries include ascarids, hookworms, trichinosis, visceral larva migrans and strongyloidiasis

Protozoan parasites, including *Giardia lamblia* and *Entamoeba histolytica*, do not characteristically elicit blood eosinophilia, with the exception of *Dientamoeba fragilis* and *Isospora belli*

Immunologic

Primary immunodeficiency: hyper-IgE syndrome, IgA deficiency, Wiskott–Aldrich syndrome

Rejection of transplanted kidneys, lungs or liver is associated with blood and tissue eosinophilia

Pulmonary diseases

Sarcoidosis.

Pulmonary eosinophilias¹⁹² are group of disorders characterized by lung shadows radiologically and blood eosinophilia

Gastrointestinal diseases

Eosinophilic gastroenteritis

Rheumatologic diseases

Occasionally, eosinophilia accompanies dermatomyositis, severe rheumatoid arthritis, progressive systemic sclerosis or Sjögren syndrome

Miscellaneous diseases

Adrenal insufficiency
Atheroembolic disease

Neoplastic disorders with secondary eosinophilia

T-cell lymphomas

Hodgkin lymphoma

Acute lymphoblastic leukemia/lymphoma

Mastocytosis

Nonhematologic malignant diseases including breast, renal, lung tumors; female genital tract neoplasms; vascular tumors

Neoplastic disorders in which eosinophilia is part of a clone

Chronic myeloid leukemia

Acute myeloid leukemia

Myelodysplastic syndromes

Other myeloproliferative disorders including both basophils and eosinophils
PV, ET, and CIMF

Clonal proliferations

Eosinophilic leukemia

Hypereosinophilic syndrome

and tissue macrophages. Phylogenetically it is a primitive system with a wide range of functions. Important functions include antimicrobial activity, participation in the inflammatory response, antitumor activity, processing and presenting antigens to T and B cells in adaptive immunity, regulating function of other cells, and removal of dead, senescent, foreign, or altered cells and particles.

The monocytes in peripheral blood are 10–11 μm in diameter, with a variable shape. The nucleus is large, centrally placed, oval or indented, with delicate nuclear chromatin and inconspicuous nucleoli. The cytoplasm is abundant, gray or grayish blue in color, with fine azurophilic granules and small vacuoles.

Monocytopenia and monocytosis^{120,194}

The mean monocyte count in adults is $0.4 \times 10^9/\text{L}$. The counts are higher in neonates, with an average count of $1.0 \times 10^9/\text{L}$. Because the monocyte is involved in many pathophysiologic processes, a modest elevation can occur in many disparate conditions.

Monocytopenia

This is commonly seen as part of marrow failure, especially in aplastic anemia. Other important causes include glucocorticosteroids, HIV and autoimmune disease.

Monocytosis

The causes of monocytosis are summarized in Table 14.15.

8. Harlan JM. Leukocyte adhesion deficiency syndrome: insights

Table 14.15 Causes of monocytosis.**Reactive**

Collagen vascular disease

- Systemic lupus erythematosus
- Rheumatoid arthritis
- Myositis
- Systemic vasculitis

Gastrointestinal disease

- Ulcerative colitis
- Crohn disease
- Alcoholic liver disease
- Sprue

Infections

- Acute bacterial infections on occasion
- Subacute bacterial endocarditis, syphilis
- Viruses, typically cytomegalovirus and varicella zoster virus

Nonhematologic malignancies and lymphomas

Miscellaneous

- Postsplenectomy state
- Chronic neutropenia causes compensatory monocytosis
- Hemolytic anemia and idiopathic thrombocytopenia

Clonal hematologic disorders

Acute myeloid leukemia, M4 and M5

Chronic myelomonocytic leukemia

Juvenile myelomonocytic leukemia

Histiocytic disorders

Amir H. Shahlaee and Robert J. Arceci

Introduction

The histiocytoses are a diverse group of hematologic disorders defined by the pathologic infiltration of normal tissues by cells of the mononuclear phagocyte system (MPS). The heterogeneity of this family of disorders, a direct result of the biologic variability of the cells of the MPS and the tissues they inhabit, makes the study of these diseases one of the most intriguing yet complex areas of modern hematology.

Advances in basic hematology and immunology over the last two decades have significantly enhanced our understanding of the histiocytic disorders. It is now accepted that the pathogenic cells central to the development of the histiocytoses arise from a common hematopoietic progenitor. More specifically, the ability to molecularly identify the hematopoietic cells has enabled us to classify the histiocytoses based on the cellular basis of the disease and to define the natural history of these disorders.^{1,2} These pathologic cells phenotypically resemble immature mononuclear phagocytes at specific stages of differentiation.⁷⁷

The Histiocyte Society, formed in 1985, has served as a forum for enhanced collaboration between international histiocytosis experts. Since its inception, the Histiocyte Society has used the cellular based classification of the histiocytoses as a guideline for therapeutic studies, which have in turn significantly advanced our ability to care for patients, improve their outcomes and advance the scientific understanding of the histiocytoses. In this chapter we use the cellular classification of histiocytic disorders, as adopted by the Histiocyte Society, to present each subgroup of this family of disorders, describe their natural history and present current therapeutic approaches and outcomes.

Histiocytes and normal immune function

The MPS is a system of cells whose primary function consists

of phagocytosis of foreign material, antigen processing, and antigen presentation to lymphocytes. This system, recognized in part through the work of Metchnikoff, was originally termed the reticuloendothelial system by Ludwig Aschoff in the early part of the twentieth century.^{3,4} The central cell of this system, the mononuclear phagocyte or histiocyte, represents a group of anatomically and functionally distinct cells arising from a common precursor, the hematopoietic stem cell.

Cells of the MPS have a wide range of morphologic, anatomic and functional characteristics that make classification of this system difficult. Our ability to identify and classify the cells of the MPS has advanced in parallel with developments in basic hematology and immunology. As our knowledge of the molecular biology regulating hematopoiesis has improved, we have been able to identify specific characteristics that have enabled us to classify the cells of the MPS. Mononuclear phagocytes can be divided into two major classes, macrophages and dendritic cells. This classification is based on (i) phagocytic and antigen-presenting abilities, (ii) morphologic and ultrastructural appearance, (iii) expression of common enzymes, (iv) presence of common cell surface antigens, and (v) common regulatory cytokine and transcription factor networks.

Tissue macrophages are derived from bone marrow hematopoietic precursors and can arise directly from circulating peripheral blood monocytes. These cells enter different tissues and assume tissue-appropriate morphology based on the local cytokine milieu. Once established in various tissues, macrophages typically do not have the ability to self-renew extensively except possibly under specialized microenvironments such as in the lungs and pituitary. Tissue inflammation increases the influx of monocytes, which in turn give rise to macrophages with an immunologically activated phenotype. Inflammatory stimuli can also further enhance the local replication of macrophages in cases of tissue injury.^{5,6} Regardless of location, macrophage growth and differentiation is a tightly controlled process regulated by specific growth factors.

Interleukin (IL)-3, IL-4, IL-13, granulocyte-macrophage colony-stimulating factor (GM-CSF) and macrophage colony-stimulating factor (M-CSF) are all stimulatory cytokines with a major role in macrophage development and differentiation.⁶ M-CSF activity is especially essential for appropriate macrophage growth and differentiation. The M-CSF receptor, a product of the *c-fms* protooncogene, is expressed by most members of the MPS. When bound by M-CSF this receptor dimerizes, leading to the activation of its kinase domain and initiation of downstream signaling pathways. The signaling cascade initiated by the binding of M-CSF to its receptor is essential for the proliferation of progenitor cells of the monocyte-macrophage lineage, differentiation and their long-term survival. Information regarding the role of M-CSF primarily arises from studies of *op/op* knockout mice, which are deficient in the M-CSF receptor.⁷ Despite their severe monocyte-macrophage deficiencies, *op/op* mice maintain normal levels of dendritic cells in their spleens and skin, thus demonstrating an alternative and M-CSF-independent pathway for their development.^{8,9} The GM-CSF receptor, also present on most members of the MPS, plays a critical role in normal cellular homeostasis, differentiation and function.⁸ There is also a positive survival effect of stem cell factor (the ligand for the c-KIT receptor) and FLT3 ligand and its cognate receptor FLT3, as well as inhibitory roles for interferon (IFN)- α/β , transforming growth factor (TGF)- β and leukocyte inhibitory factor as critical determinants in macrophage development.⁶ The phenotypic and functional heterogeneity of macrophages as a group is attributed to the tissue-specific effects of cytokine stimulation on the multipotent monocyte. Pathologic changes in this cytokine milieu play important roles in the pathogenesis of the histiocytoses.^{10,14}

Macrophages are ubiquitously distributed in the body and are heavily represented in mucosal tissues and other potential portals of entry for microorganisms, where they function in both innate and adaptive immunity. They have the capacity to phagocytose foreign organisms and release inflammatory cytokines that in turn recruit other inflammation-associated cell types. Macrophages also maintain the ability to process and present antigenic portions of foreign organisms to T lymphocytes, although not as effectively as dendritic cells. Tissue macrophages have significant functional variability depending on their location within the body. Peritoneal and soft tissue macrophages, Kupffer cells, foam cells, synovial cells, osteoclasts and microglial cells are all members of this class of cells and contribute to tissue growth, repair and remodeling. A distinguishing feature of macrophages is expression of the enzymes lysozyme, α_1 -antitrypsin, α_1 -antichymotrypsin, aminopeptidase, peroxidase, alkaline phosphatase, α -naphthol-chloroacetate esterase and β -glucuronidase.

The second class of mononuclear phagocytes, the dendritic cells, was first described by Steinman and Cohn in 1973. These cells were named because of their unique membranous, and

often branch-like, cytoplasmic aberrations (from the Greek word for tree, *δενδρεον*).¹⁵ Dendritic cells are primarily located in skin, mucosa, bone marrow, spleen, thymus and lymph nodes. This group of cells also includes dendritic cells of the lymphoid follicle, the interdigitating dendritic cells of the paracortical regions of lymph nodes, and Langerhans cells of the skin and other organs. Langerhans cells, originally identified by Paul Langerhans in the late 1800s, are mononuclear cells with little cytoplasmic vacuolization and a folded or indented nucleus. Electron microscopic observation of Langerhans cells reveals the presence of Birbeck granules, a distinguishing characteristic of these cells. Birbeck granules, or X bodies, are rod-shaped, pentalaminar, cytoplasmic inclusions, typically ending in a vesicular structure that arise as a result of receptor-mediated endocytosis and are involved in antigen processing.¹⁶

In contrast to macrophages, dendritic cells are less phagocytic but play a central role in initiating primary T-lymphocyte antigen responses. The hallmark of dendritic cells is their conversion from immature, peripherally located sentinels capable of antigen capture and processing to mature immunostimulatory cells, a process called *maturation*. This specific characteristic of dendritic cells, in combination with their ability to migrate, provides a physical and functional link between peripheral tissues and secondary lymphoid organs where lymphocyte maturation takes place.¹⁷ Langerhans cells and the interdigitating dendritic cells present antigens to stimulate primary T-lymphocyte responses. It is well established that the precursor to most dendritic cells is bone marrow derived but the biologic significance of this differentiation schema is still not completely defined as a significant amount of the data has been derived from *in vitro* studies.¹⁶ Other distinguishing characteristics of mature dendritic cells include (i) high expression levels of class II major histocompatibility complex (MHC) antigens and costimulatory receptors, making them potent at antigen presentation, (ii) adenosine triphosphatase and α -mannosidase expression and (iii) distinct paranuclear and cell surface-staining pattern with peanut agglutinin that contrasts with the diffuse staining pattern demonstrated by macrophages.^{16,18}

The development of methods to generate monoclonal antibodies in the 1970s and 1980s significantly enhanced our knowledge of the MPS. The F4/80 antibody, a murine pan-macrophage antibody, was one of the first well-recognized markers of the MPS. This antibody recognizes members of a gene family that includes the human epidermal growth factor (EGF) module-containing mucin-like hormone receptor 1 and CD97. The presence of this antigen on the surface of tissue macrophages and dendritic cells helped confirm the existence of a common origin for the diverse lineages that comprises the MPS. Other markers such as S-100 β subunit, CD1a and Langerin, are found on Langerhans cells but are usually absent on macrophages are used clinically to distinguish

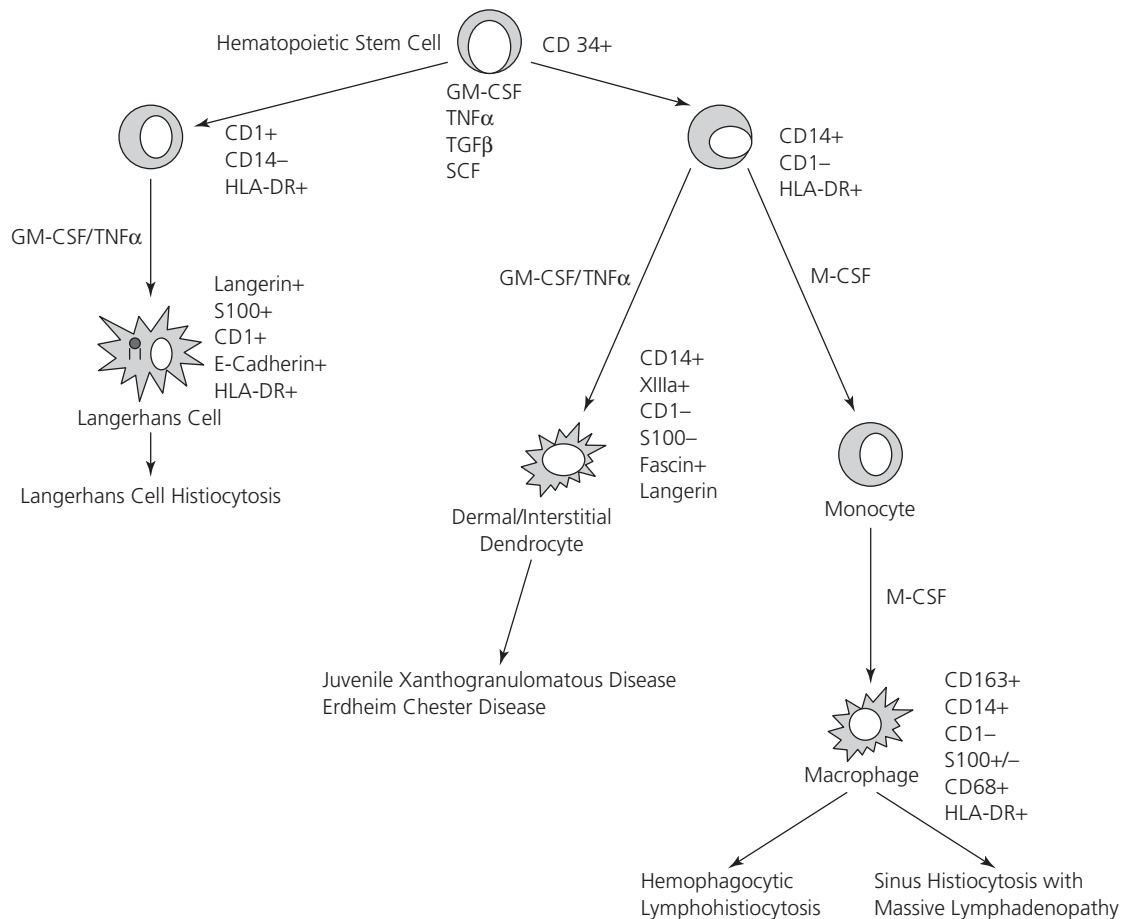

Fig. 15.1 Possible lineage relationships of hematopoietic cells and cells of the mononuclear phagocyte system along with the histiocytic disorders that arise from them. GM-CSF, granulocyte–macrophage colony-stimulating factor; M-CSF, macrophage colony-stimulating factor; SCF, stem cell factor; TGF, transforming growth factor; TNF, tumor necrosis factor. Adapted with permission from Ref. 3.

between the cells of the MPS. Conversely, monocytes and macrophages express nonspecific carcinoembryonic cross-reacting antigen, CD4 antigen, nonspecific esterase and the cell surface marker CD11c (Leu-M5). Both types of cells express class II MHC molecules and T-lymphocyte costimulatory receptors. These markers, in particular S100, CD1a and Langerin are utilized clinically to distinguish between the different histiocytic syndromes. Figure 15.1 denotes the lineage relationships thought to define the differentiation of cells of the MPS and the developmental stages from which various histiocytic disorders are believed to arise.

The development and differentiation of the cells of the MPS, much like other hematopoietic lineages, is driven by a tightly regulated pattern of gene expression governed by distinctive sets of transcription factors that control cell proliferation and differentiation. The main transcription factor families implicated in the development of this system include the *myb* family, the *Ets* family and the C/EBP family. PU.1, a member of the *Ets* family, plays a central role in monocyte–macrophage lineage as demonstrated by PU.1 knockout mice which lack functional monocytes and tissue

macrophages and display significant dendritic cell abnormalities.^{19,21} This has become clearer recently as it has been shown that PU.1 regulates the expression of *c-fms*, the gene coding for the M-CSF receptor, in addition to other critical genes such as FcγRI, FcγRIIIA, scavenger receptors type 1 and 2, CD11b, CD18 and CD14.²¹

In summary, the MPS represents a continuum of functionally distinct cell types that arise from common bone marrow progenitors and differentiate along specific lineage pathways based on environmental stimuli and intrinsically regulated gene expression patterns. The result is the generation of a diverse group of cell types with distinct but often overlapping biologic functions. Understanding this biologic heterogeneity is an important key to more accurate diagnosis and treatment of the histiocytic disorders.

Modern classification of histiocytic disorders

As proposed in 1987,¹ the histiocytic disorders can be

classified into three classes based on the pathologic cells present within the lesions.

- Class I: Langerhans cell histiocytoses and other dendritic cell disorders.
- Class II: non-Langerhans cell histiocytoses primarily consisting of hemophagocytic lymphohistiocytosis.
- Class III: malignant histiocytosis.

This system was revised in 1997 by the World Health Organization's Committee on Histiocytic/Reticulum Cell Proliferations and the Reclassification Working Group of the Histiocyte Society. The central theme of this reclassification schema consisted of distinguishing the clearly malignant histiocytoses from the remaining subtypes, the so-called "disorders of varied biological behavior". Acute myelomonocytic leukemia (FAB M4), acute monocytic leukemia (FAB M5), chronic myelomonocytic leukemia and the histiocytic sarcomas are all classified in the malignant histiocytoses category. The disorders of varied biological behavior continued to be divided into dendritic cell-related disorders (class I) and macrophage-related disorders (class II). The dendritic cell-related disorders include Langerhans cell histiocytosis, the most common type in this class, in addition to other less common subtypes. Primary and secondary hemophagocytic lymphohistiocytosis, in addition to sinus histiocytosis with massive lymphadenopathy (also known as Rosai–Dorfman disease), are the two major types of macrophage-related histiocytosis discussed in this chapter. This classification schema is summarized in Table 15.1.² The remainder of this chapter focuses on the pathophysiology, clinical presentation, treatment and outcomes of the principal histiocytoses.

Disorders of varied biological behavior: dendritic cell-related (class I) histiocytoses

Langerhans cell histiocytosis

Biology

Langerhans cell histiocytosis (LCH) is the most common member of the dendritic cell-related histiocytic disorders. LCH includes the previously identified disorders known as eosinophilic granuloma, Abt–Letterer–Siwe disease and Hand–Schüller–Christian disease. The pathologic similarity of these disorders was first noted by Sidney Farber in 1941 and by the 1950s, as a result of the work of Lichtenstein, these disorders were collectively referred to as histiocytosis X.¹⁶ The persistent use of this historical terminology in modern medical vernacular is indicative of its significance and utility for cataloging patient symptomatology. Regardless of the historical eponyms, the pathologic hallmark of all subtypes of LCH is the abnormal proliferation and accumulation of immature Langerhans cells along with macrophages, lymphocytes and eosinophils that together form granuloma-

Table 15.1 Classification of histiocytic disorders.

<i>Class I: dendritic cell histiocytoses</i>
Langerhans cell histiocytosis
Secondary dendritic cell processes
Juvenile xanthogranuloma and related disorders
Erdheim–Chester disease
Solitary histiocytomas of various dendritic cell phenotypes
<i>Class II: nondendritic cell histiocytoses</i>
Primary hemophagocytic lymphohistiocytosis
Familial hemophagocytic lymphohistiocytosis
Secondary hemophagocytic lymphohistiocytosis
Infection associated
Malignancy associated
Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy)
Solitary histiocytoma with macrophage phenotype
<i>Class III: malignant histiocytoses</i>
Monocyte related
Leukemias (FAB and revised FAB classification)
Monocytic leukemia M5A and M5B
Acute myelomonocytic leukemias M4
Chronic myelomonocytic leukemias
Extramedullary monocytic tumor or sarcoma
Dendritic cell-related histiocytic sarcoma
Macrophage-related histiocytic sarcoma

FAB, French–American–British.

tous lesions. Although the biologic role of LCH cells in the pathogenesis of LCH remains unclear, it is now generally accepted that the close physical interaction between these cells and other cell types present in these lesions is associated with an abnormal cytokine and chemokine microenvironment that underlies the pathogenesis of LCH.

In 1973 Nezelof *et al.*²² provided definitive evidence for the phenotypic similarity of normal Langerhans cells and LCH cells, including a description of the presence of Birbeck granules in both cell types. However, LCH cells, in contrast to normal Langerhans cells, typically lack dendritic cell extensions and have a rounded appearance with distinct cellular margins. These cells express CD1a, S100 and Langerin (CD207) but not the typical markers of more mature dendritic cells such as CD83, CD86 and DC-Lamp (Fig. 15.2). In addition, these cells express CD40 and intracellular MHC class II proteins but are inefficient antigen-presenting cells. When LCH cells are exposed *in vitro* to CD40L they acquire markers of dendritic cell maturation.²³ LCH cells also express CCR6, the receptor for the proinflammatory chemokine CCL20/MIP3 α , a characteristic of immature dendritic cells. Furthermore, these cells have been shown to also secrete CCL20/MIP3 α , CCL5/RANTES and CXCL11/I-TAC, all of which are believed to function in recruiting additional LCH cells, eosinophils and T cells to LCH lesions.¹² Of note, the co-expression of CCR6 and CCR7 on LCH cells has also been reported. This may be suggestive of the pathological

Fig. 15.2 Langerhans cell histiocytosis. Histology and immunohistochemical staining of a bone lesion (eosinophilic granuloma) characterized by (a, b) sheets of large pale Langerhans cells, many of which have prominent nuclear indentations or grooves, interspersed with large numbers of bilobed eosinophils (hematoxylin and eosin staining) (original magnification: a, $\times 200$; b $\times 400$). Langerhans cells strongly express CD1a (c, original magnification $\times 400$) and S100 protein (d, original magnification $\times 400$). Photographs courtesy of Dr John Reith, Department of Pathology, University of Florida School of Medicine, Gainesville, FL, USA.

maturation arrest of these cells.¹⁴ Immunohistochemical and *in situ* hybridization data also demonstrate abnormal release of specific cytokines, such as GM-CSF, IL-10, TGF- α/β , IFN- γ and tumor necrosis factor (TNF)- α , by lesional cells in LCH.^{13,24,25} The cytokine abnormalities noted in LCH lesions are hypothesized to magnify the local autocrine and paracrine effects of these cells, resulting in a focal “cytokine storm”. These cytokines also cause local tissue damage and contribute to the systemic symptoms such as fever, skin rashes and hypotension.^{16,24} Unlike hemophagocytic lymphohistiocytosis, there is no clear-cut evidence for systemic cytokine overproduction in most cases of LCH.

Despite our improved understanding of the molecular events involved in the pathophysiology of LCH, its etiology remains undetermined. Infectious, inflammatory and neoplastic mechanisms have all been postulated to play an etiologic role in LCH, but the relative contribution of each process to the development of the disease remains controversial.^{10,11,16,26–28} The human androgen receptor DNA assay and analyses of T-cell receptor gene rearrangements for detecting clonality have demonstrated the clonal nature of LCH cells but not lymphocytes in lesions, a finding consistent with a neoplastic origin for LCH.^{29,30} This is further supported by analyses of LCH lesions using comparative genomic hybridization and loss of heterozygosity, which reveal multiple chromosomal abnormalities.^{31,32} Clinical evidence of familial cases, in addition to the increased risk of malignancy seen in patients with histiocytosis, further supports a neoplastic origin for some forms of LCH.^{33,34}

However, this conclusion is tempered by several lines of evidence suggesting an inflammatory contribution to the

etiology of LCH. *In vitro* studies have demonstrated an inability to grow LCH cells in culture or in immunodeficient mice, characteristics typically observed with aggressive malignancies. Studies of isolated pulmonary LCH show no consistent or uniform evidence of clonality. Immunohistochemical evidence for human herpesvirus-6 in bone lesions, in addition to differences in HLA types among patients with single-system versus multisystem LCH, might be considered suggestive of a potential inflammatory etiology for LCH, although these data remain controversial due to methodologic issues and inconsistencies.^{32,35,36} Implications of the variable expression pattern of MDM2, p53 and p21 and the strong expression of TGF- β seen in LCH remain unclear.^{11,37} Based on this data, most experts now agree that LCH is the result of complex interactions between environmental factors and intrinsic genetic changes leading to a clonal proliferative disorder of immature Langerhans cells with variable clinical behavior.^{10,11,16,26–28,38,39} Although the pathologic findings may not be clearly different among cases of LCH, the clinical variability strongly suggests different biology and thus a possible continuum from the least to the most aggressive forms of the disease.

Incidence and epidemiology

LCH has been historically considered a disease of young children, with a peak occurrence between the ages of 1 and 3 years. A Danish study estimated the incidence of LCH in children less than 15 years old to be 0.54 per 100 000 children per year. However, this is considered to be an underestimation as a proportion of children are believed to go undiagnosed. A Swedish study has estimated an incidence of

around 0.9 per 100 000.^{40,41} LCH also shows a predilection for males, with a female to male ratio of 1 : 1.2–2.1.^{16,41} It is also now well recognized that the incidence of LCH in adulthood is likely to be underestimated. This has been attributed to the multiple subspecialties involved in the care of patients with this disease depending on the involved organ system in addition to incorrect diagnoses.⁴¹ This problem is now being addressed by the Histiocyte Society as more emphasis is being placed on studies of adult subjects, including the most recent adult therapeutic study, LCH A-1.

A case–control epidemiologic study has suggested associations between the diagnosis of LCH and maternal urinary tract infections as well as feeding problems, medication use and blood transfusions during the first 6 months of life.⁴² A subsequent study has demonstrated a significant odds ratio for postnatal infections, diarrhea and vomiting, as well as medication use in multisystem LCH, while single-system LCH was associated with thyroid disease or a family history of thyroid disease.⁴³ The results of these studies are for the most part inconclusive with regard to any etiologic associations. However, it has to be pointed out that none of the studies performed has noted a geographical or seasonal clustering of cases of LCH, making a common infectious etiology unlikely.

Clinical presentation and therapy

LCH represents a wide variety of different clinical entities recognized to be pathologically the same. LCH is clinically subclassified by the degree and location of organ involvement: localized single-system disease, multifocal single-system disease and multisystem disease. The location of involvement has been shown to be of prognostic importance, with bone marrow, pulmonary, spleen and liver involvement denoted as “risk organs” while involvement of cranial bones or spine with extradural soft tissue extension is considered to be “central nervous system (CNS) risk”.^{44,45} This clinical classification schema currently serves as the basis for risk stratification of LCH treatment protocols.

At the time of diagnosis, a complete work-up should be performed to establish the full extent of disease and delineate risk-based therapy (Table 15.2). The work-up should include

detailed history and physical examination, complete blood count and differential, metabolic panel including liver and renal function tests, bone scan, skeletal survey and chest radiograph. Urine analysis should also be performed to assess for diabetes insipidus and possible hypothalamic–pituitary involvement. Additional studies such as water deprivation test, antidiuretic hormone levels or other endocrinologic examinations evaluating hypothalamic–pituitary function may be necessary depending on a patient’s clinical presentation. Magnetic resonance imaging (MRI) of the brain with gadolinium contrast is becoming a more common part of the staging work-up of “CNS-risk” patients because of the recognition of significant CNS involvement. Bone marrow studies, computed tomography (CT) of the chest and pulmonary function tests should also be performed as clinically indicated to evaluate risk-organ involvement. The role of positron emission tomography remains undefined, but is a potentially promising imaging approach.⁴⁶

Localized LCH involving skin, lymph node or skeleton usually carries a good prognosis. Lesions of bone, a condition often referred to as eosinophilic granuloma, usually present as a painful swelling. These lesions appear radiographically as “punched-out” sites and most commonly affect the calvarium (Fig. 15.3), although they can involve any part of the skeleton. Vertebra plana, or a collapsed vertebra, is a common presentation of this disease process (Fig. 15.4). Single bone lesions rarely need therapy beyond biopsy or curettage, except in the case of severe symptoms or danger of organ dysfunction, such as spinal cord compression or loss of vision. Treatment options for these patients with nonemergency single bone lesions that recur or remain clinically problematic after surgery include nonsteroidal antiinflammatory agents or local steroid injections and, rarely, local low-dose radiation therapy (40–80 cGy). Full surgical resection (i.e., performing a “cancer operation”) of these single bone lesions, especially when other vital structures could be compromised as a result of such an operation, is not typically necessary.

Skin disease typically involves the scalp, retroauricular area, neck, upper chest, axilla and groin. This rash can vary from maculopapular to more eruptive and even nodular in appearance (Fig. 15.5). In some patients, the rash can be quite erosive and a risk factor for serious superinfection. Therapy

Table 15.2 Risk groups as defined by the LCH-III protocol (adapted from the Histiocyte Society LCH-III study).

Group 1: multisystem “risk” patients

Multisystem patients with involvement of one or more “risk” organs (i.e., hematopoietic system, liver, spleen or lungs)

Group 2: multisystem “low-risk” patients

Multisystem patients with multiple organs involved but without involvement of “risk” organs

Group 3: single-system “multifocal bone disease” and localized “special site” involvement

Patients with multifocal bone disease (i.e., lesions in two or more different bones)

Patients with localized special site involvement, such as “CNS-risk” lesions with intracranial soft tissue extension or vertebral lesions with intraspinal soft tissue extension

Fig. 15.3 Radiograph of skull of a patient with Langerhans cell histiocytosis showing multiple lytic lesions (white arrows).

for isolated skin disease typically involves topical steroids or, in some steroid-refractory cases, topical nitrogen mustard, PUVA or short-wave ultraviolet light without psoralen. Systemic steroids and vinblastine are reserved for extensive single-system disease, including skin involvement, usually with good outcomes.³⁸

In contrast to localized LCH, systemic therapy is indicated in patients with multisystem LCH. The most common presentation of multifocal LCH includes diffuse skin and multifocal bone involvement. The oral cavity, lymph nodes and, to a lesser extent, the lungs, liver and brain are other common sites of involvement in this disease. Oral cavity involvement can lead to infiltrative lesions with ulceration as well as erosion of the mandible or maxilla, leading to “floating” teeth. Figure 15.6 demonstrates the characteristic CT findings of lung involvement. Diabetes insipidus, with pituitary involvement (Fig. 15.7), is the most common manifestation of CNS involvement in LCH and is reported in 5–30% of patients. The triad of lytic skull lesions, exophthalmos and diabetes insipidus, historically referred to as Hand–Schüller–Christian disease, is not commonly observed at the time of diagnosis, although the chronic waxing/waning course is

Fig. 15.4 Magnetic resonance image depicting a vertebra plana secondary to involvement of the vertebral body with Langerhans cell histiocytosis (white arrow).

frequently seen in this group of patients. Risk factors for the development of diabetes insipidus have been reported to include the presence of multisystem disease and craniofacial lesions, especially involving the orbit, ear and oral cavity.⁴⁷ In addition to acute CNS involvement, patients with LCH may develop a severe neurodegenerative process involving loss of motor functions and cognition. This syndrome characteristically involves the cerebellum, pons and midbrain, often in a symmetric pattern (Fig. 15.8).^{48–50} The clinical severity of neurodegenerative-associated LCH can be independent of radiographic findings or progression.^{49,51} There are currently no effective means of ameliorating the progression of this process. Liver involvement is another complication of LCH that portends a poor prognosis. Transaminitis and hyperbilirubinemia are the hallmarks of acute liver involvement in LCH. Patients with hepatic LCH or with multisystem disease appear to have a higher risk of developing sclerosing cholangitis that can, in turn, lead to hepatic fibrosis, liver failure and the need for liver transplantation.

(c) Inguinal involvement in an infant. (d) Perianal involvement in an infant. Reproduced with permission from Arcenci RJ. Histiocytosis. In: Young NS, Gerson SL, High KA (eds) *Clinical Hematology*. Mosby/Elsevier, 2006. (e) Axillary, lower abdomen and oral involvement in an infant. Reproduced with permission from Ref. 39.

In addition to site of involvement, age has been thought to be an important prognostic factor in LCH, with younger patients having a significantly higher mortality rate. However, more recent clinical trial data have shown that response to initial (6–12 weeks) therapy with vinblastine and steroids is the most powerful prognostic factor, outweighing even age. Abt–Letterer–Siwe disease is a historical eponym used to describe systemic LCH characterized by extensive skin,

bone marrow, spleen, liver and lung involvement; it is usually observed in children less than 2 years old. Oral cavity and gastrointestinal involvement are other commonly seen manifestations of this severe form of LCH. Patients typically suffer from intractable fevers, failure to thrive and, in later phases of the disease, severe pancytopenia and hepatic failure leading to hemorrhage and sepsis. Abt–Letterer–Siwe disease carries a particularly poor prognosis in patients with

Fig. 15.6 Involvement of the lung in Langerhans cell histiocytosis. (a) Acute nodular involvement; (b) cystic changes often associated with chronic involvement. Photograph (b) courtesy of Dr William Cumming, Department of Radiology, University of Florida School of Medicine, Gainesville, FL, USA.

advanced hematopoietic involvement who do not show a good response to initial therapy. Patients with Abt–Letterer–Siwe disease should undergo a full evaluation for congenital and acquired immunodeficiency syndromes in addition to infectious etiologies as part of their diagnostic work-up.

It is critical that pulmonary involvement as part of multi-system disease be distinguished from isolated pulmonary LCH (PLCH). PLCH is distinguishable from other forms of LCH by its almost exclusive occurrence in young adults and close association with smoking. PLCH can cause severe inter-

Fig. 15.8 Magnetic resonance image of neurodegenerative disease in an adult patient with Langerhans cell histiocytosis. (a) Symmetric enhancing lesions involving the cerebellar peduncles on a horizontal view; (b) enhancing lesions involving the pons on a coronal view.

stitial lung disease, cor pulmonale and eventual respiratory failure necessitating lung transplantation. The first line of therapy for PLCH remains smoking cessation, followed in some patients with steroids. The role of chemotherapy in PLCH remains uncertain as prospective data are not available. The use of 2-chlorodeoxyadenosine (2-CDA) has shown some promise in PLCH, although this therapy is reserved for patients with refractory disease and has only shown anecdotal success.^{52–54} The Histiocyte Society trial for adults with LCH includes patients with PLCH.

Patients with multisystem LCH have been demonstrated to benefit from systemic chemotherapy. The current therapeutic regimens evolved from work originally performed in the 1970s and 1980s. Several studies during that time demonstrated that single-agent therapy with drugs such as methotrexate, vincristine, vinblastine, etoposide, 6-mercaptopurine and prednisone was effective treatment for LCH. These trials were subsequently followed by the larger studies (AIEOP-CNR-HX and DAL-HX 83/90), all of which used regimens with multiple agents. These studies demonstrated response rates of 60–90% using combinations of vinblastine and/or etoposide plus prednisone. These studies also demonstrated that patients with extensive disease and organ dysfunction had significantly higher mortality and recurrence rates.^{38,55,56}

The AIEOP-CNR-HX and DAL-HX-83/90 studies were then followed by the first international, prospective, randomized study, LCH-I, which also represented the first international clinical trial of the Histiocyte Society. The results of this study demonstrated that patients randomized to treatment with etoposide plus steroids did not have a better outcome than those randomized to receive vinblastine plus steroids. In addition, this study revealed that response at 6 weeks was strongly predictive of overall outcome. For example, patients without a response to therapy after 6 weeks had a survival

rate of less than 40% at 5 years. Another critical outcome of this study was the confirmation of earlier work by Lahey that patients older than 2 years of age and without pulmonary, hepatosplenic or hematopoietic involvement had an excellent prognosis, with a response rate of 90% and survival of 100% at 6 years.^{57,58} In comparison with the AIEOP-CNR-HX and DAL-HX 83/90 trials, LCH-I showed a higher recurrence rate and higher frequency of diabetes insipidus. This raised the question of whether more aggressive therapy in patients with high-risk disease would provide a therapeutic advantage.⁵⁹

The second Histiocyte Society protocol, LCH-II, attempted to answer this question in a randomized fashion. The results of this study are still under analysis although preliminary evaluations led to the following conclusions:

- 1 response by 12 weeks of therapy is an important prognostic factor;
- 2 etoposide plus vinblastine and steroids does not appear to confer any benefit over therapy with vinblastine and steroids;
- 3 prolonged therapy may decrease the reactivation rate of LCH.

In light of the risk of therapy-associated acute myelogenous leukemia/myelodysplastic syndrome in patients treated with epipodophyllotoxins (i.e., etoposide/VP-16), this study obviated the use of etoposide in LCH. This trial also confirmed that age less than 2 years without risk-organ involvement is not an independent prognostic factor. The Histiocyte Society protocol LCH-III is attempting to determine in a randomized design whether (i) intensified induction therapy, with the addition of intermediate-dose methotrexate followed by inclusion of methotrexate in maintenance therapy, improves remission induction rates and overall outcomes and (ii) whether prolonging continuation therapy reduces the rate of disease reactivation (see Fig. 15.9 for treatment

The diagram illustrates the study design for two treatment arms, Arm A and Arm B, comparing different management strategies for patients with active disease.

Arm A: Patients are initially treated with V (Vedolizumab) and P (Prednisone). If they achieve a "No active disease" state, they are managed with 6MP (6-Mercaptopurine) for 12 months. If they have an "Intermediate response or worse", they are managed with 6MP for 12 months.

Arm B: Patients are initially treated with ID-MTX/LR (Infliximab/Levodopa/Reserpine). If they achieve a "No active disease" state, they are managed with Oral MTX (Methotrexate) for 12 months. If they have an "Intermediate response or worse", they are managed with Oral MTX for 12 months.

The flowchart illustrates the clinical trial design. It begins with a group of patients receiving Vinblastine and Prednisone. This group is then divided into two main branches: 'No active disease' and 'Intermediate response or worse'. The 'No active disease' branch further splits into two subgroups, each receiving a different treatment (represented by grey boxes) for 6 months and 12 months. The 'Intermediate response or worse' branch also splits into two subgroups, each receiving a different treatment (represented by grey boxes) for 6 months and 12 months.

The diagram illustrates two treatment schedules for Ewing sarcoma. The top section shows a 3-week cycle, and the bottom section shows a 12-month cycle.

3-week cycle (top):

- Vinblastine:** 6 mg/m² per week × 6 weeks (represented by 6 downward arrows).
- Prednisone:** 40 mg/m² per day × 4 weeks then taper over 2 weeks (represented by a bar that is 4 weeks long and then tapers over 2 weeks).
- Methotrexate:** 500 mg/m² with leukovorin rescue on weeks 1, 3, 5 (represented by 3 upward arrows).

12-month cycle (bottom):

- Vinblastine:** 6 mg/m² per week × 6 weeks (represented by 6 downward arrows).
- Prednisone:** 40 mg/m² per day × 5 days each 3-week cycle (represented by 3 bars, each 5 days long, spaced 3 weeks apart).
- 6-Mercaptopurine (6MP):** 50 mg/m² per day for 12 months (represented by a continuous bar for 12 months).
- Methotrexate (MTX):** 500 mg/m² with leukovorin rescue on weeks 1, 3, 5 (represented by 6 upward arrows).

350

schema). Based on the results of the previous studies, etoposide is no longer recommended as initial therapy.

Despite past successes in the treatment of newly diagnosed LCH, the treatment of refractory disease remains problematic. Experience with immunosuppressive agents such as cyclosporin and antithymocyte globulin are limited and responses most commonly transient.⁶⁰ However, there is significant experience with the nucleoside analog 2-CDA, alone or in combination with cytosine arabinoside.^{61–64} 2-CDA has been shown to produce a remission in more than one-third of patients with refractory disease in an international phase II study. The response rate was even better in patients with a good response to initial treatment.^{38,61,63,64} 2-CDA has also shown anecdotal efficacy in the treatment of parenchymal CNS disease, although no agent has been shown to be convincingly effective in halting the progression of the neurodegenerative disease. Other approaches that have been used to treat the neurodegenerative disease associated with LCH include drugs that decrease inflammatory responses such as thalidomide and TNF inhibitors such as infliximab (Remicade) and etanercept (Enbrel).^{65–67} Alemtuzumab (Campath), an anti-CD52 antibody, may also have promise in the treatment of LCH, especially in patients with advanced disease, but should be tested in prospective clinical trials because of its profound immunosuppressive effect.⁶⁸ There are case reports of hematopoietic stem cell transplantation (HSCT) in patients with refractory LCH, but the role of this therapeutic approach remains unclear in part due to difficulty in identifying matched donors and the high mortality rate in patients with significant disease-related organ dysfunction.⁶⁹ A Histiocyte Society trial is currently testing the use of a nonablative preparative regimen for HSCT.⁶⁹

There remains a significant need for more effective agents in the treatment of patients with organ involvement and dysfunction, including those with progressive CNS, hepatic and pulmonary disease. Several new agents, including antibodies to the CD1a surface antigen as well as agents targeting cytokine receptor signaling pathways, are currently in pre-clinical/early clinical phases of development. It is anticipated that the optimization of these agents and their incorporation into routine clinical use will help increase our ability to more effectively treat patients with refractory and progressive disease.

Survivorship issues

Survivors of LCH can have significant late sequelae related to their disease after achieving remission and long-term cure. Late effects in survivors of LCH tend to be directly related to sites of original disease involvement. In one study, 42% of patients developed long-term complications, patients with multisystem disease being at highest risk. Diabetes insipidus developed in 15% of patients, CNS complications in 12% and pulmonary insufficiency in 10%.⁴¹ Others have

noted neurocognitive problems such as intellectual impairment, psychological problems and psychomotor retardation in long-term survivors of LCH.^{49,50,70} The late CNS complications of LCH also include neurodegenerative changes that can be highly disabling.^{48–50,71–73} The neurodegenerative disease is thought to be the result of a paraneoplastic process and pathologically is characterized by an inflammatory infiltrate dominated by CD8-positive reactive lymphocytes, microglial activation and gliosis. This contrasts with the T-cell infiltration and severe neurodegeneration surrounding CD1a infiltrates of CNS parenchyma.⁴⁸ Sclerosing cholangitis and liver failure necessitating liver transplant are also well recognized late effects of systemic LCH. The role of chemotherapy in the management of CNS and hepatic sequelae is limited as these complications appear to be related to an aberrant immune response and tissue fibrosis as opposed to active LCH.^{74,75} Patients with LCH also have an increased risk of malignancy, which may be further increased when treated with etoposide or radiation as part of their therapy.^{33,34,76}

It is critical for patients with LCH, especially multisystem disease, to be followed on a long-term basis at a center familiar with the care of patients with LCH. Follow-up should include imaging studies in addition to routine blood counts, liver and thyroid function testing as well as urine and electrolyte levels for assessment of diabetes insipidus. Formal neurocognitive evaluations should be done in patients with suspected or proven CNS involvement.

Non-Langerhans cell (class I) histiocytoses

Juvenile xanthogranulomatous disease and related disorders

The non-Langerhans cell (class I) histiocytic disorders represent a spectrum of disease defined by the accumulation of dendritic cells that do not meet the phenotypic criterion for diagnosis of LCH. These histiocytes, like LCH cells, phenotypically resemble a stage in the normal development of dendritic cells. It is believed that under growth factor stimulation, a common progenitor can develop along two separate differentiative pathways that can be phenotypically distinguished by the expression of CD14. The CD14-negative lineage, under the influence of TNF- α and GM-CSF, differentiates into Langerhans cells while the CD14-positive lineage can give rise to either cells of the monocyte-macrophage lineage or to interstitial/dermal dendrocytes.⁷⁷ Disorders arising from the monocyte-macrophage lineage are categorized as the class II or macrophage-related histiocytoses. However, the non-Langerhans cell (class I) histiocytoses are believed to arise from dermal dendritic cells. It is critical to emphasize that disorders arising from the dermal dendrocyte are now considered class I histiocytoses.

The non-Langerhans cell (class I) histiocytoses are histologically nonmalignant proliferative disorders that have variable

Fig. 15.10 Histopathology and immunochemical staining of juvenile xanthogranulomatous disease. (a) Juvenile xanthogranuloma characterized by oval, partially lipidized histiocytes admixed with eosinophils (hematoxylin and eosin staining) (original magnification $\times 200$). Many juvenile xanthogranulomas also contain Touton-type multinucleated giant cells. Unlike Langerhans cell histiocytosis, juvenile xanthogranulomas do not express CD1a (b, original magnification $\times 400$) but do express histiocyte antigens CD68 (c, original magnification $\times 400$) and CD31 (d, original magnification $\times 400$). Photographs courtesy of Dr John Reith, Department of Pathology, University of Florida School of Medicine, Gainesville, FL, USA.

clinical presentations. However, these disorders are all defined by the similar pathologic finding of a histiocytic proliferation that is CD1a and S100 negative but factor XIII, CD31, CD68, CD163, fascin and CD14 positive (Fig. 15.10). Clinical presentation of these disorders is variable and appears to be age dependent. It has been hypothesized that the clinical presentation of these disorders, much like LCH, depends on the variable local cytokine milieu.⁷⁸ Weitzman and Jaffe⁷⁷ have suggested that the non-Langerhans cell (class I) histiocytoses be divided into three major groups based on their clinical presentation for ease of classification: (i) disorders primarily affecting skin (cutaneous); (ii) cutaneous disorders that have a systemic component; and (iii) multisystem disorders that can also affect skin.

The juvenile xanthogranuloma (JXG) family of diseases represents the most common disorder of this subtype. Juvenile xanthogranulomatous disease is the prototypical member of this family of disorders and the most common form observed in pediatrics. The primary presentation of JXG in children is cutaneous (Fig. 15.11), although approximately 4% of children may also have systemic involvement of the CNS, liver, lungs and eyes.^{79,80} JXG lesions typically self-involute, although systemic disease may sometimes necessitate chemotherapy.⁷⁷ Optimal therapy for patients with systemic JXG who need therapeutic intervention remains unclear, although LCH regimens have been most commonly used with variable responses observed.^{79,81,82} Interestingly, a triple association between JXG, juvenile myelomonocytic leukemia and neurofibromatosis type I has been reported, possibly genetically linking these conditions in some patients.^{83–86}

Fig. 15.11 Extensive cutaneous involvement of an infant with juvenile xanthogranulomatous disease.

Erdheim–Chester disease is also a member of the class I non-Langerhans cell histiocytoses and can often present as a systemic disease. This disease is extremely rare in the pediatric age group and patients are typically older than 50 years of age. Clinically, this disease presents with xanthoma-like skin nodules and bilateral lower extremity bone pain. Radiography shows symmetrical sclerosing bone lesions typically affecting the metaphyseal ends of long bones. Patients with disseminated disease may have severe cardiopulmonary insufficiency from parenchymal involvement of heart and lung tissues, renal insufficiency due to perinephric involvement, and CNS involvement with ataxia, diabetes insipidus and mental status changes.^{87,88} This disease is frequently progressive and fatal. Limited success has been reported when treating patients with Erdheim–Chester disease with standard LCH therapy, although anecdotal

cases of response to low-dose IFN- α are notable but in need of prospective confirmation.⁹¹

Disorders of varied biological behavior: macrophage-related (class II) histiocytoses

Hemophagocytic lymphohistiocytosis

Biology

Class II histiocytic disorders are all characterized by the abnormal accumulation of activated macrophages along with lymphocytes in tissues. The predominant member of the class II histiocytoses is hemophagocytic lymphohistiocytosis (HLH), a disorder characterized by the abnormal accumulation of T lymphocytes and macrophages in normal tissues. HLH is further subdivided as follows:

- 1 primary HLH (familial erythrophagocytic lymphohistiocytosis), a heritable autosomal recessive disorder;
- 2 secondary HLH, a sporadic disease typically associated with a preexisting inflammatory condition such as infection (infection-associated hemophagocytic syndrome), malignancy (malignancy-associated hemophagocytic syndrome) or immunosuppressive therapy (macrophage activation syndrome). Primary and secondary HLH are clinically indistinguishable. The presentation of these disorders is typically fulminant and consists of fever, cytopenias, hepatosplenomegaly, hyperbilirubinemia, hyperlipidemia, hypofibrinogenemia, coagulopathy, hemophagocytosis and CNS abnormalities such as seizures.^{90,91} A family history of consanguinity and age < 2 years at time of onset are highly suggestive of primary/ inherited HLH. Positive genetic testing for genes known to cause HLH establishes the diagnosis of the primary or inherited form of the disease.

The immunologic defect underlying primary HLH is low or absent natural killer (NK) cell and cytotoxic T-lymphocyte function and number.^{92,95} This diminished cytotoxic function is responsible for the pathologic expansion of cellular immune responses and infiltration of tissues by inflammatory cells.

This accumulation of activated macrophages and lymphocytes in tissues is perpetuated by the release of inflammatory cytokines by both lymphocytes and antigen-presenting cells, resulting in systemic hypercytokinemia which in turn contributes to organ damage and the signs and symptoms of HLH.^{96–98}

Mutations in three genes have now been identified in patients with primary HLH: *PRF1* (perforin),⁹⁹ *UNC13-D* (Munc13-4)¹⁰⁰ and *STX11* (syntaxin 11).^{99–101} Perforin is stored in cytotoxic granules of NK cells and cytotoxic T cells and is released to the cell surface during the formation of an immunologic synapse, where it functions to create pores in the cytoplasmic membranes of target cells leading to cell death. Munc13-4 and syntaxin 11 are both involved in the stabilization and transport of cytotoxic granules in NK and T cells. Normal NK-cell and T-cell function is crucial in the clearance of infections, particularly viral infections through lysis of infected cells.^{102,103} The association of *PRF1*, *UNC13-D* and *STX11* mutations with HLH and the observed NK-cell defects in patients with HLH clearly point to the central role of this pathway in the pathogenesis of HLH. Furthermore, *in vitro* NK-cell enumeration and cytotoxicity data suggest significant variability among patients with HLH that is directly related to the nature of their genetic defect.¹⁰⁴

This pathophysiologic model for HLH is further supported by the reports of HLH-like syndromes in patients with other immunodeficiency diseases such as Chédiak–Higashi syndrome (*LYST*), Griscelli syndrome (*RAB27A*) and X-linked lymphoproliferative syndrome (*SH2D1A*).^{105–107} Mutations in the perforin gene are thought to account for 20–58% of cases of primary HLH (Table 15.3) [101, 110–112]. Interestingly, patients with HLH with missense mutations and higher levels of perforin expression appear to have a delayed onset of symptoms relative to patients with no expression of perforin.¹¹¹

Incidence and epidemiology

The incidence of primary HLH is estimated to be around 1 in 50 000–300 000 live births based on several retrospective epidemiologic studies.^{112–114} However, these estimations may

under estimate the true incidence of HLH secondary to lack of familiarity of many primary physicians with this diagnosis. Interestingly, the prevalence of primary HLH is noted to be geographic in distribution, a finding attributed to the familial nature and the founder effect seen in this disease.^{113,115,116}

The majority of cases of primary HLH occur within the first year of life, although cases have been reported as late as the third decade of life.^{117,118} Secondary HLH, however, occurs sporadically and can be seen at any age depending on the primary initiating event. The male to female ratio of primary HLH is estimated to be 1 : 1, with some studies suggesting a slight male predominance.^{113,117,118}

Clinical presentation

HLH is fatal if the diagnosis is delayed and appropriate therapy not instituted rapidly. The most common presenting symptoms include fever and hepatosplenomegaly, although rash, lymphadenopathy and CNS symptoms are common. Signs and symptoms also include cytopenias, transaminitis, coagulopathy, hypofibrinogenemia, hypertriglyceridemia, hyperferritinemia, and evidence of hemophagocytosis from bone marrow aspiration (Fig. 15.12). As significant variability in clinical presentation may impede diagnosis, specific diagnostic criteria have been established by the Histiocyte Society to aid in more expeditious diagnosis and treatment (Table 15.4).⁴¹ In particular, some children may present with solely or primarily CNS-related symptoms; in these children a high level of suspicion on observing characteristic brain MRI changes is important in making an early diagnosis. If strong clinical suspicion is present, it is recommended that therapy be initiated even if all criteria are not fully satisfied.

Table 15.4 Diagnostic criteria for hemophagocytic lymphohistiocytosis.*

<i>Clinical</i>
Fever
Hepatosplenomegaly
<i>Laboratory</i>
Hematologic
Cytopenias (more than two of three lineages in peripheral blood)
Hemophagocytosis
Biochemical
Hypertriglyceridemia (fasting triglycerides ≥ 2 mmol/L or ≥ 3 SD above normal)
Hypofibrinogenemia (≤ 1.5 g/L or ≤ 3 SD below normal)
Hyperferritinemia
Immunologic
Low or absent natural killer cell function
Elevated soluble CD25 serum levels
<i>Additional</i>
Molecular demonstration of known gene mutation
Presence of familial disease

* Diagnosis requires five of the eight clinical and laboratory criteria or the identification of specific gene mutations or presence of familial disease.

In such cases, bone marrow studies should be repeated if initially negative to help establish a diagnosis by documenting hemophagocytosis. The presence of a family history positive for consanguinity or another affected sibling as well as the availability of molecular testing for gene mutations can further assist in establishing a diagnosis.

Treatment

Current therapy of HLH, as prescribed by the HLH-2004 protocol of the Histiocyte Society, consists of dexamethasone, etoposide and cyclosporin in combination with intrathecal methotrexate and prednisolone when indicated by the presence of cerebrospinal fluid pleocytosis. Antithymocyte globulin has also been used, but mostly as second-line therapy.¹¹⁹ Primary HLH tends to be recurrent and does not permanently respond to chemotherapy, thus necessitating HSCT for cure.^{66,120,121} However, secondary HLH, with the exception of refractory cases, can often be effectively treated with chemotherapy or immunomodulatory approaches such as intravenous immunoglobulin.^{122–126} Treatment of an underlying infection or malignancy, while necessary, may be inadequate in cases of secondary HLH, necessitating HLH-type therapy. Thus, in cases of infection-associated or malignancy-associated HLH, there is often a need to sequentially treat both the HLH and the underlying disorder in order to achieve complete remission. HSCT is usually necessary in patients with recurrent secondary HLH.

The current Histiocyte Society international study, HLH-2004, is based on the HLH-94 study. The HLH-94 protocol

achieved an estimated survival rate of 55% at a median of about 3 years of follow-up. This rate was slightly lower in patients with familial HLH (51%), although patients who underwent bone marrow transplantation had a 3-year survival probability of 62%. As a significant number of patients on HLH-94 died prior to receiving bone marrow transplantation, the HLH-2004 protocol has been modified so that cyclosporin is administered concurrently with dexamethasone and etoposide at the beginning of therapy with the goal of improving on the early treatment failure rate.⁶⁶

Survivorship issues

The primary long-term sequelae of HLH are mainly related to the extent of CNS involvement. Prompt initiation of systemic therapy is critical for reducing CNS morbidity in HLH. Although the benefits of intrathecal therapy have not been clinically proven, inclusion of intrathecal therapy in patients with documented CNS disease is recommended.^{91,127–129} Close follow-up of neurologic function is critical in order to assess the developmental delay that has been observed in these patients. It remains unclear if the neurologic complications are a direct result of disease involvement, therapy or infectious complications.¹³⁰ Long-term follow-up is a critical part of the care of HLH patients and should include observation for CNS effects, bone marrow transplant-related morbidities, and secondary acute myeloid leukemia related to the use of etoposide.¹³¹

Sinus histiocytosis with massive lymphadenopathy (Rosai–Dorfman disease)

Other members of the class II histiocytoses tend to have a more indolent course than HLH. Sinus histiocytosis with massive lymphadenopathy (SHML), also known as Rosai–Dorfman disease, is characterized by a lymphohistiocytic accumulation in the sinuses of lymph nodes without architectural effacement.¹³² The proliferative macrophages seen in this disorder are typically S100 positive but CD1a negative and can be characteristically observed to wrap around intact lymphocytes or other cells, a process known as emperipolesis. SHML has a predilection for lymph nodes of the head and neck but can be seen in any organ including the CNS.^{133–137} SHML more commonly occurs in patients of African ancestry; and is not typically responsive to most therapeutic approaches.¹³⁸ Recent reports have documented response to therapy with high-dose dexamethasone and also with 2-CDA.^{133,139,140} Although SHML can be potentially disfiguring, it is only rarely life-threatening.

Malignant (class III) histiocytoses

This class of disorders consists of malignant histiocytosis, his-

tiocytic sarcoma and acute monocytic leukemia. For the most part, these disorders can be characterized by malignant transformation of cells of the MPS with significant cellular atypia. Those disorders characterized by malignant transformation of dendritic cells are often treated with lymphoma/leukemia protocols, including HSCT, although outcomes remain relatively poor. The wide variety of these conditions, the rarity of occurrence in pediatrics, and discussion elsewhere in this book (see Chapter 16) preclude a more detailed discussion here.

Challenges

Important landmarks have been achieved in our understanding of LCH since the first descriptions from the 1800s. We have a better understanding of the normal and abnormal responses of cells belonging to the MPS as well as of the etiology, presentation, natural history and treatment of LCH. Nevertheless, large numbers of patients remain undiagnosed or inadequately treated or simply do not respond to current therapies. The outcome for patients with LCH, particularly with refractory disease or disease involving organs such as the bone marrow, liver, lung and CNS, remains poor. The cure rate of HLH still remains close to 50%, with many survivors having significant adverse long-term sequelae. The formation of the Histiocyte Society has helped establish a framework within which collaborative studies can be undertaken. Future efforts should focus on further defining the etiology of LCH and understanding the molecular pathways with the goal of identifying molecular targets for more effective treatment and improved outcomes. Additionally, improved clinical understanding of the natural history of the histiocytoses is an important key to early diagnosis and appropriate therapy. Cooperative group clinical trials involving multidisciplinary approaches, particularly involving medical and pediatric oncologists, should help establish future improvements in outcome for patients with histiocytosis.

Acute myeloid leukemia

Leslie S. Kean, Robert J. Arceci and William G. Woods

Overview

Acute myeloid leukemia (AML) constitutes a heterogeneous group of hematologic malignancies that are derived from early hematopoietic progenitors and show myeloid, monocytic, erythroid and megakaryocytic phenotypic characteristics.^{1–5} AML is the major subtype of acute leukemia in adults, but only represents 15% of newly diagnosed cases of acute leukemia in children. The complexity and challenge of AML is revealed in the fact that despite its relatively low prevalence, it nonetheless accounts for over 30% of the annual pediatric mortality attributed to leukemia.^{5–8}

Before the 1970s, nearly all patients who were diagnosed with AML died of their disease. The introduction of cytarabine (AraC) and the anthracycline class of chemotherapeutic

agents to the treatment of AML in the 1960s and early 1970s marked a major milestone, and for the first time resulted in the majority of patients (60–70%) achieving a remission.^{9,10} Optimization of AraC/anthracycline-based regimens resulted in greater rates of first remission (70–85%), and dose-intensification of therapy led to increased 5-year survival (Fig. 16.1). Currently, most large studies achieve 5-year event-free-survival (EFS) approaching 50%.^{4,5,11–37} Although this represents a major improvement in cure, most patients with AML still die of their disease. The current focus of AML research and treatment is thus twofold. First, new therapeutic regimens are being studied that are designed both to increase the rate of first remission and to improve the “quality” of this remission, so that the risk of relapse is reduced. Second, a

Fig. 16.1 AML 5-year relative survival rates by sex, race, age and time period, comparing SEER (Surveillance, Epidemiology and End Results) data from 1975–1984 and 1985–1994.³⁹

molecular dissection of this heterogeneous class of diseases is ongoing. This will allow risk-stratification of patients based on their individual molecular defects and provide the knowledge base for future therapeutic strategies based on targeted inhibitors of the aberrant pathways that lead to the development of AML.

Epidemiology

Each year, approximately 10 000 children (ages 0–21 years) worldwide develop AML. Current epidemiologic studies predict approximately 600 new cases of AML in the USA and 100 new cases of AML in the UK per year.^{38–40} This is in contrast to acute lymphocytic leukemia (ALL), which remains four times more common than AML in US children. The exception to this statistic is the neonatal period, in which AML incidence shows a relative peak. The incidence of AML is stable until the teenage years, when a small increase in incidence is noted, followed by a steadily increasing incidence during adulthood (Fig. 16.2). There is no difference in the incidence of AML in males compared with females and there has been no change in the worldwide incidence of childhood AML when statistics for the past two decades are compared.^{39,40}

Racial variation can be observed in AML. In the USA, white children have historically exhibited an increased incidence compared with black children, whereas Hispanic children had the highest incidence of the three racial groups (as high as 9 cases per million in Los Angeles).^{39,41} The most recent Surveillance, Epidemiology and End Results (SEER) data (years 1986–1995) demonstrated less marked differences between white and black children < 20 years, with the incidence of AML in these two populations being 6.7 and

6.4 per million, respectively.^{39–41} A higher incidence of AML appears to occur in Asia (11 cases per million in China) compared with the USA, and a lower incidence in India (3.5 cases per million). The mechanisms underlying these differences have not yet been determined.

In addition to ethnicity, environmental and genetic risk factors have also been shown to influence the risk of developing AML (Tables 16.1 and 16.2).^{3,38,41–52} The most common genetic risk factor is trisomy 21/Down syndrome (DS), which is associated with a 15-fold increase in the risk of leukemia (both ALL and AML) during childhood. Other genetic syndromes characterized by either chromosomal instability or cell-cycle dysregulation also increase the risk of developing AML. These include Bloom syndrome, neurofibromatosis type I and Klinefelter syndrome. Additionally, virtually all of the constitutional inborn errors of hematopoiesis are asso-

Table 16.1 Genetic risk factors in childhood AML.

Heavy metals

* Proven risk factors.

ciated with an increased risk of developing AML, including Fanconi anemia, Diamond–Blackfan syndrome, Kostmann disease, thrombocytopenia–absent radii syndrome, Shwachman–Diamond syndrome and familial thrombocytopenia.

Environmental risk factors for AML include both pre- and postnatal exposures (Table 16.2). Prenatally, diagnostic ionizing radiation and maternal drug and cigarette use have all been implicated.^{42,44–47,49–51,53} Maternal prenatal diet may also affect the AML risk in children. Ross found that increased maternal consumption of foods containing topoisomerase 2 during pregnancy was associated with a tenfold higher risk of infant AML in a case-control study.⁴⁸ Postnatally, ionizing radiation and exposure to chemotherapeutic drugs including alkylating agents and epipodophyllotoxins both have been confirmed as increasing the risk of AML.^{45,46,50,51,53–55} In addition, exposure of either the patient or the patient’s parent to pesticides, petroleum products, benzene and heavy metals all have been associated with an increased risk of AML.^{40,41} Although concerns persist about the possible leukemogenesis associated with exposure to electromagnetic fields, results of the case-control studies into the importance of this risk factor have been mixed. Thus, while studies from the UK,⁵⁶ Denver,^{57,58} and Los Angeles⁵⁹ each supported an association between childhood leukemia and either proximity to high-voltage power lines or home wiring-configuration, other studies, based in Rhode Island,⁶⁰ Canada,⁶¹ and Japan⁶² found no such association. In addition, several small, case-control studies have shown that prenatal and postnatal electric blanket exposure was not associated with a statistically significant increase in the incidence of childhood or adult leukemia.^{63,64}

Clinical manifestations at diagnosis

There is a large range of presenting signs and symptoms for pediatric AML. Life-threatening complications occur due to decreased normal hematopoiesis secondary to leukemic infiltration of the bone marrow as well as to organ dysfunction and failure as a result of leukemic infiltration.

Whereas the total white blood cell count (WBC) is often elevated in patients with AML, the number of normal, functional neutrophils is often quite low, resulting in neutropenia that places patients at increased risk for bacterial infections. Normocytic, normochromic anemia is another common hematologic abnormality that can result in headache, dizziness, fatigue, pallor and sometimes congestive heart failure. Patients with AML often present with bone pain, secondary to marrow replacement with leukemic blasts resulting in periosteal pressure. This may result in night-time waking, limp or back pain. Coagulopathy is a common presenting complication of AML, particularly in acute promyelocytic leukemia (APL) but also in acute myelomonocytic leukemia (AMML) and acute monocytic leukemia (AMoL) subtypes. The coagulopathy may result from thrombocytopenia as well as from disseminated intravascular coagulation (DIC) due either to infection or to the release of coagulant activity (e.g., thromboplastin activity) associated with the cytoplasmic granules of some AML blasts. DIC may worsen as therapy is initiated due to the increased release of these coagulant proteins associated with tumor lysis and leading to factor depletion and bleeding. Aggressive clotting factor replacement and platelet transfusions are frequently necessary to avoid catastrophic bleeding. Treatment with low-molecular weight heparin in order to inhibit microthrombi generation may be useful but remains controversial.

Organomegaly is seen in approximately half of patients with AML due to hepatic and splenic infiltration with leukemic blasts. Extramedullary leukemia (EML) is observed in 10–20% of patients, with gingival hypertrophy, lymphadenopathy, and leukemia cutis (palpable nontender nodules in the skin) being most common. Granulocytic sarcomas, or “chloromas,” may involve other anatomic locations such as periorbital, paraspinal and intraorgan sites. Periorbital involvement may cause proptosis, and paraspinal chloromas invading the spinal canal may result in spinal cord compression. These manifestations are seen more commonly with the monocytic subtype of AML (M5 FAB subclass, described in detail below).

Given the large size of AML blasts and their adhesion properties, hyperleukocytosis can result in life-threatening complications. When the peripheral WBC is $> 100 \times 10^9/L$, AML blasts can begin to clump, resulting in leukostasis and sludging of the blasts in small vessels. This in turn leads to cellular hypoxia, tissue infarction, and ultimately tissue hemorrhage. When this occurs in the central nervous system (CNS), the patient is at greatly increased risk for stroke and a somnolence syndrome that may progress to coma. Manifestations of hyperleukocytosis in the lungs include parenchymal infiltrates, pulmonary edema, respiratory failure and occasionally hemorrhage. Rapid lowering of the WBC is necessary, often using leukapheresis along with aggressive hydration. Definitive cytoreduction using chemotherapy should be instituted promptly, because other mechanisms for lowering

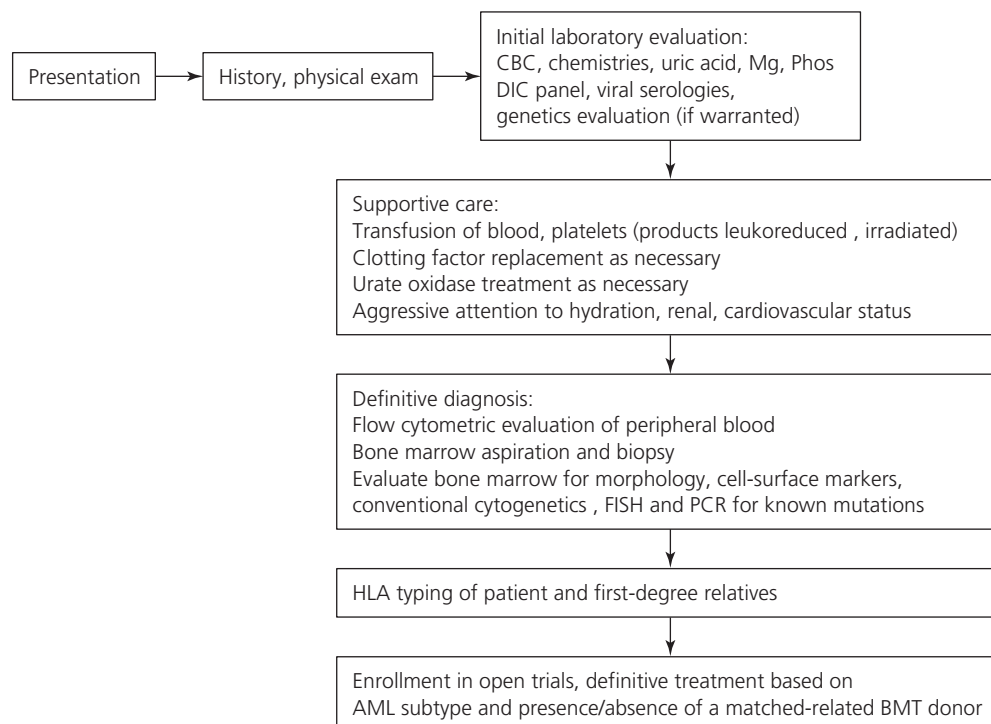

Fig. 16.3 Treatment algorithm for patients newly diagnosed with AML. BMT, bone marrow transplant; CBC, complete blood count; DIC, disseminated intravascular coagulation; FISH, fluorescence *in situ* hybridization; PCR, polymerase chain reaction.

the WBC will only provide temporary improvement. An exception to the recommendation of using leukapheresis for cytoreduction is APL. In APL, leukapheresis may activate the leukemic promyelocytes causing them to release coagulant-containing granules, thereby increasing the chance of DIC and fatal hemorrhage. Cytoreductive chemotherapy using all-*trans* retinoic acid (ATRA) and chemotherapy should instead be instituted promptly, with strong consideration for also using steroids.

After the initiation of cytoreductive therapy, tumor lysis syndrome can also lead to serious complications, especially in the setting of an initially high WBC. Treatment of hyperuricemia with the newly commercially available urate oxidase enzymes may lessen the renal complications associated with this by-product of leukemic blast lysis, but the complications of hyperphosphatemia, hypocalcemia and hyperkalemia continue to demand intensive supportive care interventions. Figure 16.3 depicts the treatment algorithm that should be followed in patients with newly diagnosed AML, from the initial patient encounter to the initiation of definitive therapy.

AML classification

AML is a heterogeneous group of diseases in which ultimate outcome varies widely. Although morphologic and cytogenetic changes (discussed below) have a major impact on outcome,

other factors may also play a role. These include initial WBC, age, race, the presence of primary versus secondary AML, and the ease with which first remission is achieved. WBC $< 100 \times 10^9/L$ at diagnosis, patients greater than 1 year but less than 15 years of age, Caucasian race, the absence of secondary AML and rapid induction of complete remission (CR) are all associated with improved long-term outcome. These characteristics are often closely tied to morphologic and cytogenetic features that are increasingly appreciated as important predictors of AML prognosis.

The first comprehensive morphologic classification system for AML, was the French–American–British (FAB) classification, which was established in 1976 and later revised in 1985.⁶⁵ Although this classification is based only on morphology and histochemical analysis of malignant cells (and not on either flow cytometric or molecular genetic phenotyping), it nonetheless provides a useful framework for classifying the subgroups of AML (Table 16.3). The FAB classification divides AML into eight subcategories based on morphology after staining with Wright, Wright–Giemsa, or May–Grunwald stains as well as a panel of histochemical markers. With the exception of the M6 and M7 subtypes, the original classification schema required 30% myeloblasts in the bone marrow in order to render a diagnosis of AML.

In 1997 the World Health Organization (WHO) revised the FAB classification by adding cytogenetic analysis to the classification of AML subtypes (Table 16.3).^{66–70} Additionally, the WHO classification system lowered the malignant blast

Table 16.3 AML classification by both FAB and WHO criteria.**FAB**

M0: minimally differentiated
 M1: myeloblastic leukemia without maturation
 M2: myeloblastic leukemia with maturation
 M3: hypergranular promyelocytic leukemia
 M4: myelomonocytic leukemia
 M4Eo: variant, increase in marrow eosinophils
 M5: monocytic leukemia
 M6: erythroleukemia
 M7: megakaryoblastic leukemia

WHO

AML with recurrent cytogenetic translocations
 AML with t(8;21)(q22;q22) AML1-ETO fusion

AML not otherwise categorized

AML minimally differentiated

percentage in the bone marrow needed for diagnosis of AML to 20% myeloblasts.

Although neither the FAB nor the WHO classification schemes formally utilizes flow cytometric immunophenotyping for subclassification, its clinical diagnostic use is now routine, and its use in evaluating the response to therapy is being intensely studied.^{71–83} Flow cytometric detection of leukemic blasts is based on the multiparameter analysis of their aberrant pattern of expression of normal differentiation antigens. Using this approach, flow cytometry can also be used to determine quantitatively the persistence of leukemic blasts at levels as low as 1 blast per 10 000 mononuclear cells. What level of minimal-residual disease (MRD) will most accurately predict outcome is under investigation.^{78,80,82,84}

Immunophenotyping studies have demonstrated significant associations between the expression of specific cell-surface markers and the WHO classification of AML subtypes. CD13, CD33, and c-Kit are the most commonly expressed myeloid markers in AML (present on the blasts of ~90% of patients). The FAB M4 subtype commonly expresses CDw14 (73% of M4 blasts expressed this antigen), CD15 (100%), CD13 (57%) and CD33 (92%). The M5 subtype shows a similar pattern of antigen expression, with the exception of CD13, which this

subtype rarely expresses. In contrast, M1 and M2 blasts express lower levels of these markers, with CDw14 present in only about 14% of M1 and 19% of M2 cases. CD15 is expressed on about 38% and 44% of M1 and M2 cases, respectively. M1 and M2 blasts often express CD13, with 80% of M1 or M2 cases being positive for this marker.⁷¹ AML blasts also frequently express lymphoid surface antigens. In a retrospective study by the Children's Cancer Group (CCG), 24% of AML cases expressed the B-lineage marker CD19 and 48% expressed one or more T-lineage cell surface antigens.⁷¹ Expression of terminal deoxynucleotidyl transferase was much less common, being present in only 6% of AML cases. When analyzed across multiple multicenter trials over the last two decades, between 30 and 60% of AML cases express lymphoid markers.^{71,76,78,82,83} There has been no definitive association with clinical outcome demonstrated due to lymphoid antigen expression in AML.

Cytogenetics and molecular markers

Cytogenetic and molecular analysis have identified molecular abnormalities that often correlate with morphologic and immunophenotypic subtypes as well as with AML prognosis.^{71,85–91} Three approaches are commonly used. The first is conventional karyotyping, which demonstrates chromosome number (ploidy) as well as chromosomal structural changes such as regional amplifications and deletions, inversions or translocations. The second technique, fluorescent *in situ* hybridization (FISH), makes use of fluorescently labeled nucleic acid probes that are used to detect more subtle chromosomal abnormalities in both metaphase and interphase cell chromosomes as well as in many more leukemic cells (>500 cells routinely analyzed by FISH) than conventional cytogenetic analysis (~20 metaphase preparations routinely analyzed). FISH probes specific for distinct chromosomes, chromosomal segments or novel translocations are also a sensitive means to help establish a diagnosis or follow patients for the presence of MRD. Third, polymerase chain reaction (PCR) techniques can be used to identify specific genetic abnormalities such as inversions, deletions or translocations, based on their unique sequences. When coupled to DNA sequencing, this technique can detect single base-pair mutations in DNA, and is highly sensitive, being able to identify one mutation in as few as 100 000 bone marrow cells. Abnormal RNA transcripts, resulting from chromosomal translocations, can also be detected with high levels of sensitivity using reverse-transcription PCR (RT-PCR).

Gene expression profiling

The application of DNA microarray technology to the study of AML has already begun to reveal gene expression

profiles that are both biologically important and clinically relevant.^{92–105} In 2003, Yagi *et al.*⁹¹ used microarray analysis to identify a subset of genes that were associated with AML prognosis, regardless of underlying karyotype or morphologic subtype. In 2004, Ross *et al.*⁹³ published the first large gene expression study of pediatric AML, which showed that expression profiles could be identified that correlate with each of the major prognostic and cytogenetic subtypes. Furthermore, this study determined that the gene clusters identified for pediatric AML subtypes also accurately predicted adult AML subtypes, underscoring the molecular similarity between AML diagnosed within a wide age range. Similar results with adult AML series are also emerging, confirming the diagnostic and prognostic power of microarray analysis. Larger studies with more AML patient samples, as well as increasingly detailed analysis of the important prognostic groups, are ongoing and should make this technology a part of standard-of-care for AML diagnosis and treatment planning in the future.

Risk-group stratification and prognostic factors

The last decade of AML research and treatment has witnessed a growing appreciation of the importance of identifying prognostic risk groups within the broader diagnosis of myeloid malignancies.^{11,71,73,88,90,91,106–112} This stratification allows prediction of outcome based on the molecular phenotype at the time of diagnosis and can be used to direct different treatments. Stratification now includes several risk groups as well as treating patients with APL or infants with DS with separate therapeutic approaches.

Prognostically good cytogenetics

Several chromosomal abnormalities have emerged as predictors of good prognosis in children with AML: t(15;17)(q22;q12), inv(16)(p13q22), and t(8;21)(q22;q22).^{85,86,88,89,106–108,113,114}

The t(15;17) translocation involves the fusion of the PML gene on chromosome 15 to the retinoic acid receptor alpha (RARA) on chromosome 17. It is pathognomonic of APL and absent in all other subtypes. This translocation results in recruitment of chromatin repressor complexes that involve both histone deacetylases (HDAC) and DNA methyltransferases, which in turn result in aberrant silencing of key genes in hematopoiesis.^{115–120} Leukemic cells with the t(15;17) translocation are highly responsive to ATRA, which causes differentiation and apoptosis.^{88,121–126} The latest results confirm that the combination of ATRA and chemotherapy results in an excellent prognosis, both in terms of success at achieving first remission (96%), survival (10-year overall survival of 89%), and EFS (76%).¹²⁶

The inv(16) and t(8;21) translocations are characterized

by disruption of *CBFβ* and *AML1* (also known as *CBFA2* or *RUNX1*) genes respectively.^{108,113,114} These genes encode subunits of the core binding factor (CBF), a regulator of normal hematopoiesis. The t(8;21) translocation generates a novel fusion protein, AML1/ETO, which combines the DNA-binding properties of AML1 with the protein-binding properties of the product of the ETO gene. This fusion results in abnormal protein–protein signaling, blocking the normal function of AML1 in the transcriptional regulation of hematopoietic development. The chimeric protein continues to interact with CBFβ and bind DNA at the core enhancer sequence. However, the presence of ETO in the chimeric protein leads to the recruitment of proteins involved in transcriptional repression, similar to that observed with the PML/RARα fusion observed in APL. The inv(16) abnormality results in the creation of another fusion protein, CBFβ/MYH11, which also disrupts transcriptional regulation through CBFβ. The CBFβ/MYH11 chimeric protein continues to interact with AML1, but inhibits the binding of AML1 to DNA, functionally inactivating this crucial transcriptional regulator. These two different fusion proteins thus affect, in part, a common pathway, the core binding factor pathway, which normally functions as a transcriptional activation complex. Much work is now focused on identification of therapeutic approaches that could target these leukemia-specific fusion proteins.

The t(8;21) translocation is found predominantly in M1 and M2 AML subtypes, whereas the inv(16) mutation is seen most often in the M4 subtype associated with dysplastic eosinophilic precursors (M4Eo).⁷¹ Patients who have inv(16)-positive AML have higher CR rates, superior EFS and better response to therapy after relapse. For this reason, most treatment approaches do not recommend allogeneic hematopoietic stem cell transplantation (HSCT) from HLA-matched family donors in first CR.^{108–110} European and North American pediatric groups have extended this approach to include the t(8;21) subgroup, although there is still considerable data that indicate that allogeneic HSCT from HLA-matched family donors improves outcome for t(8;21) AML.^{11,108–110}

Prognostically intermediate cytogenetics

Patients with normal cytogenetics and those with chromosomal translocations other than those described above have an intermediate prognosis. Although the patients without identifiable mutations by classic cytogenetic analysis have previously been classified as AML “not otherwise categorized” by the WHO, new data have recently emerged concerning the etiology of AML in a substantial number of these patients.¹²⁷ It was found that in approximately 30% of patients (ages 15–60 years) with primary AML and a normal karyotype, mutations occurred in the nucleophosmin (NPM) gene, which encodes a nucleocytoplasmic shuttling protein regulating the Alternative Reading Frame ARF–p53 tumor suppressor pathway.¹²⁷ Mutations often result in the

aberrant cytoplasmic subcellular localization of this protein, which can be easily detected by immunohistochemical analysis. This new finding promises to have both diagnostic and prognostic significance. It may permit the identification of a new subgroup of intermediate-prognosis AML; and given that it was found to be absent in cases of secondary AML, could also be used to differentiate these two entities. The ultimate role of NPM in predicting the outcome of patients with AML and a normal karyotype will await more studies.

The *MLL* (for “mixed lineage leukemia”) gene (also known as *HRX* and *ALL-1*), located on chromosome 11 (11q23), is frequently involved in translocations in AML,^{55,87,90,128–130} with 65% of children diagnosed with AML before their 2nd birthday having 11q23 translocations.⁸⁷ The chimeric *MLL* gene fusions found in AML result from reciprocal translocations involving the portion of the gene encoding the amino-terminal portion of the *MLL* fused to the carboxy terminal region of the product of the partner gene. Nearly 50 *MLL* partner genes have been identified. These fusion proteins disrupt normal *MLL* function, resulting in aberrant control of hematopoiesis through its role as a transcriptional regulator. Of interest, the *Hox* genes, *HoxA9* and *HoxD13*, are known target genes for *MLL* and play roles in hematopoiesis and, when mutated, leukemogenesis.^{131–135} While AML that expresses an 11q23 translocation is often of the M5 subtype, cases of M0, M1, M2 and M4 AML have also been observed. Furthermore, while the prognosis of *MLL* gene rearrangements is worse than for those with *inv(16)* and *t(8;21)* translocations, individual translocation partners can differentially influence prognosis. For example, in a study from St Jude Children’s Research Hospital, the *t(9;11)* translocation responded better to therapy and had a better overall outcome than other 11q23 translocations, particularly *t(4;11)*.¹³⁰ However, the German AML Cooperative Group failed to observe a similarly good prognosis for this *MLL* fusion partner.^{21,32,34,106} The basis of these differences is not known, but could reflect other underlying heterogeneity in the patients studied, including ethnic and racial differences between the European and American study populations.

Translocation between the 11q23 region and the 10p11–13 region represents an example of a translocation resulting in a particularly poor prognosis. Patients with this translocation have shorter durations of first CR and have a much higher rate of CNS relapse compared with other AML patients.¹²⁸ While the molecular mechanisms leading to this poor prognosis are still not completely understood, *MLL* fusion proteins involving two genes found on chromosome 10 (i.e., *AF10* and *ABI-1*) have both been implicated. The mechanisms by which such partner gene products influence the transforming ability of *MLL* remain unknown.

Prognostically poor cytogenetics

Although chromosomal translocations clearly play important

roles in leukemogenesis, abnormalities of individual chromosomes also play an important role in AML. Monosomy 7 or specific deletions of its long arm (7q–) can occur either as a single abnormality or in the context of complex karyotypic abnormalities. This abnormality, whether found in the context of myelodysplasia or AML, carries a very poor prognosis.^{7,86,106,109,110} In the CCG-2891 study, only 53% of AML patients with monosomy 7 achieved remission, compared with the 78% overall remission rate. EFS for this group was 19% at 6 years compared with 39% overall. However, overall survival for patients with monosomy 7 (47% at 6 years) was no different than for the general AML population (46%). This is thought to be possibly explained by the fact that many of the relapsed monosomy 7 patients can be rescued by bone marrow transplantation, suggesting a robust graft-versus-leukemia effect.^{7,11,12,136} Given the poor prognostic characteristics associated with this chromosome abnormality and the efficacy of HSCT in this population, monosomy 7 AML is an indication for stem-cell transplant in first CR, even if a matched unrelated donor is all that is available.^{109,110}

Monosomy 5 and *del(5q)* abnormalities, while exceedingly rare in the pediatric population, also portend a poor prognosis, with decreased responsiveness to induction chemotherapy and decreased length of time in first CR if response to induction does occur. The trisomy 8 mutation is found both in isolation and also in association with complex karyotypic abnormalities. Whereas most data indicate that patients with trisomy 8 in isolation do not show a particularly aggressive disease, when combined with other cytogenetic abnormalities, trisomy 8 may contribute to poor response to therapy and poor EFS.^{71,137}

FLT3

In addition to chromosomal deletions, additions and translocations, the impact of specific biologic markers of disease responsiveness or resistance to chemotherapeutic regimens is becoming increasingly important. Activating mutations of the class I receptor tyrosine kinases, including mutations in the *FLT3*, *c-KIT* and *c-fms* genes have shown promise as potent indicators of poor prognosis. *FLT3*, in particular, has been intensely studied.^{111,138–145} Multiple reports have shown that the presence of internal tandem duplication of *FLT3* (*FLT3/ITD*) identifies pediatric and adult patients with particularly poor outcomes. These mutant *FLT3* genes result in constitutively active *FLT3* tyrosine kinase activity, which contributes to leukemogenesis and chemotherapy resistance.^{111,146} Indeed, remission induction in pediatric studies has been reported to be as low as 40% in patients expressing *FLT3/ITD*, in contrast to the overall rate of remission induction for AML, which is now reported as 70–85%.¹¹¹ While *FLT3/ITD* interferes with remission in some studies, there are also some AML patients who express *FLT/ITD* and who do well with conventional chemotherapy.¹⁰⁰ One

hypothesis to explain this is that the effect of FLT3/ITD is modified by the presence or absence of a normal *FLT3* allele.¹⁴⁷ Current studies are examining the effect of the ratio of normal to mutated *FLT3* on treatment outcome to determine if an informative ratio can be used to identify those patients at highest and lowest risk for treatment failures. Future therapies are being tested in terms of targeting the FLT3 pathway for therapeutic intervention.

Principles of therapy

Historical overview

Current chemotherapeutic regimens for treating children with AML follow five treatment principles.⁵

- Aggressive induction therapy improves induction success rates as well as long-term survival.
- Consolidation or intensification therapy after remission is achieved is important for long-term disease-free survival.
- Maintenance therapy may give results comparable with the use of consolidation or intensification therapy, but it does not have a role in patients receiving aggressive postremission therapy.
- The type of treatment or prophylaxis for CNS leukemia does not appear important in influencing long-term survival.
- Targeted treatment of other extramedullary disease appears not to affect long-term survival.

The mainstay of treatment remains cytoreduction and remission induction through conventional chemotherapeutic regimens. The introduction of both AraC and anthracyclines for the treatment of AML in the early 1970s transformed a once uniformly fatal illness into one that was curable in a small percentage of patients.^{9,10} Regimens employing dose intensification and improved supportive care measures have increased rates of remission induction and EFS. However, refractory AML is still the cause of death in nearly half of all children that it affects.

Chemotherapy phases consist of remission-induction therapy, CNS prophylaxis and postremission therapy. The initial trials for treatment of AML were modeled after the successful strategies for ALL: namely, intensive induction therapy to induce remission followed by a prolonged maintenance course including cranial radiation. However, unlike ALL, after an intensive consolidation/intensification phase of treatment, maintenance therapy did not lead to increased overall survival, but rather, to AML resistant to salvage therapy in the event of relapse.^{16,148,149} Most current protocols have increased the intensity of induction therapy while eliminating maintenance therapy.

The Goldie–Coldman hypothesis represented a fundamental paradigm shift in the treatment of AML.^{150–152} This hypothesis stated that the early use of potent combinations of non-cross-resistant drugs delivered simultaneously and

in sequential rotation would provide a more potent anti-leukemic effect. In comparison with the first attempts at monotherapy or limited combination chemotherapy, this strategy was significantly more successful, leading to an increase in the 5-year survival estimates from less than 10% to 25–35% during the 1970s and 1980s. This approach represents the platform upon which more contemporary AML trials are built.

The first successful AML combination therapy was called “7 and 3”; it included 7 days of AraC at 100 mg/m²/day continuous infusion and 3 days of daunorubicin at 30–60 mg/m²/day. One or two courses of “7 and 3” induced remission (defined as < 5% AML blasts present in the bone marrow by morphologic analysis in the presence of recovery of trilineal hematopoiesis) in about 75–80% of children.^{149,153} The CCG-213 trial compared “7 and 3” with a five-drug combination called “Denver,” which added etoposide, thioguanine and dexamethasone to the AraC/daunorubicin backbone of the “7 and 3” regimen. There was no statistically significant difference in remission induction rate or long-term outcome with the five-drug regimen.^{6,16,149,153} Dose escalation of AraC has also played an important role in improving survival of patients with AML, particularly in some good prognostic subsets.^{12,108} The introduction of non-cross-resistant anthracyclines (idarubicin, mitoxantrone, amsacrine) to the AraC backbone, as well as the number of chemotherapy courses, may also have contributed to the increase in survival observed over the last decade.^{9,32,154,155}

The MRC AML-10 and AML-12 trials (Fig. 16.4)

Several trials performed subsequent to the introduction of the “Denver” regimen achieved induction remission rates higher than the historical 75–80% of “7 and 3.” The Pediatric Oncology Group (POG) trial 8821 used “7 and 3” plus 6-thioguanine (TAD) and reported a remission induction rate of 85%.⁹⁰ The Medical Research Council (MRC) AML-10 trial randomized patients to receive either DAT (daunorubicin/AraC/6-thioguanine) or ADE (AraC/daunorubicin/etoposide) for two courses, followed by two subsequent chemotherapeutic courses of MACE (amsacrine/AraC/etoposide) and MidAC (mitoxantrone/AraC). After these four mandatory courses of dose-intensive chemotherapy, patients were biologically randomized to allogeneic HSCT if they had an HLA matched-sibling donor, or, if not, were entered into another randomization of either no further therapy or autologous HSCT.^{18,20,29,108,110} This study showed that the dose-intensive four courses of chemotherapy were highly effective in inducing first CR; no significant difference in CR was observed in children receiving either the DAT or ADE for induction therapy. Overall, AML-10 reported 92% CR after four cycles of chemotherapy; 63% of patients achieved CR after one cycle, an additional 20% achieved CR after two cycles, 7% after three cycles and 2% after four cycles. Thus, these

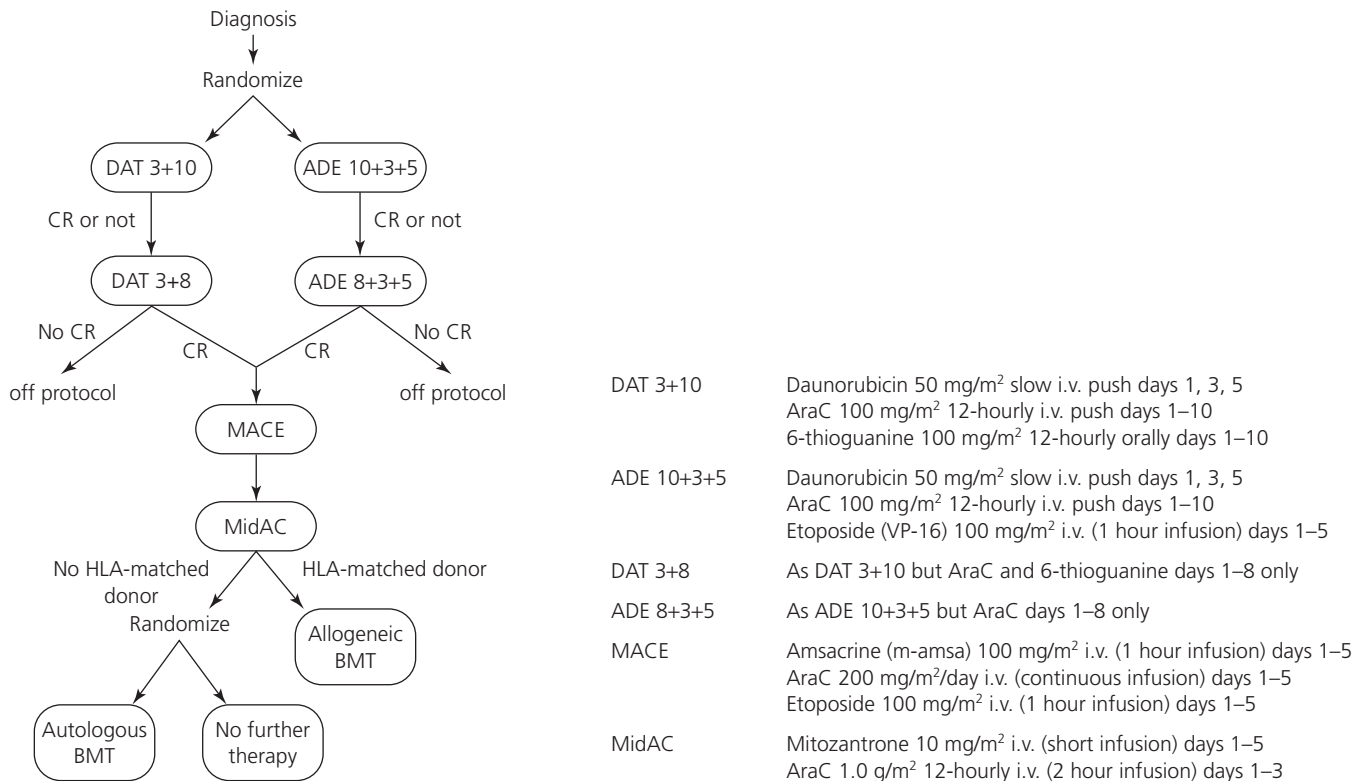

Fig. 16.4 Treatment algorithm followed by the AML-10 trial. AraC, cytarabine; BMT, bone marrow transplant; CR, complete remission.

outcomes are very similar to the results reported by both the POG-8821 and the CCG-2891 trials, which demonstrated ~80% CR after two cycles of induction chemotherapy.

Of the patients achieving CR during the MRC AML-10 trial, 6% died during induction, mostly of toxic deaths. The relapse rate was relatively low, with a 26% rate of relapse in the first year following CR, which dropped to 11% in year 2, 3% in year 3, and 2% in year 4. Overall survival in this study was also good, with a reported 59% of patients alive after 5 years. While AML-10 showed that both allogeneic and autologous HSCT reduced the risk of relapse after therapy when compared with a “no further treatment” arm, a statistically significant overall survival benefit was not detected. This was likely due to the increased number of treatment-related deaths after HSCT. However, disease-free survival (DFS) was significantly greater in the HSCT group compared with the “no further treatment” group (50% vs. 42%, $P = 0.01$).

Nearly all multicenter trials performed to date have shown a survival benefit for allogeneic HSCT compared with chemotherapy, although, like the MRC AML-10 trial, some of these studies were not sufficiently powered to reach statistical significance.^{10–14,19,23,32,34–36,154,156,157} While the MRC AML-10 trial reported a survival advantage for those patients undergoing autologous HSCT, it is important to note that this survival advantage occurred when these patients were compared with those who received no more chemotherapy.

Thus, those in the autologous transplant arm received an additional cycle of intensive chemotherapy compared with those not randomized to receive the transplant. In the CCG-2891 trial, where autologous HSCT was compared with further chemotherapy, autologous transplantation did not confer a survival advantage, whereas allogeneic HSCT improved both disease-free and overall survival.¹¹ Similar results were found in the POG-8821 trial.²³ Although autologous HSCT may be less effective because of the reinfusion of viable leukemic cells,¹⁵⁸ these results also implicate a potent graft-versus-leukemia effect for AML. This concept is supported by data also reported by the CCG, which correlates graft-versus-host disease (GVHD) – as a surrogate marker for graft-versus-leukemia (GVL) – with increased survival after allotransplantation.²⁴

MRC AML-10 resulted in the UK cooperative establishing three different risk groups for childhood AML.^{18,29,108} The first is a good-risk group, which includes patients with favorable cytogenetic abnormalities, including t(8;21), t(15;17) and inv(16). The second is a poor-risk group, which includes those with a partial ($\geq 15\%$ leukemic blasts) or no response after course 1 of chemotherapy and those with adverse cytogenetic abnormalities, including monosomy 5, monosomy 7, del(5q), abnormalities of 3q, or complex karyotypes containing more than four chromosomal abnormalities. The remainder of patients are classified as standard-risk. MRC AML-10 noted that outcome differences for the three risk groups were

significant: Good-risk patients had 78% survival from first CR, while standard-risk patients displayed 60% survival and poor-risk patients had only a 33% survival. Survival from first relapse was also significantly different between the three groups: good-risk patients had a 61% survival from relapse, while standard-risk patients only had a 17% survival and poor-risk patients displayed 0% survival from relapse. As discussed below, this risk-stratification has directed the UK collaborative group's treatment decisions in subsequent trials. While MRC AML-10 did not detect a statistically significant difference in overall survival between the three final treatment arms, there was increased DFS for autologous HSCT when compared with no further therapy. Because those receiving autologous HSCT received an additional intensive cycle of chemotherapy compared with those randomized to no further therapy, this result implied that further chemotherapy alone might also lead to increased DFS in AML. Thus, in MRC AML-12, patients were randomized to receive either four or five rounds of chemotherapy, to determine whether this extra course would produce improved survival. Early results have not confirmed an advantage in MRC12 for five courses of therapy, thus leading the MRC group to propose four dose-intensive courses of chemotherapy.¹⁵⁹

The AML BFM-93 trial

The German-based BFM-87 trial also led this cooperative group to establish a risk profile for newly diagnosed AML.¹⁶⁰ Two prognostic groups were identified, which were based both on initial morphologic parameters as well as on the efficacy of induction therapy to produce blast cell reduction in the bone marrow on day 15. The standard risk group included FAB M1 or M2 subtypes, the presence of Auer rods, as well as FAB M3 and FAB M4Eo with $\leq 5\%$ blasts in the bone marrow on day 15. High-risk patients included all others, plus patients initially allocated to the standard-risk group but whose day-15 bone marrow showed $> 5\%$ blasts. Patients with FAB M3 were always treated as standard risk, regardless of their blast count on day 15. The BFM-93 trial was designed to determine whether the addition of consolidation chemotherapy consisting of high-dose AraC and mitoxantrone ("HAM") could improve EFS for the high-risk patients, who had been found to do relatively poorly when treated according to BFM-87 (5-year EFS, 31%).^{21,32} The trial, whose design is shown in Fig. 16.5, included two randomized study questions: (i) the relative efficacy of idarubicin versus daunorubicin in producing an induction CR; and (ii) the relative effect of "early HAM" therapy prior to consolidation or "late HAM" postconsolidation on survival and toxicity. Each of these study questions enrolled only those patients assigned to the high-risk stratification.

BFM-93 demonstrated excellent outcomes, both in CR and EFS: 82% of patients (both standard and high risk) achieved a CR, and overall 5-year EFS was 51%. While the idarubicin-

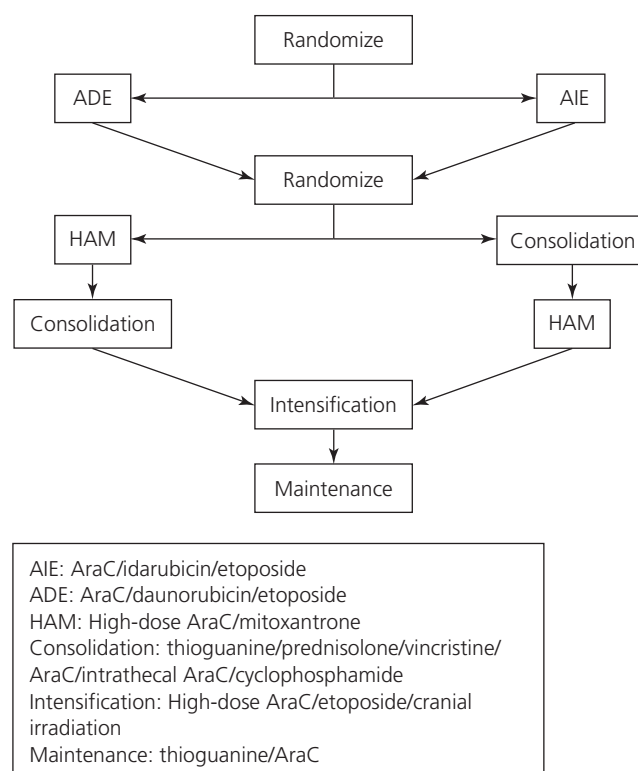

Fig. 16.5 Treatment algorithm followed by the BFM-93 trial. AraC, cytarabine.

based induction regimen showed significantly better blast reduction on day 15, the 5-year EFS and DFS for the idarubicin and daunorubicin arms were similar. Infection rates and length of pancytopenia for the idarubicin arm showed a trend toward being longer, but the differences did not reach statistical significance. The overall results of patients randomized to early versus late HAM were also similar: 5-year EFS of $52 \pm 5\%$ (early HAM) versus $45 \pm 5\%$ (late HAM) were observed. However, the timing of HAM was more important in those patients who received daunorubicin during induction rather than idarubicin: 5-year EFS of $51.9 \pm 7.4\%$ for daunorubicin plus early HAM versus $35.6 \pm 7.3\%$ for daunorubicin plus late HAM ($P = 0.05$). These results indicate that in the setting of reduced early blast reduction with daunorubicin, early escalation of dose intensity with HAM (expected to give significant blast reduction) could be an important mediator of stable remission status. Given the efficacy of HAM treatment demonstrated in BMF-93, and its acceptable toxicity profile, it was incorporated into the BFM-98 study, and its use extended to standard-risk patients as well.

The CCG-2891 trial (Fig. 16.6)

The CCG-2891 trial was the first to test in a randomized design the hypothesis that time-intensity of drug delivery might be an important approach to intensification. This

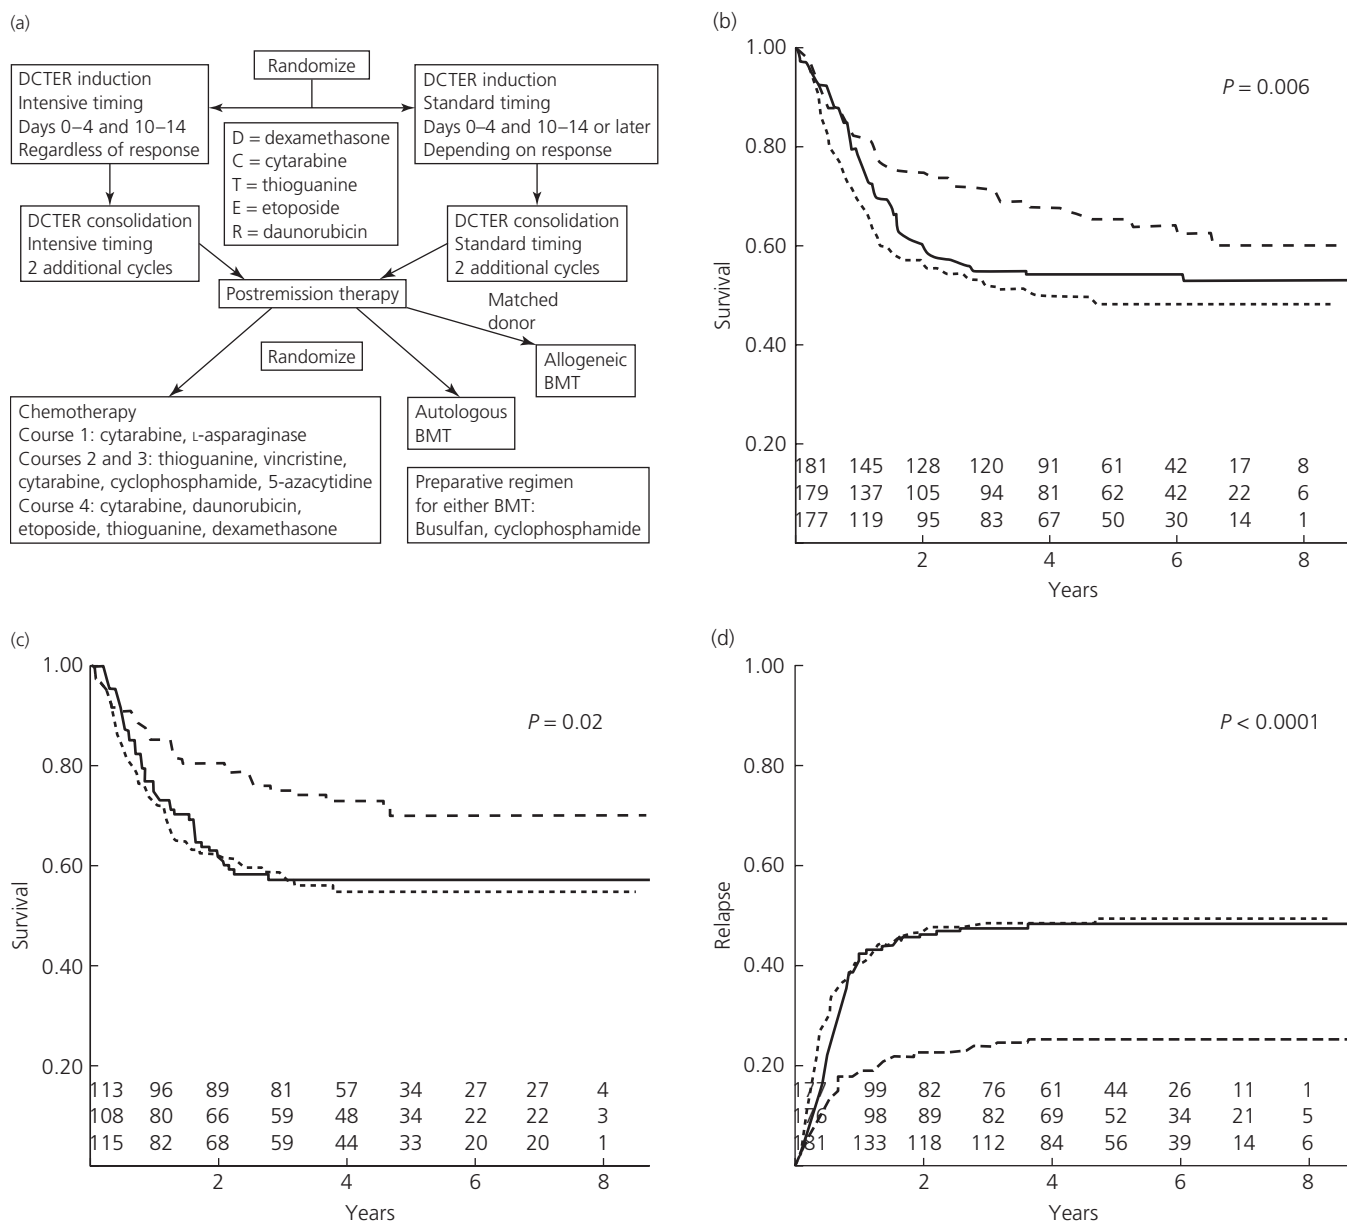

Fig. 16.6 (a) Treatment algorithm followed by CCG-2891. (b) Actuarial survival from AML remission, comparing the three postremission regimens from CCG-2891.¹¹ Dashed line: allogeneic human stem cell transplant (HSCT); solid line: chemotherapy; dotted line: autologous HSCT. (c) Actuarial survival from AML remission for the CCG-2891 patients who received intensive-timing induction therapy, comparing the three postremission regimens.¹¹ Dashed line: allogeneic HSCT; solid line: chemotherapy; dotted line: autologous HSCT. (d) Actuarial probability of relapse after AML remission, comparing the three postremission regimens from CCG-2891.¹¹ Dashed line: allogeneic HSCT; solid line: chemotherapy; dotted line: autologous HSCT.

hypothesis was based on previous preclinical *in vitro* studies that had documented that AML blasts show maximal recruitment and synchronization into S phase 6–8 days after cessation of AraC.^{161,162} CCG-2891 therefore tested a kinetically based, timed-sequential approach to induction therapy to determine whether timing of chemotherapy delivery could produce a “better quality” first CR, which had a reduced propensity for relapse.^{12,13,15,24}

CCG-2891 compared standard timing of a five-drug

induction regimen called DCTER – dexamethasone, AraC, 6-thioguanine, etoposide, rubidomycin (also known as daunorubicin) – with intensive timing of DCTER. With standard timing, the second course of DCTER was given only after hematologic recovery unless a bone marrow exam performed at day 14 showed residual leukemia (in which case, the second course was given immediately). Intensive DCTER was given on days 0–3 and repeated on days 10–13 regardless of marrow status. Remission induction rates were similar

between the two arms: 78% with intensively timed therapy and 74% with conventionally timed therapy. Furthermore, induction mortality was higher with intensively timed therapy, especially prior to the institution of mandatory hospitalization during the period of pancytopenia and cytokine support with granulocyte colony-stimulating factor (G-CSF) (although these improvements in mortality were not subjected to randomized analysis). However, despite the similarities in rates of remission-induction, the 8-year EFS was significantly higher for intensive compared with standard timing (43% vs. 27% respectively, $P = 0.008$). These results suggest that not all remissions are equal, and that increased intensity of induction therapy may be one way to achieve a higher “quality” remission, that is, a remission that is more likely to continue without relapse.

Targeted therapy for APL

APL is distinguished from the other AML subtypes both by its distinct cytogenetic abnormality, $t(15;17)$, and by the targeted therapy that is now the standard-of-care for its treatment.¹⁶³ ATRA is central to the treatment of this AML subtype, due to the ability of ATRA to induce differentiation of the APL leukemic blasts into mature granulocytes.^{126,163–166} Current treatment paradigms lead to excellent results for APL in children: CR rates have most recently been reported at about 96%, with 10-year EFS of 76%.¹²⁶ The treatment of APL benefits from the ability to measure MRD with high sensitivity, by performing PCR for the disease-specific PML-RAR α transcript. The ability to measure this transcript allows patients to be categorized by the presence or absence of molecular remission, and to have their treatment modified accordingly. Those in molecular remission have a high continuous CR rate, while those in molecular relapse, despite morphologic remission, almost uniformly progress.¹²⁶ For these patients, reinduction therapy followed by HSCT (either auto- or allo-transplantation) has been successful.^{126,167,168} The unique biology of APL has led to important differences in the therapy for this disease compared with other AML subtypes. In addition to the efficacy of ATRA therapy, APL patients, unlike patients with other AML subtypes, have been shown to benefit from maintenance chemotherapy, as long as this maintenance therapy contains further treatment with ATRA.¹²⁶ Furthermore, in patients with APL, auto-HSCT has been shown to be beneficial, if it is performed with cells that are demonstrated by PCR to be PML-RAR α -negative.^{163,167–170} Thus, in one study, 7 of 7 patients receiving auto-HSCT with PML-RAR α -positive marrow relapsed within 9 months, while only 1 of 8 patients transplanted with PML-RAR α -negative marrow experienced a relapse.¹⁶⁸ In another report, 3 of 28 patients receiving PML-RAR α -negative auto-HSCT subsequently relapsed while one of two patients receiving PML α -positive auto-HSCT recurred.¹⁶⁷ These results, although representing small numbers of patients, underscore the

power of MRD detection to direct treatment for APL, and to improve outcome, even for those patients with relapsed disease. Recently, arsenic trioxide has been added to the collection of unique agents able to treat APL, and is currently in trials in both adult and pediatric patients (reviewed in refs 171–173). While the precise mechanisms by which arsenic works to induce remission in APL are not completely known, it has been shown to produce degradation of the PML-RAR α fusion protein, increase cellular apoptosis and induce differentiation of the APL leukemic clone. Whether it will show increased efficacy with acceptable toxicity in pediatric patients when combined with ATRA-based therapy is currently under investigation.

Gemtuzumab ozogamicin

Current trials from both North America and Europe are testing the efficacy of gemtuzumab ozogamicin (GO), a recombinant humanized anti-CD33 monoclonal antibody linked to the genotoxic antibiotic calicheamicin, in eliminating AML blasts. CD33 is a cell-surface protein that is expressed on both normal and leukemic myeloid progenitors, but appears to be absent from the pluripotent hematopoietic stem cell. Calicheamicin belongs to a class of potent antitumor antibiotics that were originally identified by their ability to damage double-stranded DNA. This antibody-toxin conjugate is able to kill CD33⁺ myeloid precursors, because the CD33 molecule is internalized after binding to the monoclonal antibody, thus allowing efficient intracellular delivery of the DNA-damaging agent.^{174–179} Both single-agent studies and studies in which GO was combined with conventional chemotherapeutic agents in both adults and children have documented efficacy.^{178–184} This agent is now being tested in both pediatric and adult phase II/III trials.

Although GO promises to be highly efficacious in selectively targeting AML blasts, liver toxicity has occurred in adult randomized trials in combination with chemotherapy when higher doses (6 and 9 mg/m²) of this drug are used.^{177,184–187} This toxicity is manifested as both hypertransaminemia and hyperbilirubinemia. There is also a risk of hepatic venoocclusive disease. In the MRC AML-15 pilot study, the addition of 6-thioguanine to a GO-containing regimen was a significant risk factor in the development of liver toxicity, when compared with other chemotherapeutic combinations.¹⁸¹ This pilot study also showed that GO at 3 mg/m² was well tolerated, but that dose escalation beyond 3 mg/m² was not feasible when GO was included with the intensive combination chemotherapy regimens tested. Given these results, the new COG pilot study uses GO at 3 mg/m² in combination with an MRC-based ADE induction regimen (Fig. 16.7). A critical question will be whether GO results in improved outcome through targeting a self-renewing leukemic stem cell or whether GO will only be an effective cytoreduction agent.

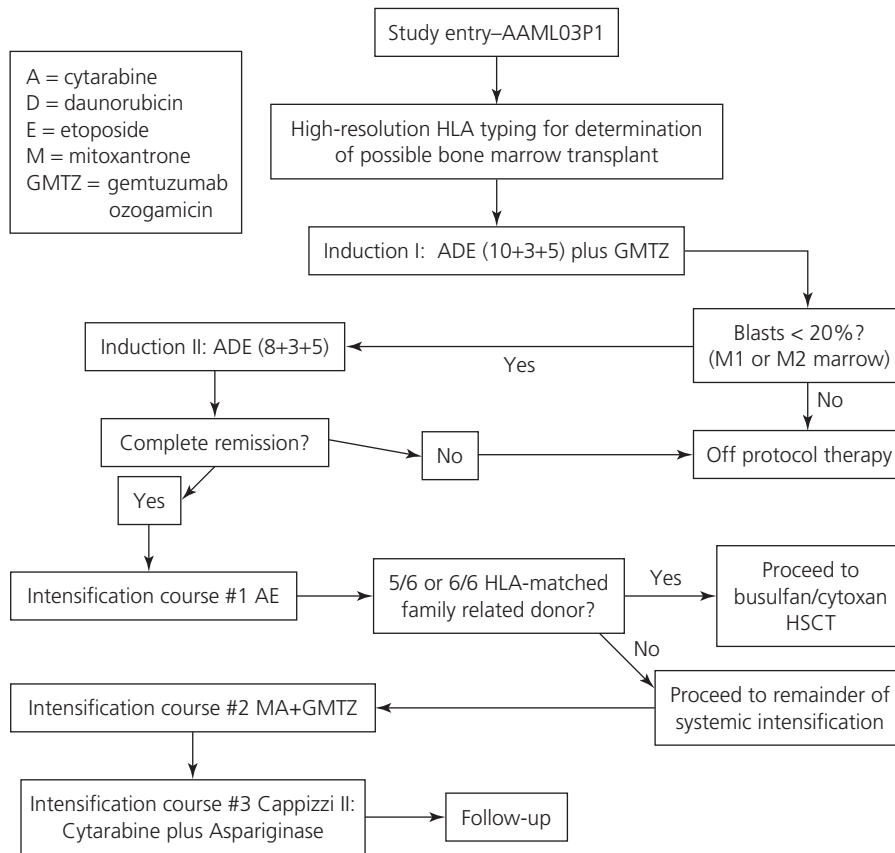

Fig. 16.7 Treatment algorithm for AAML03P1. HSCT, hematopoietic stem cell transplant. Cappizzi II includes high dose cytarabine and h-Asparaginase.

Allogeneic HSCT as consolidation therapy for AML

The most intensive postremission therapy that is available for AML is high-dose chemotherapy with or without total body irradiation (TBI) followed by stem cell transplantation. Several studies have been designed to test whether chemotherapy, autologous HSCT or matched-sibling allogeneic HSCT was more effective in increasing survival following remission with intensive induction therapy for AML.^{2,3,11–13,18,20,21,23,24,31,37,153} The CCG-2891 study reported the highest compliance with receiving the assigned treatments as determined by randomization. In this study, a total of 537 children were analyzed, of whom 181 received allogeneic HSCT, 177 received autologous HSCT and 179 received chemotherapy. Allogeneic HSCT was statistically superior to either autologous HSCT or chemotherapy in terms of overall survival: 60% survival after 8 years for allogeneic HSCT versus 53% and 48% survival for chemotherapy or autologous HSCT (see Fig. 16.6b,d).¹¹ Results in those patients receiving intensively timed DCTER chemotherapy showed a similarly superior efficacy of allogeneic HSCT, with a 72% survival for allogeneic HSCT versus ~ 60% survival with either chemotherapy or autologous HSCT (see Fig. 16.6c).¹¹ These results showed a statistically significant

survival difference compared with either of the other two treatments whereas survival differences for HSCT after the latter two treatments were not statistically different.

The mechanism of this improved survival after allogeneic HSCT may be related to a GVL effect. Neudorf *et al.*²⁴ recently showed, in an analysis of the CCG-2891 data, that grade I–II GVHD positively correlated with improved survival after allogeneic HSCT, suggesting that there was a GVL effect secondary to the GVHD. Likewise, Nordlander *et al.*¹⁸⁸ showed that in their single-institution experience, chronic GVHD also predicted better DFS after allogeneic HSCT for AML. Taken together, these results provide strong support for the role of an immunologic antileukemia effect and for matched sibling allogeneic HSCT in first remission for AML in children. Importantly, in the CCG studies, with the exception of t(15;17)/M3 and inv(16) AML, neither FAB subtype nor cytogenetic subtype analysis changed the positive results of allogeneic HSCT when compared with other postremission therapies.¹¹ The MRC cooperative group has been more cautious about using HSCT in first remission. Given the toxicity and procedure-related mortality associated with allogeneic HSCT, the MRC cooperative group currently recommends that patients in the good-risk group (which includes those with t(8;21) in addition to t(15;17) and inv(16)) do not receive HSCT until after the first relapse and induction of second

remission; those in the standard- and poor-risk groups should receive HSCT in first CR if a matched sibling is available.^{108,110,189} A major challenge that remains is to determine how to accrue significant numbers of patients in rare subgroups in order to rigorously test such questions.

Supportive care

Given that AML therapy is intensive and nearly myeloablative, supportive care measures have a large impact on overall survival and morbidity. Current standards of care include mandatory hospitalization for the duration of pancytopenia, with prompt initiation of an empiric antibiotic regimen for fever, which includes initial use of vancomycin for α -streptococcal coverage.^{190,191} Antifungal prophylaxis is standard, as is prompt initiation of empiric antifungal treatment for prolonged fever without a source. Nutritional support is important, in addition to routine transfusional support with both platelets and packed red blood cells. The CCG-2891 study showed that cytokine support with G-CSF did not affect the incidence of grade 3 and 4 toxicities, infections, or fatal infections, and that induction remission rates, overall survival, and EFS were similar with and without G-CSF.¹⁹² For these reasons, G-CSF is not currently a mandated component of AML supportive care. However, CCG-2891 provided data from a nonrandomized comparison that those patients who received G-CSF demonstrated a significantly shorter time to neutropenic recovery and that the use of G-CSF reduced the median length of induction by 9 days and hospital stay by 6 days.¹⁹² Randomized trials may better determine the role of cytokine therapy in pediatric AML.

CNS prophylaxis

CNS involvement with AML occurs in approximately 20% of cases, with the highest incidence in patients with very high peripheral WBC or with M4 and M5 subtypes. All current treatment protocols for pediatric AML utilize CNS prophylaxis, either with intrathecal AraC, triple therapy including AraC, methotrexate and hydrocortisone, or, in trials performed through the BFM Cooperative group, cranial radiation. These treatments, along with high-dose systemic AraC, result in good control of CNS leukemia, with the incidence of CNS relapse reported as approximately 5%.^{3,5,11,12,18,20,21,29,193} While all of the original trials included cranial radiation as part of CNS prophylaxis, current trials in the UK and the USA have eliminated this modality. The BFM Cooperative group has continued to include cranial radiation in its treatment regimens. This decision stems from a somewhat surprising result that arose from the BFM-83 trial, which showed an effect of cranial radiation on systemic rather than CNS relapse.^{21,194} In this trial, a statistically significant increase was observed in the number of patients experiencing systemic relapse in the absence of cranial radiation. Of note, in

the BFM trial, the difference in systemic relapse was noted only in patients who did not undergo randomization; no difference in systemic relapse was noted when cranial radiation was eliminated in the randomized cohort.

Extramedullary leukemia

Non-CNS extramedullary disease also occurs in AML. These extramedullary leukemic masses, known also as chloromas or granulocytic sarcomas, occur in a variety of anatomic locations in approximately 10% of patients with AML. The most common site is the orbit or the periorbital areas. Chloromas may also involve the spinal cord, where they can lead to symptoms related to cord compression. They are also frequently noted in the skin, and, if present in the lymphatic system, can cause multifocal lymphadenopathy. While EML is often associated with bone marrow disease, it can also present in an isolated fashion, and may precede bone marrow involvement by up to 1–2 years. EML is most commonly seen with M4 and M5 subtypes of AML, but is also seen in M1 and M2 AML.^{5,30,193,195} Without systemic treatment, bone marrow involvement will eventually occur. Thus, even if diagnosed in isolation, extramedullary disease requires intensive AML therapy.^{5,30,193} Several studies have shown that patients with isolated extramedullary disease do exceedingly well with AML therapy.^{12,193}

Historically, when EML was present, local control in the form of radiotherapy was often added to systemic chemotherapeutic regimens. However, a recent retrospective of CCG-2891 results concluded that there was no difference in recurrence in those patients with chloromas who received radiation therapy in addition to systemic therapy and those patients who only received systemic therapy.¹⁹³ Therefore, radiation therapy is not currently recommended for patients with extramedullary AML, unless a chloroma is creating a life-threatening situation, due to obstruction or compression of vital structures.

Secondary AML

With the increasing number of survivors of other childhood cancers, there is a growing number of children and adolescents who are diagnosed with secondary AML. Known treatment-related risks of AML (primarily of the monosomy 7 subtype) include exposure to radiation or alkylating agents such as cyclophosphamide, ifosfamide, nitrogen mustard and melphalan. These secondary AML cases usually have a peak incidence 4–7 years after the initial genotoxic exposure.⁵⁴ Treatment regimens that use epipodophyllotoxins, such as VP-16, clearly lead to an increased risk of AML with 11q23 abnormalities involving the MLL gene. These MLL secondary leukemias usually develop 2–3 years following exposure.⁵⁵ Evaluation of patients treated for secondary AML on the CCG-2891 trial⁵⁴ demonstrated that these patients

were older at presentation than those presenting with *de novo* AML, had lower WBC and were more likely to have preceding myelodysplastic syndrome. Patients with secondary AML had a poor induction rate (50%) and overall survival (26%). If remission was successfully achieved, patients with secondary AML demonstrated lower (but not statistically significantly different) rates of DFS (45%) compared with those in whom AML was the primary diagnosis. These results are, however, possibly misleading due to the small number of such patients.

Down syndrome and AML

Children with DS have an approximately 15-fold higher risk of developing leukemia than the general population. Furthermore, in DS children younger than 2 years old, there is a greater than 400-fold increased risk of developing megakaryoblastic leukemia compared with the general population.^{3,41,196} In addition to their increased propensity to develop AML, approximately 10% of patients with DS will develop transient myeloproliferative disorder (TMD), which is clinically indistinguishable from AML.^{197–199} However, TMD is distinguished from true AML by the fact that the majority of these patients undergo a spontaneous regression of their disease. Nevertheless, children with TMD may experience significant morbidity and mortality. Some patients with DS and TMD or megakaryoblastic leukemia may present with severe organ infiltration, particularly of the liver. Hydrops fetalis may develop in the most severe cases.

As many as 30% of DS patients with TMD will go on to develop AML.^{197–204} In these cases, karyotypic evolution of the leukemic clone may be seen coincident with the development of the megakaryoblastic leukemia. The progression from TMD to AML may be explained by the multiple gene mutating hypothesis. For example, patients with DS are thought to start with “one genetic hit” given their constitutional trisomy 21. Subsequent mutations involving the GATA-1 transcription factor are found in nearly all patients with DS and TMD or megakaryoblastic leukemia. Additional chromosomal abnormalities may then develop leading to true AML.^{197–204} The observation of cytogenetic evolution of the TMD clone upon progression to AML, and the fact that many more DS patients develop TMD (10%) than AML (1%), support this multiple-hit hypothesis.

Children with DS have a superior response to AML therapy when compared with other children. This was shown in the POG-8498 trial, wherein the 12 DS patients enrolled had an EFS of 100%.¹⁹⁶ The CCG-213 trial reported similar results, with 80% overall survival for DS children compared with 40% survival with non-DS patients.¹⁵³ In the CCG-2891 trial, DS children did better when placed on the standard arm of therapy, in contrast with the general population, which showed improved EFS when on the intensive-induction protocol. This difference was attributable to the increased tox-

icity observed in the children with DS when given intensively timed therapy.^{205–210} DS children placed on the intensive-timing arm of CCG-2891 experienced 33% treatment-related mortality with only 5% persistent disease. Those patients on the standard arm showed similar results for CR induction with much less treatment-related mortality.¹² Similarly, children with DS allocated to HLA-matched-related HSCT on CCG-2891 did significantly worse than those randomized to receive chemotherapy with high-dose AraC, with an overall relapse-free survival of 67% compared with 91% in the chemotherapy arm. All of these studies have thus shown that patients with DS have an excellent DFS and overall survival with less therapy than other children with AML.

Treatment of refractory/recurrent AML

Although current treatment strategies for AML routinely yield remission rates above 80%, only about 50% of children with AML are long-term survivors.^{11,19,211,212} In general, patients who relapse, or who have disease that is refractory to remission induction, are less responsive to reinduction therapies, and, if they achieve a second remission, stay in remission for shorter periods than their first remission. Only a small proportion (~20%) of these patients become long-term survivors.^{213,214} Those patients who experience longer periods in CR prior to relapse (i.e., > 1 year) do better, with a 5-year survival for this population of 30–40%.^{211,213} While there is no standard therapy for relapsed patients, most regimens now rely on high-dose AraC in combination with other agents, including etoposide, mitoxantrone, idarubicin, fludarabine or GO.^{186,215,216} Given the poor results when chemotherapy alone is used to treat relapsed or resistant disease, allogeneic HSCT is used for these patients whenever possible. Allogeneic HSCT from HLA-matched family or unrelated donors offers the only curative therapy for such patients at this time.^{217–219} Other marrow stem cell sources include cord blood or haploidentical donors, although the latter are much less studied. While allogeneic HSCT promises an increased chance at long-term survival (up to 50% in some subgroups), there is also the risk of acute and chronic treatment-related morbidity and mortality.^{220–223} In most studies, the treatment-related mortality associated with alternative-donor transplants ranges from 30 to 50%.^{221,224,225} Furthermore, the presence of minimal residual disease adversely affects the results of either autotransplant or allotransplant, further decreasing the efficacy for these patients with highly resistant disease.^{226–232} These results underscore the need to develop novel therapies that are able to overcome chemotherapy resistance.

Late effects

With increasing numbers of pediatric patients becoming

long-term survivors of AML, there is a growing need to analyze late effects and offer appropriate treatment. Although no large study of this patient population has been published, several smaller group and single-institution retrospective analyses are available.^{233–236} With respect to late effects, patients treated for AML can be most accurately divided into four groups:

- those who received chemotherapy alone;
- those receiving chemotherapy and additional cranial or cranial/spinal irradiation;
- those receiving allo-HSCT with a TBI-based preparative regimen; and
- those who received allo-HSCT with a busulfan-based preparative regimen.

All four groups have shown decreased vertical height. Those receiving cranial radiation tended to have increases in weight, while those not treated with cranial radiation had decreased weight, with this being especially prominent in post-HSCT patients. The adverse effect on growth by TBI and HSCT was thought to be multifactorial, with contributions from coexistent endocrinopathies, the effects of chronic GVHD, and the direct growth-limiting effects of radiation on the musculoskeletal system.²³³ While most patients who did not receive TBI-based HSCT progressed through puberty normally and were fertile, those receiving TBI prior to HSCT exhibited high rates of infertility. Furthermore, patients receiving TBI-based HSCT also experienced an increased risk of cataracts and radiation-related dental abnormalities. Cardiac dysfunction was noted in approximately 10% of AML survivors, with the risk correlating with the cumulative dose of anthracycline received. While the number of AML survivors that have been analyzed is small, these patients have also been reported to develop second malignancies, probably due to the carcinogenic effects of both the chemotherapy and radiation-based therapy that they have received.²³³ In one series,²³³ approximately 18% of patients reported neurocognitive deficits, including academic difficulties, decreases in IQ, and subjective problems with immaturity, shyness and low self-esteem. Both the dose of radiation, and the age at which diagnosis and radiation therapy occurred correlated with this increased risk of neuropsychological sequelae. As these first late-effects studies have documented, given the intensive therapy that AML survivors receive in order to cure their primary disease, they are, by necessity, subject to many and varying late effects. These sequelae demand close monitoring and, as the treatment for AML becomes more effective, these effects will undoubtedly influence future therapeutic decisions.

Conclusions

The ability to achieve remission in patients with newly diagnosed AML has significantly increased over the past 40 years

with a > 80% chance of achieving a first remission being a reality. However, resistant disease remains a critical barrier to long-term cure, and approximately half of all pediatric patients will still die of their primary disease. Several key concepts have emerged concerning therapy for pediatric AML:

- intensive cytoreduction is essential for disease control with currently used chemotherapeutic agents;
- timed, sequential therapy is an effective approach to treatment; and
- for most patients, postremission treatment with allogeneic HSCT offers the best chance for long-term cure when there is a matched family donor.

New targeted therapies for AML provide potentially less toxic and more effective treatment approaches. Future trials will test such targeted agents in combination with conventional chemotherapeutic regimens.

Chronic myeloid leukemia

Irene A.G. Roberts and Inderjeet S. Dokal

Epidemiology

Chronic myeloid leukemia (CML) constitutes 2–3% of all childhood leukemias and has an incidence of 0.6–1.2 per million per year in Western countries.^{1–5} The incidence is higher in adolescents (age 15–19 years: 1.2 per million per year³) than in younger children (0–14 years: 0.6–0.8 per million per year^{3,5}). This is similar to the incidence of juvenile myelomonocytic leukemia (JMML), from which CML is now usually readily distinguished because of its distinct clinical, biologic and molecular features (see Chapter 18). In all age groups CML is slightly more common in males than females, with a male to female ratio varying from just over 1.0 to 2.8.^{5,6} CML is exceptionally rare in infancy, although it has been reported in a 3-month-old baby, and more than half of affected children are > 10 years old at diagnosis.⁶

Etiology

Although the molecular basis of CML has been well characterized for some time, its etiology is unknown in the vast majority of children. There is no clear evidence of a hereditary predisposition; with one exception,⁷ identical twins appear to be discordant for the disease and CML is no more common in siblings of affected children. There is also no increased risk of CML in preleukemic chromosomal disorders such as Fanconi anemia and Down syndrome.

In occasional cases, an association with ionizing radiation has been described;⁸ a sevenfold increase in CML, particularly in children under 5 years of age, was reported in Japan following the nuclear explosions in the 1940s. It has also been proposed that the close proximity of the *BCR* and *ABL* genes (see below) during interphase in hematopoietic cells may favor translocations between these genes.⁹ The identification of a DNA repeat sequence on chromosome 9 near the *ABL* gene and on chromosome 22 near the *BCR* gene has led to

speculation that these may be involved in the genesis of the translocation.¹⁰

There are also reports of CML arising in children who are immunosuppressed, including one case in a child with HIV infection,¹¹ and following prolonged immune suppression in association with renal transplantation.¹²

Natural history

As in adults, CML in children is a triphasic disease. The majority of children present in the chronic phase,⁶ the most indolent phase of the disease, which usually responds rapidly to oral chemotherapy and is readily curable by stem cell transplantation (SCT) (see below). In adults the median duration of the chronic phase in patients treated with hydroxycarbamide is around 4 years; there are no comparable data available for children. Transformation of chronic phase to accelerated phase disease is inevitable as a result of additional genetic changes to the abnormal leukemic clone responsible for chronic phase. Accelerated phase is defined on the basis of clinical, hematologic and cytogenetic features as described below. In adults the average duration of the accelerated phase is 6–18 months; comparable data are unavailable for children. CML inevitably further transforms to a rapidly progressive terminal phase known as blast crisis. This behaves as an acute leukemia: the blasts may have predominantly lymphoid morphology (lymphoid blast crisis) or myeloid morphology (myeloid blast crisis). Blast crisis is poorly responsive to chemotherapy and has a high relapse rate after transplantation. The average duration of blast crisis in adults is 3–9 months.

Molecular biology

As in CML in adults, CML in children is characterized by the presence of the Philadelphia (Ph) chromosome in all, or most,

Fig. 17.1 (a) Metaphase showing the normal chromosomes 9 and 22 and the 9q+ and 22q- (Ph) derivatives from the t(9;22)(q34;q11) rearrangement. Kindly provided by Andy Chase. (b) Schematic diagram of the normal chromosomes 9 and 22, and of the 9q+ and 22q- (Ph) derivatives from the t(9;22)(q34;q11). The arrows indicate the breakpoints on 9 and 22 that disrupt the *ABL* and *BCR* genes, respectively. Kindly provided by Junia Melo.

hematopoietic stem cells.^{13,14} The Ph chromosome (22q-) results from the reciprocal translocation of the distal parts of the long arms of chromosomes 9 and 22 (Fig. 17.1). The translocation breakpoints disrupt genes on both chromosomes; the *ABL* (Abelson) protooncogene on chromosome 9 (9q34) and breakpoint cluster region (*BCR*) gene on chromosome 22 (22q11).^{15–18} The consequence of this molecular rearrangement is the formation of an abnormal *BCR-ABL* fusion gene, which encodes a 210-kDa *BCR-ABL* fusion protein (Fig. 17.2). Breakpoints in *ABL* almost invariably occur upstream of exon 1b, between 1b and 1a, or between 1a and a2. The breakpoints in *BCR* usually occur within M-*bcr* (major breakpoint cluster region) (Fig. 17.2).

In around 90% of cases of CML, the Ph chromosome is readily detectable by standard cytogenetic preparations of bone marrow cells; in most of the remaining 10%, chromosomes 9 and 22 appear normal but identical patterns of *BCR-ABL* rearrangement to those found in cases of CML with the Ph chromosome can be clearly demonstrated by molecular techniques. A small proportion of children with CML (probably <5%) either have variant translocations (see below) or no evidence of *BCR-ABL* rearrangement even after extensive investigation at the molecular level.

Despite the fact that the Ph chromosome was first described in 1960 and its molecular basis determined in the 1980s, the exact role played by the novel *BCR-ABL* fusion gene in the pathogenesis of CML remains unclear. Most evidence points to *BCR-ABL* being the major factor determining the leukemic phenotype;^{19–21} however, *BCR-ABL* rearrangement may not always be the initiating step in the development of CML. The identification of families in which several members have developed CML or another malignancy suggests an inherited predisposing factor;⁷ the *BCR-ABL* rearrangement in these cases is likely to represent the second step in the neoplastic process. In addition, both epidemiologic data²² and animal models of CML suggest that a minimum of two mutations are necessary for the development of chronic-phase CML.^{20,21}

It is clear that the p210^{*BCR-ABL*} fusion protein is a potent, constitutively active tyrosine kinase and, like other tyrosine kinases in hematopoietic cells, it is likely to play a direct role in stimulating cell proliferation, perhaps in an unregulated or dysregulated fashion. The functional significance of the reciprocal fusion gene, *ABL-BCR*, remains unknown.²³ The p210^{*BCR-ABL*} fusion protein characteristic of CML is distinct from that seen in Ph-positive acute lymphoid leukemia

Fig. 17.2 Schematic representation of the *ABL* and *BCR* genes disrupted in the t(9;22)(q34;q11). Exons are represented by boxes and introns by connecting horizontal lines. Breakpoints in *ABL*, illustrated as vertical arrows, almost invariably occur either upstream of exon lb, between lb and la, or between la and a2. The *BCR* gene contains 25 exons, including two putative alternative first (e1') and second (e2') exons. The breakpoints in *BCR* usually occur within M-bcr (major breakpoint cluster region), the location of which is shown by the double-headed horizontal arrows. The lower half of the figure shows the structure of the *BCR-ABL* mRNA transcripts. The breaks in M-bcr occur either between exons b2 (e13) and b3 (e14) or between b3 and b4 (e15), generating fusion transcripts with a b2a2 (also referred to as e13a2) or a b3a2 (also referred to as e14a2) junction, respectively. Kindly provided by Junia Melo.

(ALL), in which rearrangement of *ABL* and *BCR* results in a 185-kDa fusion protein, p185^{BCR-ABL} (see Chapter 20).²⁴

The oncogenic potential of the p210^{BCR-ABL} protein resides in the fact that the normally regulated tyrosine kinase activity of the *ABL* protein is constitutively activated by the juxtaposition of the *BCR* sequences. The uncontrolled kinase activity of *BCR-ABL* results in altered signal transduction via interaction with a variety of effectors. The net result of this is deregulated cell proliferation, altered cell adherence and reduced apoptosis. The oncogenic potential of p210^{BCR-ABL} has been demonstrated in a number of *in vitro* and *in vivo* model systems. p210^{BCR-ABL} binds and/or phosphorylates more than 20 proteins, many of which can be directly linked to signal transduction pathways (Fig. 17.3).²⁵ For example, p210^{BCR-ABL} activates RAS, and an intact RAS protein is required for p210^{BCR-ABL} transformation and antiapoptotic activities.^{26–28} Recent advances in our understanding of the biology of CML have been succinctly reviewed by Goldman and Melo.²⁹

Biology

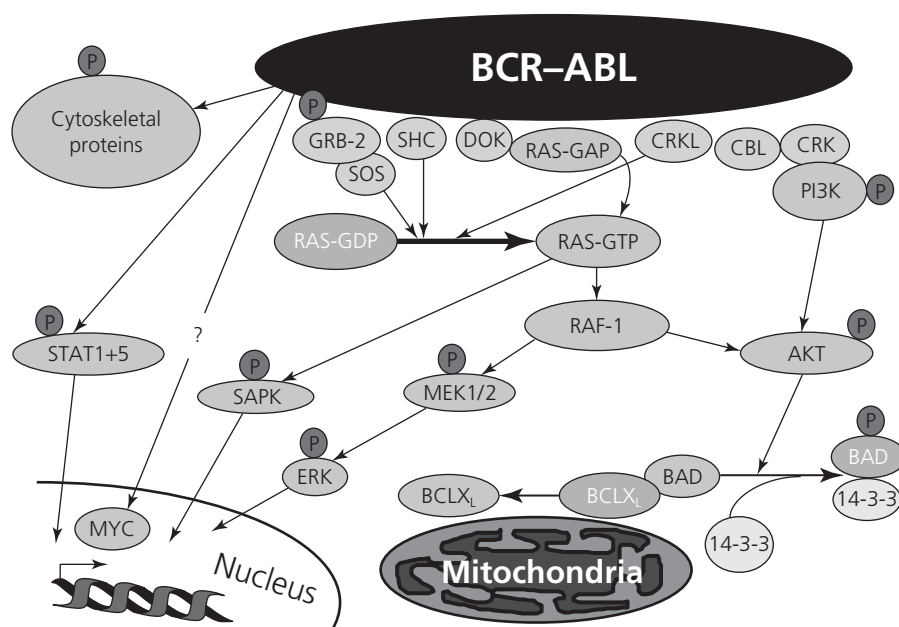

CML, like other hematologic malignancies, is a clonal disorder originating in a multipotent stem cell. This is clear from well-defined subpopulations of stem and progenitor cells studied by immunophenotyping and colony growth *in vitro*

and *in vivo*.³⁰ Thus, the Ph chromosome and/or *BCR-ABL* rearrangement can be demonstrated and expression of *BCR-ABL* is found in progenitor and mature cells of the granulocytic, erythroid and megakaryocytic lineages. In some, but not all, cases B lymphocytes and, less often, T lymphocytes have also been shown to be part of the malignant clone.³¹ This suggests that leukemic transformation in these cases has occurred in a pluripotent lymphohemopoietic stem cell. In other cases, where the lymphocytes do not contain the Ph chromosome, CML may have arisen in a more mature multipotent stem cell, “sparing” the lymphoid lineage. However, the interpretation of such data is difficult and it remains uncertain whether the clonal origin of CML is truly heterogeneous or whether all cases arise in the pluripotent lymphohematopoietic stem cell, lymphocytes without the Ph chromosome representing long-lived cells arising prior to leukemic transformation. An alternative explanation, for which there is some evidence, is that in a proportion of patients with CML defective hematopoiesis precedes the acquisition of the Ph chromosome, that is, the Ph translocation may not be the initiating leukemogenic event.³²

The clinical hallmark of CML is the hyperproliferation of the *BCR-ABL*-containing clone leading to expansion of the granulocytic compartment at all stages of maturation and variable suppression of normal hematopoiesis. Expansion of the abnormal clone presumably occurs because of failure of the normal control mechanisms that regulate hematopoiesis, perhaps as a result of activation of the β -catenin signaling pathway.³³ Interestingly, despite predominantly granulocytic hyperplasia, all lineages and classes of committed progenitor cells appear to be similarly dysregulated. Thus, in addition to granulocyte/monocyte progenitors, erythroid and megakaryocyte progenitors are also increased.

The exact mechanism(s) mediating the expansion of the *BCR-ABL*-positive clone are complex and controversial. Some studies indicate that there is increased proliferative activity of CML stem cells; others that there is increased self-renewal of more mature, committed progenitors, and this does seem more likely than myeloid expansion secondary to enhanced differentiation of progenitor cells.^{30,33–35} There is also some evidence for reduced susceptibility of CML cells to apoptosis,³⁶ although whether this property is relevant to the myeloid expansion in CML is unclear. In addition, CML progenitors have been shown to have diminished adhesive properties, which result in reduced contact with stromal cells, possibly releasing them from physiologic inhibitory regulatory mechanisms.³⁷ Although the exact mechanisms remain unclear, the abnormal growth characteristics of CML cells and their progenitors are thought to be the result of the *BCR-ABL* rearrangement as suggested above. Direct evidence in support of this is provided by studies in cell lines and animal models of CML. The *BCR-ABL* gene can confer growth factor independence on previously factor-dependent cell lines.^{38,39} Complementary evidence for a pathogenetic

Fig. 17.3 Signal transduction pathways affected by BCR-ABL. BCR-ABL exerts its effects via its interaction with numerous proteins that are responsible for the activation or repression of gene transcription, the apoptotic pathways and cytoskeleton organization. The pathways implicated include those involving RAS, mitogen-activated protein (MAP) kinases, signal transducers and activators of transcription (STAT), phosphatidylinositol 3-kinase (PI3K), and MYC. The majority of interactions are mediated through tyrosine phosphorylation and require the binding of BCR-ABL to adaptor molecules such as growth factor receptor-bound protein 2 (GRB-2), DOK, CRK, CRK-like protein (CRKL), SRC-homology-containing protein (SHC), and casitas-B-lineage lymphoma protein (CBL). Kindly provided by Junia Melo.

role of the *BCR-ABL* rearrangement is provided by the demonstration that it is possible to induce a CML-like disorder in a mouse model by insertion of the *BCR-ABL* gene into hematopoietic cells.^{20,21,35}

Clinical features

CML most commonly presents in children with non-specific symptoms, such as fatigue, malaise and weight loss (Table 17.1).^{6,40} Abdominal discomfort, due to an enlarging spleen, is also fairly common.^{6,40} A recent French study of 40 children found that CML is an incidental finding in 23% of children as a result of the increased use of routine blood counts.⁶ Other symptoms at presentation that occur less

frequently are bleeding (usually with a normal platelet count and coagulation studies) and bone pain. If there is a marked leukocytosis ($>100 \times 10^9/L$), affected children may present with symptoms of a hypermetabolic state, including fever and night sweats.^{6,40}

Examination

The majority of children have mild or moderate splenomegaly; otherwise findings on examination are usually unremarkable.^{6,40,41} Palpable hepatomegaly (1–2 cm) is sometimes found but gross hepatomegaly and lymphadenopathy are very uncommon unless the disease has progressed to accelerated phase or blast crisis. Signs of leukostasis (e.g., retinal hemorrhages, papilledema, priapism) are usually only seen if the leukocyte count at presentation is very high ($>300 \times 10^9/L$).^{6,42} Some reports have suggested that such signs are more common in children than in adults with CML,⁴² although this was not the case in the recent study of 40 children in which leukostasis was reported in only 3 (7.5%) of the children.⁶ Skin nodules due to leukemic deposits (chloromas) are occasionally seen, usually in association with accelerated-phase disease or blast crisis.

Table 17.1 Clinical features at diagnosis of chronic myeloid leukemia.

Common

Fatigue
Weight loss
Abdominal discomfort/splenomegaly
Asymptomatic (incidental finding)

Uncommon

Bone pain
Bleeding
Fever
Sweating
Leukostasis (e.g., priapism)
Gout
Splenic infarction

Diagnosis

Peripheral blood

In chronic-phase disease the most consistent finding at presentation is the characteristic leukocytosis made up predominantly of mature granulocytic cells (neutrophils, bands and

metamyelocytes) and their precursors (myelocytes and promyelocytes). In chronic-phase CML, blasts constitute < 5% of peripheral blood leukocytes. As in CML in adults, eosinophilia and basophilia are commonly present at diagnosis. The total white cell count at presentation is usually $> 100 \times 10^9/L$; indeed, the recent French study reported a median white blood cell count at diagnosis of $242 \times 10^9/L$.⁶ Most children have a normal or slightly increased platelet count at presentation;^{6,40,41} the presence either of thrombocytopenia or of marked thrombocytosis ($> 1000 \times 10^9/L$) suggests accelerated-phase disease. By contrast, mild or moderate anemia is a presenting finding in the majority of children.⁶

Bone marrow

The marrow in CML is markedly hypercellular in all phases of the disease. In the chronic phase the increase in cellularity is mainly due to hyperplasia of granulocytic cells. A characteristic “myelocyte” peak is commonly seen at presentation, and blast cells constitute < 5% of nucleated cells in chronic-phase CML. Eosinophils, basophils and their precursors are frequently increased and are sometimes dysplastic. In addition, pseudo-Gaucher cells similar to sea-blue histiocytes are seen in a small proportion of cases. Megakaryocytes are usually present in increased numbers but they are usually morphologically normal.

The trephine biopsy is often useful in CML and should be performed at presentation if a bone marrow harvest is planned and if accelerated-phase disease is suspected. At presentation, the main features seen on biopsy in chronic phase are hypercellularity, granulocytic hyperplasia and increased megakaryocyte numbers. However, the biopsy is useful for assessing the extent of accompanying myelofibrosis and may show increases in blast cells in advanced-phase disease. Myelofibrosis is not usually prominent at presentation but it is a common feature of advanced-phase disease and may make marrow harvesting extremely difficult.

Cytogenetics

Cytogenetic studies on bone marrow at presentation show the classic Ph chromosome in around 95% of patients with chronic-phase CML. In almost all such patients, the Ph chromosome is seen in 100% of the metaphases but occasionally small numbers of cytogenetically normal cells are still detectable at presentation. Variant translocations are seen in < 5% of children in chronic phase. These are of two types: rearrangements involving two chromosomes, one of which is chromosome 22; and rearrangements involving chromosomes 22 and 9 together with at least one other chromosome. Variant translocations, and some cases that are cytogenetically normal, virtually always show *BCR* rearrangement by Southern blotting despite the absence of the Ph chromosome using classical cytogenetics.⁴³ Fluorescent *in situ* hybridiza-

tion (FISH) is almost as accurate at detecting the Ph chromosome *BCR-ABL* fusion gene in bone marrow from adults with CML.^{44,45} More widespread introduction of FISH may make the diagnosis of CML easier, quicker and cheaper and may also render the miscellaneous rapid confirmatory tests described below redundant in CML.

There remains a very small number of children with CML who are Ph-negative and who have no evidence of *BCR-ABL* rearrangement even after extensive molecular investigation. Most, if not all, such children meet the diagnostic criteria for JMML or other types of myelodysplasia or myeloproliferative disorders (see Chapter 18). Thus, the existence of true Ph-negative CML is extremely unlikely and in adults, although of scientific interest, the distinction does not appear to be of practical clinical importance because the clinical features, laboratory findings and natural history of Ph-positive and Ph-negative, *BCR-ABL*-negative CML are so similar that their treatment is the same.⁴⁶

A number of cytogenetic abnormalities, such as isochromosome 17q, in addition to the Ph chromosome may be seen in bone marrow cells in CML.⁴³ However, these changes are associated with accelerated disease or blast crisis (see below) and therefore cast doubt on the diagnosis of CML, still in chronic phase.

Miscellaneous and possible prognostic tests at diagnosis

A number of other laboratory tests are abnormal in CML and may be used to substantiate the diagnosis where cytogenetic or molecular studies are unavailable. These include reduced leukocyte alkaline phosphatase (LAP) activity (measured cytochemically as a low LAP “score”) and increased vitamin B₁₂-binding protein (usually measured as a reduced serum B₁₂ level). In addition, the serum uric acid is often elevated although clinical gout is unusual.

Approximately 20% of CML patients have deletions of chromosomal material of varying size on the derivative 9q; these patients have significantly shorter survival than those who do not. Therefore assessment of derivative 9q deletion status may be a useful prognostic factor although this has not been assessed in children.⁴⁷ Assessment of telomere shortening at presentation at diagnosis also appears to be a useful prognostic factor in adults but remains to be investigated in children with CML.⁴⁸

Accelerated-phase CML

There is no single specific feature that defines the accelerated phase. Most studies use a combination of clinical and hematologic features to classify patients as accelerated rather than chronic-phase disease. We have found the International Bone Marrow Transplant Registry definition⁴⁹ of accelerated phase

Table 17.2 International Bone Marrow Transplant Registry definition of accelerated-phase chronic myeloid leukemia.

*Accelerated phase is defined by the presence of **any** of:*

Clinical criteria

- Increasing splenomegaly
- Chloroma(s)
- Previous blast crisis (BM blasts > 30%)

Hematologic criteria

- WBC difficult to control or doubling in 5 days
- Hb < 10 g/dL or platelets < $100 \times 10^9/L$ not responsive to treatment
- Platelets > $1000 \times 10^9/L$
- Blasts (BM or blood) > 10% but < 30%
- Blasts + promyelocytes (BM or blood) > 20%
- Basophils + eosinophils (PB) = 20%

Other criteria

- Cytogenetic abnormality in addition to single Ph chromosome
- Marrow fibrosis (stages 3–4)

BM, bone marrow; Hb, hemoglobin; PB, peripheral blood.

useful for assessing prognosis and planning management in children (Table 17.2).

One of the commonest signs is a change in the platelet count; this may manifest either as thrombocytopenia or thrombocytosis increasingly resistant to chemotherapy. Similarly, the leukocyte count may become refractory to treatment and there may be increased numbers of basophils and/or eosinophils in comparison with earlier in the disease course. Blast cells in the marrow may also increase. Many patients become anemic. In part this may be due to increasing myelofibrosis, a common feature of accelerated-phase CML, and in part due to hypersplenism in association with a larger spleen.

The progression of CML to the accelerated phase is often associated with the acquisition of new cytogenetic abnormalities. The commonest are a second Ph chromosome, isochromosome 17, trisomy 8 and trisomy 19.^{43,50,51} The genes involved in the evolution of CML in adults and children have not yet been fully characterized (see below).

Blast crisis

Blast crisis is defined by the presence of > 30% blasts in peripheral blood or bone marrow. It usually evolves relatively gradually from accelerated phase, but not infrequently the switch from chronic phase is dramatic, blast cells appearing in the peripheral blood without a distinct period of “acceleration.” Occasionally, children with CML present in blast crisis or relapse straight into blast crisis following allogeneic SCT. The majority of patients with blast crisis have a rapidly rising leukocyte count together with anemia and are frequently thrombocytopenic. In > 60% of cases, the blast cells have the morphologic and immunophenotypic

characteristics of myeloblasts.^{51,52} However, 20–30% of patients undergo lymphoid blast transformation, most commonly with a pre-B phenotype;^{51–53} among adults, the median age of this subset is lower than that of patients developing myeloblastic crisis⁵⁴ but there are no large series to confirm whether or not children are more likely to undergo lymphoid rather than myeloid transformation. Classification into lymphoid versus myeloid blast crisis on morphologic grounds is often very difficult; immunophenotyping to confirm the myeloid or lymphoid characteristics of the blasts is therefore very important because this has a major impact on treatment and prognosis.

As in accelerated phase, cytogenetic changes in addition to the Ph chromosome are common.⁵⁴ As well as those affecting chromosomes 8, 17 and 19, the translocations associated with acute myeloid leukemia (AML) and ALL are sometimes seen in blastic crisis (see Chapters 16 and 20). At the molecular level, blast crisis has been variably associated with abnormalities of tumor suppressor genes, in particular *P53*, *P16* and *RB*, or protooncogenes, such as *RAS* and *MYC*, or with the generation of chimeric transcription factors, as in the *AML–EVII* gene fusion.^{55–59} It is likely, therefore, that multiple and alternative molecular defects underlie the acute transformation of the disease.

Differential diagnosis

The most important differential diagnosis in young children is JMML (see Chapter 18). JMML is seen more commonly in children < 2 years of age in contrast to CML, which occurs predominantly in children > 6 years. The profile of clinical signs is also rather different: skin rashes and lymphadenopathy are very common in JMML but rare in chronic-phase CML, while prominent splenomegaly is suggestive of CML because it is usually less marked in JMML. The laboratory features are also usually distinct: in JMML the white cell count tends to be < $100 \times 10^9/L$ and there is a monocytosis, thrombocytopenia and a raised fetal hemoglobin (HbF), none of which is common in CML. The diagnosis is generally not in doubt once the bone marrow karyotype is available but the absence of the Ph chromosome in up to 10% of cases of CML may lead to diagnostic uncertainty in occasional cases.

A transient CML-like blood picture is also occasionally seen in association with severe bacterial infections, chronic Epstein–Barr virus infection and nonhematologic cancers. Similar granulocytic hyperplasia may also be found during the first year of life in 60–70% of cases of thrombocytopenia with absent radii syndrome. Finally, the blood film and marrow of children who present in lymphoid blast crisis may be difficult to distinguish from *de novo* Ph-positive ALL on morphologic grounds: molecular analysis for the p210^{BCR–ABL} and p185^{BCR–ABL} proteins in CML and ALL, respectively, may clarify the underlying diagnosis.

Management

Management of chronic-phase disease

General considerations

Soon after diagnosis a decision must be made about long-term treatment because there are several different options with the potential to cure or to significantly prolong survival.^{60–64} The only proven cure for CML is SCT. The mortality and morbidity associated with SCT are relatively high (see below), particularly in adults. Thus, the recent development of drugs targeted to the leukemia-specific protein BCR–ABL, such as imatinib mesilate, has completely changed the management of CML in adults, as the response rate to these agents is extremely good.^{60–64} However, because sustained molecular remission in response to imatinib is rare, because there is increasing evidence of primary and secondary imatinib resistance (see below), as there are very few data about imatinib in children,^{65,66} and as there is no evidence yet that imatinib can cure CML, SCT remains the treatment of choice in children where an HLA-identical donor has been identified. For children without an HLA-identical sibling, the decision to transplant may be difficult if a well-matched donor is not available and in this situation imatinib is appropriate for front-line therapy. A suggested treatment algorithm is shown in Fig. 17.4.

Initial management

Discuss SCT

For children presenting in chronic phase it is rarely necessary to start treatment immediately. Except in cases where the

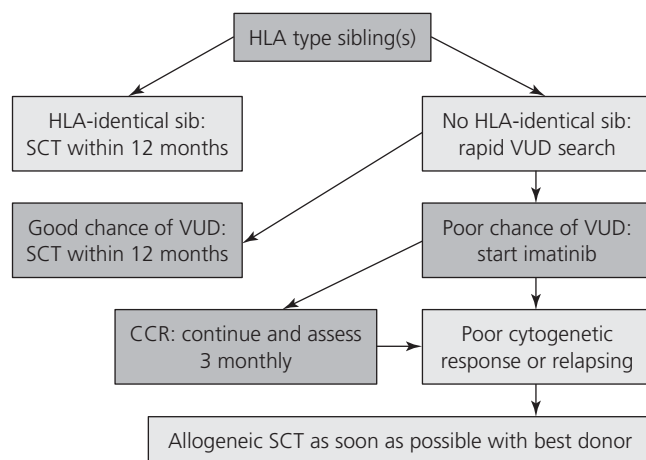

Fig. 17.4 Management of childhood CML in chronic phase. A suggested algorithm for planning the management of children with CML in first chronic phase. CCR, complete cytogenetic remission; SCT, stem cell transplantation; VUD, volunteer-unrelated donor.

leukocyte count is $> 100 \times 10^9/L$, treatment can be deferred for 1–2 weeks as it is important to spend time with the family explaining the natural history of the disease, particularly because it differs in so many ways from most childhood malignancies. Unlike acute leukemias, CML can only be cured by SCT. It is therefore appropriate to raise this with families and to proceed to HLA typing of family members at an early stage because the availability of an HLA-identical sibling donor has a major impact on the choice of treatment (Fig. 17.4).

Cryopreserve autologous cells

Prior to initiating treatment, hematopoietic stem cells should be collected from all children in chronic phase and cryopreserved for possible later autologous transplantation. In the majority of children, sufficient stem cells can be collected by leukapheresis (aim for $7\text{--}8 \times 10^8$ cells/kg), but where this is not possible (e.g., poor vascular access) autologous bone marrow harvesting is a satisfactory alternative (aim to cryopreserve 2×10^8 cells/kg). If stem cell harvesting is not possible prior to starting chemotherapy, it should be carried out at a later stage after control of the white count has been achieved and before SCT (this will require temporary cessation of chemotherapy; usually for 2–4 weeks or until the leukocyte count is $> 25 \times 10^9/L$).

Oral chemotherapy for initial disease control

While an HLA-identical donor is being sought and pending a decision about allogeneic SCT, oral chemotherapy should be started to bring the disease under control. For asymptomatic children the aim of chemotherapy is to “normalize” the blood count and thereby delay onset of symptoms. In symptomatic children and/or those with white cell counts $> 100 \times 10^9/L$, chemotherapy should be started promptly and most will feel considerably better after only a few days. In the rare cases presenting with symptoms of hyperviscosity, leukapheresis should be carried out as soon as possible followed by oral chemotherapy.

Several well-known oral agents are active in CML, including hydroxycarbamide, busulfan, 6-mercaptopurine and 6-thioguanine. Hydroxycarbamide has a number of advantages and is usually the best drug for initial disease control. It causes a rapid fall in both white cell and platelet counts, usually within 1–2 weeks; myelosuppressive hydroxycarbamide-associated pancytopenia is generally rapidly reversible, particularly in comparison with busulfan, and it has fewer serious side-effects. In contrast to busulfan, there is no clear evidence that hydroxycarbamide is leukemogenic or tumorigenic in humans; it does not appear to cause pulmonary fibrosis, even with long-term use and, in the doses used, it does not cause infertility. Furthermore, a history of busulfan use in adults prior to bone marrow transplantation (BMT) has been identified as one of the factors predicting a poorer outcome compared with the use of no chemotherapy or

hydroxycarbamide for disease control before BMT.⁶⁷ The starting dose of hydroxycarbamide is 15–20 mg/kg, increasing up to 30 mg/kg depending on response, with the aim of bringing the white cell count down below $10 \times 10^9/\text{L}$. A uricosuric agent, such as allopurinol, should be started 2–3 days before oral chemotherapy is commenced. Imatinib may be used to achieve initial disease control but is not the drug of choice for this purpose in children as it tends to achieve a response more slowly, is less well tolerated initially and may induce imatinib resistance.

Definitive management of chronic-phase CML

The options available include imatinib mesilate (STI571), allogeneic SCT, interferon (IFN)- α and experimental treatment.

Imatinib mesilate

Imatinib mesilate (previously known as STI571) is a potent tyrosine kinase inhibitor that blocks the kinase activity of BCR-ABL.⁶⁸ It also inhibits a small number of other protein kinases, including KIT (the receptor for stem cell factor) and the platelet-derived growth factor receptors (PDGFR-A and -B). The remarkable selectivity of imatinib means that it is able to inhibit the proliferation of Ph-positive hematopoietic progenitor cells while leaving normal cells relatively unscathed.⁶⁹ Imatinib probably acts mainly by binding to and stabilizing BCR-ABL in its inactive form,⁷⁰ in this way preventing phosphorylation of its downstream targets (Fig. 17.5).

Clinical trials of imatinib in adults

The first clinical trials of imatinib were completed in 2001 in IFN-refractory chronic-phase disease and in blast crisis in adults.^{71,72} These trials showed a remarkable 98% complete hematologic response rate together with a 54% cytogenetic

response rate for the previously treated chronic-phase patients.⁷¹ As would be expected the results were not quite so good in accelerated-phase disease although much better than any other nontransplant approach, with a hematologic complete response rate of 78% and cytogenetic complete response rate of 17%.⁷³ Shortly afterwards a prospective multinational study in over 1000 adult patients of imatinib versus IFN- α plus cytarabine was published and showed a dramatic increase in the complete cytogenetic response rate in the imatinib-treated patients (74%) compared with the IFN- α /cytarabine patients (8.5%).⁷⁴ Recent data show that the frequency of major molecular responses (≥ 3 log reduction in BCR-ABL transcript levels) was also much greater in the imatinib group compared with the IFN- α /cytarabine group.⁷⁵ The side-effects (discussed below) were modest and acceptable. More recently even higher response rates have been reported in a nonrandomized study in 114 adults with newly diagnosed chronic-phase CML, when a higher dose of imatinib was used (400 mg twice daily vs. 400 mg once daily).⁷⁶ In this study 90% of patients have achieved a complete cytogenetic response (100% Ph chromosome negative). The most important trials in adults and children are summarized in Table 17.3.

The short duration of follow-up even in the earliest studies makes it unclear if the dramatic increase in hematologic and cytogenetic response rates will translate into improved survival. Encouragingly, two recent retrospective studies suggest that imatinib does prolong survival compared with other nontransplant therapies, including IFN- α ,^{77,78} but it will be several years until meaningful survival data from prospective studies become available. Unfortunately, recent studies of imatinib in blast crisis confirm the poor response of myeloid blast crisis (15–23% hematologic complete response; median survival 6–8 months^{78,79,80}) and even poorer response of lymphoid blast crisis.⁷⁸ Other problems with imatinib include the emergence of imatinib resistance,^{81–83} side-effects,^{74–76} and the very small amount of information about the effects of imatinib in children.^{65,66}

Clinical trials of imatinib in children

The two published series of imatinib used to treat children with CML include 24 patients; the results are shown in Table 17.3.^{65,66} These data are too preliminary to draw many conclusions. They do show that so far the response rate seems to be similar to the adult series. In addition, Champagne and colleagues carried out pharmacokinetic studies to try to estimate the optimal dose of imatinib and evaluate its safety profile in children.⁶⁶ They found that there was considerable interpatient variance in pharmacokinetic parameters.⁶⁶ However, plasma concentrations at steady state were comparable with those in adults.⁶⁶ They reported that imatinib was well tolerated over a dose range of 260–570 mg/m² (260 mg/m² is equivalent to the 400 mg daily dose in adults, and 570 mg/m² to the 800 mg daily high-dose regimen in adults.⁷⁶ The

Fig. 17.5 Schematic representation of BCR-ABL inhibition by imatinib mesylate. (a) Binding of ATP by BCR-ABL facilitates phosphorylation (♦) of tyrosine residues (Y) on substrates (S), which then bind effectors (E) transmitting a downstream mitogenic signal. (b) Imatinib (I) binds to the inactive conformation of ABL in the region where ATP would normally bind thereby preventing phosphorylation of substrate tyrosines and impeding downstream signaling by BCR-ABL.

Table 17.3 Clinical trials of imatinib in adults and children with chronic myeloid leukemia.

Trial	No. of patients			Hematologic CR	Cytogenetic CR	Molecular response	Dose per day	Discontinued*
	Total	CP1	AP					
Adult trials

* Reasons for discontinuation included adverse events, disease progression, death and proceeding to SCT.

† 43% of the 235 patients originally entered into the trial (only 181/235 were subsequently confirmed to be in accelerated phase but the discontinuation data are only provided for the whole group of 235 patients).

AP, acute phase; BC, blast crisis; CP, chronic phase; CR, complete remission; NA, not available; RT-PCR, reverse-transcription polymerase chain reaction.

commonest adverse effects were nausea, vomiting, fatigue, abnormal liver function tests and diarrhea. These are similar in nature to the adverse effects reported in the large adult series:⁷⁴ nausea (44%), vomiting (17%), fatigue (35%), abnormal liver function tests (43%) and diarrhea (33%); this series also reported a fairly high frequency of edema (55%), muscle cramps (38%), rash (34%) and headache (31%). Myelo-suppression (anemia, thrombocytopenia and neutropenia) has been common in the adult series but little information is available in children and advice about monitoring is discussed below.

Imatinib resistance

The major limitation to the use of imatinib in children is that it is not curative, at least on the basis of current evidence. The inability of imatinib to eradicate all leukemic cells is due to imatinib resistance, which may be either primary or secondary (Table 17.4). Primary resistance to imatinib would occur in patients in whom the leukemic process is no longer entirely dependent upon BCR-ABL and could be perpetuated by BCR-ABL-independent mechanisms (see, for example, refs 84, 85). It could also occur if the quiescent pool of leukemic stem cells was insensitive to imatinib, as has recently been reported.⁸⁶

Secondary imatinib resistance develops as a result of exposure of the leukemic cells to imatinib. Most commonly,

Table 17.4 Mechanisms of resistance of chronic myeloid leukemia to imatinib.

Primary imatinib resistance

Leukemic stem cell proliferation occurring by a BCR-ABL-independent pathway

Quiescent leukemic stem cells are insensitive to imatinib, e.g., because imatinib is not available intracellularly

BCR-ABL point mutations prior to imatinib exposure

Secondary imatinib resistance

BCR-ABL point mutations in the ABL kinase domain

BCR-ABL amplification/overexpression

Reduction of imatinib activity by production of an inhibitor (e.g., α_1 -acid glycoprotein) or enzymatic modification by a P450 enzyme or overexpression of *MDR1*

secondary resistance is due to point mutations in the BCR-ABL kinase domain,^{87–89} but resistance due to BCR-ABL amplification has also been described.^{88,90} Secondary resistance may also arise due to reduction in the activity of imatinib, for instance through production of the inhibitor α_1 -acid glycoprotein,⁹¹ through reduced plasma concentrations of imatinib due to increased *MDR1* overexpression,⁹² or through enzymatic modification of imatinib by a P450 enzyme.⁸¹

Perhaps most worrying from the point of view of the use of imatinib in children is the recent evidence that mutations in

the BCR–ABL kinase domain may be present in the leukemic cells before therapy with imatinib,^{93,94} presumably because of the inherent genetic instability of the BCR–ABL-expressing clone and the fact that these mutations may confer a growth advantage to the mutant clone.⁹⁵ This is a very important observation as it suggests that imatinib should be used with caution in patients for whom SCT is the treatment of first choice.

Treatment of children with imatinib

At present the balance of evidence does not favor imatinib as treatment of choice for newly diagnosed children although the position may change as increasing information about imatinib becomes available. The main concerns about using imatinib as treatment of first choice are:

- there is no evidence that it can cure;
- imatinib resistance is now known to be an inherent property of the leukemic clone in some patients and in such patients imatinib would be likely to favor the outgrowth of rapidly proliferating drug-resistant clones;
- the development of chromosomal abnormalities in Ph-negative cells in 2–17% of imatinib-treated adult patients;^{85,96}
- the long-term toxicity in children is completely unknown;
- some patients relapse on imatinib straight into blast crisis,^{97–99} which has a much poorer outcome after SCT than chronic-phase disease;
- the outcome of SCT is better when it is carried out within a year of diagnosis.

Indications for imatinib in children with CML. The role of imatinib pre-SCT to reduce the leukemic cell burden is not clear and until evidence from clinical trials is available it seems unwise to use imatinib in this way in children. Similarly there is no proven role for imatinib as adjuvant therapy post-SCT in children especially when molecular monitoring of residual BCR–ABL cells posttransplant is so effective (see below). Where imatinib does have a role is:

- as first-line treatment for children who do not have an HLA-identical donor (see Fig. 17.4);
- for relapse after SCT where donor lymphocyte infusion (DLI) is unavailable or ineffective or families/clinicians choose this option (see below);
- for accelerated-phase CML while SCT is being arranged;
- for myeloid blast crisis following or in place of conventional chemotherapy and while SCT is being arranged.

The two studies of imatinib in children with CML suggest that imatinib should be started at a dose of 260–340 mg/m², rounded to the nearest 100 mg because of the formulations available. If initial disease control with hydroxycarbamide is used this should be tapered for 2–3 weeks prior to starting imatinib. Allopurinol should only be necessary if the leukocyte count is $>20 \times 10^9$ /L. We recommend monitoring the full blood count weekly for the first 6 weeks and then every 2 weeks. The leukocyte count normally starts to fall within 1–2 weeks and normalizes in 6 weeks; platelet counts normalize after 1–3 weeks. Myelosuppression occurs in around 50% of patients and is more common in accelerated phase than chronic phase. Data from adult studies suggest that the dose of imatinib should be increased if a complete cytogenetic response has not been achieved by 3–6 months.¹⁰⁰

Allogeneic stem cell transplantation

Allogeneic SCT remains the only curative treatment for CML in children.^{101–105} Thus, despite the efficacy and specificity of imatinib, SCT is the treatment of choice for children with CML who have an HLA-identical donor.^{61,64} There are now three fairly large published series of BMT for CML in children: one from the European Group for Blood and Marrow Transplantation (EBMT) involving 314 children; a study from the Société Française de Greffe de Moëlle et de Thérapie Cellulaire (SFGM-TC) in 76 children; and an older study from Germany in 47 children.^{101–103} The results of the two recent studies are summarized in Table 17.5 and the details are discussed below. There are also several studies of cord blood

Table 17.5 Outcome of allogeneic stem cell transplantation in children with chronic myeloid leukemia.

transplantation in which a substantial proportion of children were transplanted for CML.^{106–108}

Conditioning: chemotherapy vs. chemoradiotherapy

Early experience showed that the combination of high-dose cyclophosphamide and total body irradiation (TBI) is an effective conditioning regimen for cure of CML in adults and children.^{67,104,105} This regimen is still used for transplants from unrelated or mismatched donors, but for transplants from an HLA-identical sibling more recent results indicate an equivalent antileukemic efficacy for cyclophosphamide in combination with busulfan,^{101,109,110} thus eliminating the need for radiotherapy. Long-term toxicity may be less than with TBI regimens, although this has not yet been established. There is no benefit of additional splenic irradiation where the spleen is small or impalpable,¹¹¹ but for children in accelerated phase or blast crisis where there is significant splenomegaly (>5 cm), splenectomy prior to BMT may enable the disease to be controlled better and will facilitate engraftment, although there is no effect on overall survival.¹¹²

Outcome

First chronic phase. In view of the major advances in the management of relapsed chronic-phase CML (see below), the most clinically relevant measure of cure from these studies is the overall survival as most children who relapse can be cured by DLI^{113–116} and possibly imatinib.¹¹⁷ In the EBMT study the overall survival at 3 years was 75% for children transplanted in the first chronic phase;¹⁰¹ this is similar to the SFGM study, which reported 73% event-free survival for such children.¹⁰² The overall survival for children in first chronic phase transplanted from unrelated donors was not significantly different on multivariate analysis (65%) but the transplant-related mortality was significantly higher (31%) after unrelated donor transplantation in this study.¹⁰¹ In both studies it was clear that the main cause of death, after both sibling donor and unrelated donor transplantation, was graft-versus-host disease (GVHD).

Accelerated phase and blast crisis. In advanced-phase disease the relapse rate is high, particularly when the donor is an HLA-identical sibling. In the EBMT study 49% of the advanced-phase children transplanted from a sibling donor relapsed,¹⁰¹ and the hazard ratio for relapse from unrelated donors versus sibling donors was 0.38 ($P < 0.01$). In the SFGM study 59% of the advanced-phase children transplanted from a sibling donor relapsed and the relative risk of relapse was 5.9 for a child transplanted in advanced phase from a sibling donor ($P < 0.01$).¹⁰² Because the response to DLI (or imatinib) of relapsed patients transplanted for advanced-phase disease is often temporary, it is more important to consider leukemia-free survival as a measure of cure for children transplanted in advanced-phase disease. In the EBMT study, leukemia-

free survival in children transplanted from sibling donors or unrelated donors was virtually identical: 35% and 34% respectively.¹⁰¹ This is similar to the SFGM study¹⁰² and a number of studies in adults supporting the contention that SCT for advanced-phase disease remains a worthwhile therapeutic option because leukemia-free survival of around 30% is vastly superior to the negligible chance of long-term survival without SCT.^{118–120}

Predictive factors for the outcome of SCT

The principal factors determining overall survival after SCT in children with CML are:

- the phase of CML at the time of transplant, with the best results in chronic phase and the worst in accelerated phase and blast crisis, as described above;^{101,102}
- the interval between diagnosis and BMT, with the best results in those transplanted within 1 year of diagnosis;^{101,121–123}
- administration of methotrexate as GVHD prophylaxis: the hazard ratio in multivariate analysis in the EBMT study was 0.6 for inclusion of methotrexate ($P = 0.038$).¹⁰¹

Interval between diagnosis and SCT. Data from large adult series convincingly show a better outcome for patients transplanted within a year of diagnosis.^{121–123} This is also likely to be true for children: the EBMT study found inferior leukemia-free survival (Relative Risk 1.5) in children transplanted > 12 months after diagnosis, although this did not quite reach statistical significance ($P = 0.064$). Early transplantation also reduces the time interval in which transformation to accelerated phase or blast crisis may occur because around 10% of children progress to more advanced disease within a year of diagnosis. Thus, for children with an HLA-identical donor, SCT within 12 months of diagnosis is commonly recommended (see Fig. 17.4). However, for those without an HLA-identical donor, a better option is to treat with imatinib and monitor the response closely using sensitive molecular methods as discussed above. Where there is evidence of imatinib resistance or loss of imatinib response, SCT from a mismatched donor needs to be considered because overall long-term survival is around 40%,¹²⁴ and hence likely to be superior to chemotherapy.

Graft-versus-host disease

GVHD is the most important cause of transplant-related mortality and morbidity.^{101,102,125,126} However, it appears that in CML more than any other hematologic malignancy the occurrence and clinical behavior of GVHD mediated by allogeneic donor cells is intimately linked with the “graft-versus-leukemia” (GVL) effect of the donor cells.^{127–129} While it is not yet known whether these two processes are mediated by the same or distinct cell types or subtypes, it is clear that the need to maintain an effective GVL effect of allogeneic donor cells has a major impact on the choice of regimen employed to prevent GVHD after BMT for CML both in

children and in adults.^{68,125,127} Broadly, the two approaches to GVHD prevention are T-cell depletion and pharmacologic immunosuppression.

T-cell depletion. A number of methods of T-cell depletion have been employed in CML. These include *ex vivo* T-cell depletion of donor marrow using antithymocyte globulin¹²⁵ or monoclonal antibodies (e.g., anti-CD6, anti-CD8, anti-CD2 or anti-CD52 (Campath-1M)), counterflow elutriation or soybean lectin agglutination, and *in vivo* T-cell depletion by intravenous infusion of antibodies such as Alemtuzumab.^{130,131} There are numerous data on the impact of T-cell depletion on the outcome of BMT for CML in adults; many of these trials have included children and it is likely that the conclusions from the adult studies apply also to pediatric practice. The principal benefit of T-cell depletion is that it is highly effective in reducing the incidence and severity of GVHD both from HLA-matched siblings and alternative donors.^{125,130,131} However, the benefits of T-cell depletion are achieved at the expense of a significantly increased rate of early graft rejection and relapse of CML.^{131,132} The rate of relapse after sibling transplants may be as high as 60%,^{131,132} and this has led several groups to abandon T-cell depletion in favor of immunosuppression, particularly in patients under 20 years of age who have a lower incidence of severe GVHD. The clear association between a low rate of GVHD and a high rate of relapse after BMT for CML (and vice versa) provides strong clinical evidence for the GVL effect of allogeneic T cells,^{127–132} and has led to the development of a number of possible strategies to prevent GVHD without sacrificing important elements of GVL (see below).

Immunosuppression. There is clear evidence that combination treatment with ciclosporin and methotrexate is, apart from T-cell depletion, the most effective way of preventing GVHD.^{101,133} Most regimens combine short-course methotrexate during the first 2 weeks after BMT with 6–12 months' maintenance treatment with oral ciclosporin. Acute GVHD still develops in around 30% of children treated with these regimens but in the majority of cases this is mild and responds to topical or low-dose steroids. In children who develop GVHD of severity greater than grade II the treatment of choice is high-dose steroids, usually by the intravenous route.

Graft-versus-leukemia effect

As mentioned above, GVL and GVHD are closely linked and it seems likely that similar mechanisms control both processes.^{127–129} In GVHD, donor T cells recognize antigens presented by major histocompatibility complex molecules on recipient cells (in skin, gut, biliary tree, etc.) leading to the clinical features of acute and chronic GVHD. In GVL, donor T cells instead suppress or eradicate residual leukemia. Evidence for this derives not just from the clinical studies of GVHD and relapse in CML, but also directly from the

demonstration of dramatic expansion of leukemia antigen-specific cytotoxic T lymphocytes coincident with the onset of durable molecular remissions of CML¹²⁸ and from animal models.¹²⁹ The target antigens for the GVL effect have not been identified but they are likely to include not only leukemia-specific antigens (e.g., BCR-ABL¹³⁴), but also minor histocompatibility antigens expressed either ubiquitously or in a tissue-restricted fashion (e.g., those on normal lymphoid or myeloid cells).^{135–137} Despite uncertainties about the exact mechanisms involved in the GVL effect, clinical protocols that utilize the GVL activity of donor T cells are already in widespread use in the treatment of children and adults with CML relapsing after SCT,^{115,116,138–140} and for preemptive T-cell infusion in conjunction with transplantation of purified CD34⁺ cells.¹⁴¹

Management of relapse

Although the majority of patients who relapse after BMT do so into chronic-phase CML, a small proportion relapse straight into blast crisis. The options for managing relapse into chronic phase are: DLI, imatinib, IFN- α and second BMT. The most effective and least toxic options are DLI (see below) and imatinib, and there are currently no data in children to show which approach produces the best long-term outcome. The treatment of choice for an individual patient will depend upon a number of factors, including:

- the preference of the family;
- the age, size and health of a sibling donor or availability of an unrelated donor;
- whether or not the child had significant GVHD during the transplant;
- and, possibly, the stage of disease at relapse.

For example, DLI is most effective when given to patients with molecular relapse (i.e., no cytogenetic or hematologic evidence of disease) and less effective when given for frank hematologic relapse.¹⁴² Indeed, for patients in hematologic relapse it may be preferable to aim to induce molecular remission with imatinib and then treat any further detectable disease by DLI.

Second transplant may still be contemplated for those patients resistant to both DLI (see below) and imatinib.^{143–146} The available literature suggests that the second procedure should be delayed for at least 12 months after the first to reduce transplant-related mortality.¹⁴³ For children conditioned with busulfan/cyclophosphamide for the first transplant, a TBI regimen may be preferable for the second, although there is no definite evidence of greater antileukemic efficacy; for those who received TBI for the first transplant, second transplants with busulfan alone have been successful.¹⁴⁶ However, there is little information in the literature to guide the clinician.

For children who relapse into blast crisis, particularly myeloid blast crisis, following BMT the outlook is often, but not always, bleak. The management is that for blast crisis (see

below). If chronic-phase disease is reestablished, consideration should be given to DLI or imatinib if donor cells remain detectable, or a second BMT where there is no evidence of residual donor cells.

Donor lymphocyte infusion

Since the first successful reports of DLI to treat leukemia relapsing after BMT in 1990, this approach has become part of the routine management of this difficult problem.^{115,116,138–140} DLI is particularly effective in CML because of the GVL effect described above. For DLI to be successful, molecular monitoring for residual BCR-ABL-positive cells using a quantitative technique is essential as this will detect relapse before cytogenetic and hematologic relapse is apparent.^{147–150} The most robust technique is quantitative reverse-transcription polymerase chain reaction (RT-PCR); many protocols are adapted to take advantage of automated analysis, such as Taqman.¹⁵¹ An example of persistent and rising numbers of BCR-ABL mRNA transcripts detectable on serial blood samples by RT-PCR is shown in Fig. 17.6. Peripheral blood samples can be used, making serial bone marrow aspirates post-SCT unnecessary.¹⁵¹ Monitoring with FISH has not been shown to be sensitive enough for this purpose. We recommend monitoring samples every 3 months for the first year and then every 6 months thereafter; any positive results should be followed up by monthly monitoring to watch for rising levels of disease.^{115,152} Because a weakly positive result within the first 6 months of SCT is not predictive of relapse and neither is an occasional weakly positive result, DLI is generally only indicated when there are clearly rising levels

Fig. 17.6 Examples of competitive reverse-transcription polymerase chain reaction (RT-PCR) in peripheral blood leukocytes from CML patients: ethidium bromide-stained agarose gels for quantification of BCR-ABL (b3a2 and b2a2 junctions) and of G6PD and ABL transcripts as internal controls. Serial dilutions of a linearized competitor were added to fixed amounts of patient cDNA. The number of competitor molecules added is shown above each track. The equivalence point, at which competitor and sample bands have the same intensity, can be estimated by visual inspection or, more accurately, by densitometry. This point permits calculation of the number of target transcript molecules in the sample per unit volume of cDNA. Kindly provided by Junia Melo.

or two consecutive results of $> 0.05\%$ BCR-ABL compared with ABL transcripts.¹⁵²

The main factors that determine the efficacy and toxicity of DLI are the cell dose and the phase of disease at the time of DLI.^{153,154} There is good evidence that the success rate of DLI is higher where there is molecular or cytogenetic relapse rather than hematologic relapse, and therefore DLI should be considered as soon as any measure of recurrent disease is detected and recommended where there is evidence of disease progression.^{142,153,154} There is also good evidence that escalating dose regimens that start with a low initial cell dose ($\leq 2 \times 10^7$ mononuclear cells/kg) produce the best results in terms of high efficacy with a low rate of GVHD and myelo-suppression.^{153,154} With escalating dose protocols each dose is normally separated by 3–4 months as this is the time required to determine the response to DLI in CML.¹⁵⁴ These data derive from adult studies as there are only anecdotal pediatric reports in the literature, but we have used DLI successfully for children for several years. Overall the response rate is around 90% and 70% for patients treated in molecular/cytogenetic and hematologic relapse, respectively.^{115,116,138–140,142,151,153,154} For those patients who respond, the response is usually apparent by 3–6 months after DLI. Unfortunately for patients relapsing into blast crisis, the outlook is poor because most patients do not have a sustained response.¹⁵³

Although DLI has an established role in reinducing complete remission and long-term cure, it also has significant side-effects. GVHD of greater than grade II severity occurs in around 10% of patients treated in molecular/cytogenetic relapse and in around 20% of patients treated in hematologic relapse.¹⁵⁵ GVHD can be fatal, although in most cases it responds to reinstitution of ciclosporin with or without steroids. Prolonged or irreversible aplasia (sometimes requiring “top up” SCT without conditioning) also occurs in around 20% of patients treated in hematologic relapse but is rarely seen in patients treated in molecular/cytogenetic relapse when an escalating dose protocol is used.¹⁴²

Interferon- α

IFN- α was introduced as treatment for CML in adults in the early 1980s.¹⁵⁶ There have been seven large randomized trials in CML involving > 2000 patients, some of which have included children,¹⁵⁷ and several small pediatric studies.^{41,158} Overall there is no significant difference between the response of children to IFN- α compared with the response of young adults. In adults the overall response rate is 70%, with around 20% of patients achieving a major or complete cytogenetic response usually within 6 months.¹⁵⁷ Patients who achieve a complete cytogenetic response to IFN- α ($> 65\%$ Ph-chromosome-negative) live longer than those treated with hydroxycarbamide.¹⁵⁹ However, it is not clear whether those with a minor response or those who are nonresponders

have any survival advantage with IFN- α compared with hydroxycarbamide. The role of IFN- α in the management of children with CML has reduced since imatinib became available. It should probably be considered before experimental therapy as an option for the small group of children with no suitable SCT donor who are also resistant to or intolerant of imatinib.

Mode of action

The mechanism of action of IFN- α in CML is not fully understood. It reduces cellular proliferation, at least in part due to its effects on progenitor cell–stromal cell interactions, and may have immunomodulatory effects leading to increased recognition of CML cells.¹⁶⁰

Dose

The standard starting dose is 3 mega units (MU) daily by subcutaneous injection.¹⁵⁷ The dose should be adjusted after the first few weeks of treatment to maintain the white cell count between 2 and 4×10^9 /L and platelets $> 80 \times 10^9$ /L (maximum dose 5 MU daily). Response to IFN- α is assessed both by hematologic parameters and by marrow cytogenetics at 3–6-month intervals. It normally takes at least 6 months to determine whether patients are going to show a major cytogenetic response ($>35\%$ Ph-chromosome-negative) to IFN- α . IFN treatment should therefore be continued in all patients who achieve a hematologic response for at least 6 months. For children who have only a minor cytogenetic response ($<35\%$ Ph-negative), or no response by 6 months, it is unlikely that continuing IFN- α will confer a survival advantage and other treatment should be considered (allogeneic SCT, a further trial of imatinib or experimental therapy). Children who fail to achieve a hematologic response to IFN- α may be developing acceleration of disease and should be reassessed as soon as possible.

Side-effects

The commonest problems are flu-like symptoms (including fever, chills, rigors, headache, muscle aches and malaise), which usually occur during the first 2 weeks of treatment. The symptoms resolve completely on continuing therapy in most patients; however, it may be helpful to administer the IFN- α just before bedtime and to give a dose of paracetamol half an hour beforehand, particularly if fever is a prominent feature. Convulsions in association with fever have also occasionally been reported in children treated with IFN- α . Other side-effects include lethargy, depression, alopecia, rash, myelosuppression, anorexia, weight loss, abnormal liver function and autoimmune phenomena (idiopathic thrombocytopenic purpura, hypothyroidism and hemolytic anemia).

Combination treatment

Data from a French multicenter study¹⁶¹ in which adult

patients were randomized to IFN- α with or without cytosine arabinoside suggested that this combination can prolong survival; the 3-year survival in the IFN-cytarabine group was 86% compared with 79% for the IFN group. This difference appeared to be due to an increased proportion of patients achieving a major or complete cytogenetic response in the combination group at 12 months: 41% in the IFN-cytarabine group versus 24% in the IFN group.

Experimental treatment

There are several new drugs under clinical trial for CML (see below) which are not available yet for use in children.⁶² The only situation where experimental therapy is likely to be considered in children with CML is the small group of patients who become resistant to both imatinib and IFN- α and who are unable to undergo SCT (or have relapsed after SCT and failed standard relapse therapy). In this situation two options that could be considered are autologous SCT and reduced-intensity conditioning (RIC) SCT. Whilst the exact role of autologous BMT for CML is still unclear, in adults there is considerable experience in the use of autologous stem cells.^{162,163} Of the 559 transplants for CML in children reported to the EMBT since 1982, only 30 were autologous transplants, and no data on the outcome of this small group of children have been published. Nonmyeloablative RIC SCT is being investigated by a number of groups.^{164,165} The results in adults are fairly promising in that transplant-related mortality seems to be low and the short-term results in chronic phase disease are encouraging.¹⁶⁵ However, there seems to be a high risk of GVHD even with sibling donors and the outcome for blast crisis patients is poor.¹⁶⁵

Management of accelerated-phase CML and blast crisis

Accelerated-phase CML

Management of accelerated-phase CML depends on the nature of any previous treatment and the specific problems experienced by the child. Any child who develops evidence of acceleration while awaiting BMT should be transplanted at the earliest opportunity. Imatinib is the most useful drug for disease control until the transplant is carried out; for children who have relapsed on imatinib hematologic control can usually be achieved for a short time with hydroxycarbamide, 6-mercaptopurine or 6-thioguanine. The commonest manifestations of accelerated-phase disease are splenomegaly and thrombocytosis. Splenectomy is indicated for massive splenomegaly and, if SCT is planned, should preferably be carried out at least 6 weeks beforehand. Routine splenectomy and splenic irradiation prior to SCT are no longer recommended as they have not been shown to improve survival. Thrombocytosis may be difficult to control because it is

sometimes resistant to imatinib and often resistant to hydroxycarbamide, or the doses required lead to unacceptable leukopenia. Fortunately, even platelet counts in excess of $1000 \times 10^9/L$ are usually well tolerated and are not usually associated with thrombosis or hemorrhage in children.^{6,166} Where thrombocytosis is resistant to oral chemotherapy, IFN- α or anagrelide are often effective.¹⁶⁷

Lymphoid blast crisis

The approach to treatment of lymphoid blast crisis of CML in children is similar to that of ALL. Remission induction with vincristine and steroids is successful in the majority of children.^{53,168} The response to imatinib is disappointing, with a complete hematologic response in only 10–25% of patients,^{72,80} and CNS relapse is common even in those with hematologic remission.¹⁶⁹ For those with an HLA-identical donor, allogeneic SCT is the treatment of choice following remission induction. For children in whom it is possible to proceed straight to SCT, further chemotherapy prior to SCT should not be necessary. In most cases, however, SCT is likely to be delayed for a few months and in this situation there is a choice between some form of intensification chemotherapy, as in childhood ALL protocols, or imatinib. Relapse of blast crisis within a few months is usual and SCT should not be delayed if at all possible.^{72,79,80} The most appropriate CNS-directed treatment for such children is not clear. It seems wise to give regular intrathecal methotrexate, as is standard in most ALL protocols, because imatinib may not penetrate the intact blood–brain barrier.¹⁶⁹ Where no HLA-identical marrow donors can be identified, the options are SCT from a mismatched donor or haploidentical donor or cord blood transplantation because imatinib and maintenance chemotherapy are not curative.

Myeloid blast crisis

The remission rate for myeloid blast crisis remains poor, even with the most recent AML-type chemotherapy regimens and, in contrast to lymphoid blast crisis, vincristine and steroids are of little benefit. Several studies now show that around 50% of patients respond to imatinib but of these < 20% have a complete hematologic response and a complete cytogenetic response is uncommon.^{72,79,80} Overall the median survival of adults with blast crisis on imatinib is 6–8 months.^{79,80} Therefore for children with myeloid blast crisis of CML the choice lies between imatinib and AML-type chemotherapy (including daunorubicin or mitoxantrone, cytarabine and etoposide or thioguanine) as a bridge until SCT, which should be carried out as soon as possible. Where no HLA-identical marrow donors can be identified, SCT from a mismatched donor or haploidentical donor or cord blood transplantation are recommended because imatinib and maintenance chemotherapy are not curative.

Future directions

This is a very exciting time for physicians managing CML because there are several areas of clinical investigation that are likely to lead to improved management not only with respect to an increased cure rate but also to reduced toxicity. Broadly the three areas of most intense investigation are innovative forms of SCT, new drugs for imatinib-resistant CML, and immunotherapy targeted at enhancing the host immune response to BCR–ABL-expressing cells.

SCT

Because CML is a stem cell disorder, successful therapy will continue to require elimination of all of the CML clone or at least reduction in the CML clone to levels barely detectable by current techniques (around 1 in 10^5 cells). It is likely that low levels of disease can persist for long periods, and possibly indefinitely, clonal expansion being prevented by the patient's own immune response. For these reasons, SCT is likely to remain the principal therapeutic approach to CML in children. Improvement in the outcome of SCT is most likely to derive from advances in donor matching, better understanding of individual prognostic factors, GVHD prevention and treatment, increased understanding of the GVL response and the development of effective RIC regimens.

Novel drugs and new combinations

A large number of new agents are currently under investigation in adults with CML as increasing evidence points to imatinib resistance being the major limitation to cure of CML without SCT (Table 17.6). A major area of interest has been to target other signaling molecules on the downstream pathways triggered by BCR–ABL (see Fig. 17.3). This has led to the development of several new kinase inhibitors, including JAK2 inhibitors, SRC kinase inhibitors¹⁷⁰ and tyrophostins and farnesyl transferase inhibitors, which block the action of RAS.^{171,172} In addition, safer and more effective formulations of several older drugs are being investigated as possible agents for use alone or in combination, for instance arsenicals, such as arsenic trioxide,^{173–175} troxacitabine,¹⁷⁶ and

Table 17.6 New drugs under investigation in chronic myeloid leukemia.

Farnesyl transferase inhibitors
New kinase inhibitors, e.g., AG957, AG940, AP23464
Homoharringtonine
Nucleoside analogs, e.g., troxacitabine
Arsenicals, e.g., arsenic sulfide
Antiangiogenic agents, e.g., bevacizumab ¹⁸⁰
Polyethylene glycol (PEG)-IFN
Proteasome inhibitors, e.g., bortezomib ¹⁸¹

polyethylene glycol (PEG)-IFN.¹⁷⁷ It seems most likely that a combination of agents will be necessary to cure CML as with the acute leukemias.^{174,175,178,179}

Immunotherapy

There is considerable interest in the development of peptide vaccines in CML. This has the advantage that at least one leukemia-specific target antigen can be readily identified (BCR-ABL-derived peptides) and there is extremely good evidence of potent T-cell-mediated antileukemia activity both from clinical and animal models.^{134,182} This approach has already reached the stage of phase II trials.¹⁸²

Summary

- CML constitutes 2–3% of all childhood leukemias and has an incidence of 0.6–1.2 per million per year in Western countries.
- Over 90% of children with CML are Philadelphia (Ph) chromosome-positive, defined by the balanced translocation t(9q34;22q11), which causes the formation of a BCR-ABL fusion gene.
- Over 95% of children with CML express BCR-ABL protein, a 210-kDa constitutively active tyrosine kinase.
- CML is a triphasic disease, with an indolent chronic phase (median duration 4 years), a symptomatic accelerated phase (median duration 6–18 months) and a terminal blast crisis phase (median duration 3–9 months) that responds poorly to treatment.
- The only known cure for CML is SCT.
- SCT is the treatment of choice as it cures 65–75% of children but has a high initial transplant-related mortality.
- Relapse after SCT is fairly common but is exquisitely sensitive to donor lymphocyte infusion, which cures > 80% if given during molecular relapse.
- Children without an HLA-identical stem cell donor or who relapse after SCT usually respond to imatinib mesylate, a newly developed tyrosine kinase inhibitor with high specificity for BCR-ABL.
- Imatinib mesylate is the first of several new drugs targeted to leukemia-associated proteins in CML and currently in clinical trials but not curative when used alone due to drug resistance.
- Cure of children with CML in the future may be possible using combinations of leukemia-targeted drugs, immunotherapy and reduced-intensity conditioning SCT.

Acknowledgments

We are grateful to Andy Chase for providing Fig. 17.1a, Junia Melo for Figs 17.1b, 17.2 and 17.3, and David Swirsky for many of the morphology slides.
